Welcome

Foreword

We are happy to welcome you to our second Open Educational Resource (OER) textbook, Biochemistry Free For All. Biochemistry is a relatively young science, but its rate of growth has been truly impressive. The rapid pace of discoveries, which shows no sign of slowing, is reflected in the steady increase in the size of biochemistry textbooks. Growing faster than the size of biochemistry books have been the skyrocketing costs of higher education and the even faster rising costs of college textbooks. These unfortunate realities have created a situation where the costs of going to college are beyond the means of increasing numbers of students.

With this in mind, KGA and IR created, in 2012, a free, electronic book for introductory biochemistry, Biochemistry Free and Easy. That book was met with extraordinary enthusiasm, with over 175,000 downloads from around the world and adoption for use for several courses across the country. At OSU, we use the book for a basic course, taught over one quarter. In 2013, Oregon State University rolled out a new open textbook initiative, in partnership with OSU Libraries, OSU Press and Open Oregon State, with the mission of partnering with faculty to create open, online educational resources. Our proposal to create a biochemistry book that could be used for courses needing greater depth and breadth of coverage was chosen as one of the first projects of the Open Textbook initiative. As a result, we were able to draw on the technical expertise of several multimedia specialists for our interactive learning modules, and to hire a talented group of students to make figures, where suitable open source illustrations were not available. We also enlisted our third author, Dr. Taralyn Tan, a former student, who designed and oversaw the creation of the interactive modules.

As an OER, this book is free for anyone to use, modify, adapt, etc. for free educational purposes. It may not be used for profit-making, or where any fee is required for its use. We are providing all of the figures in this book free of cost to anyone wishing to use them for free educational purposes.

Helping students understand and enjoy biochemistry (without going broke) is our primary motivation for writing this book. We have aimed to provide a more thorough coverage of topics than in Biochemistry Free and Easy, but we do not aim to provide an encyclopedic biochemistry tome covering content that no instructor would fully cover in a single course. Neither do we aim to be the “go to” source for information on biochemistry. This is not a reference work. Consequently, we have focused on core concepts with key information. Descriptions are kept brief and to the point. Between us, we have over forty years of teaching biochemistry, and our experience is that more information does not translate to better learning. However, this does not mean that students will be shortchanged in using this book.

We have used the Foundational Concepts defined by the American Society for Biochemistry and Molecular Biology (ASBMB) and the associated learning goals as our guide in choosing and organizing the information presented.

The electronic format of Biochemistry Free For All allows us to provide multimedia to help students learn the subject. If you are not familiar with our previous efforts, you will probably see humor as another unconventional component of the structure of this book. We believe in keeping things light, fun, and informative. As certified (some might say, certifiable) biochemistry nerds and unrepentant lovers of corny jokes, we firmly believe that students can have fun while learning the subject. Toward this end, we have sprinkled each chapter with rhymes and songs that we hope will have you learning biochemistry happily. The multimedia approach also allows us to expand the content offerings in the written content by providing access to videotaped lectures, interactive learning modules; and rotatable 3-D molecules. We hope to enhance learning by creating a book that students look forward to reading and using.

We would like to express our deep appreciation for the ongoing support of Faye Chadwell, Director of the OSU Press, and Dianna Fisher, Director of OSU Extended Campus' Open Oregon State initiative. They are tireless champions of the cause of open educational resources and have been instrumental in increasing awareness and promoting the development of open educational materials at Oregon State. They also made it possible for us to avail of the skills of Victor Yee, Assistant Director of Course Development and Training for OSU ecampus; Warren Blyth, Nicholas Harper, Michael Miller and James Roberts, multimedia developers; and Rebecca Pietrowski, instructional designer. The support of Open Oregon State also gave us access to a talented pool of students, Martha Baker, Ben Carson, Penelope Irving, Pehr Jacobsen and Aleia Kim, who made many of the beautiful illustrations in the book. We also appreciate the help of Elizabeth Pendergrass, Tommy Tran, and Dmitriy Strelkov in assembling the glossary. We also appreciate the numerous people who sent us their pictures for use in assembling the cover image (which was created by Taralyn Tan). People whose images made it onto the cover include Berkman Gulenc, Clare Banister, David Shumway, Anna Pickering, Norbert Schoenberg, Margit Kjetsaa, Regina Golser, Alex McFadden, Garth Kong, Ayse Yosemin, Davis Hull, Annabelle Hull, Chelsea Parker Harp, Jennifer Shepard, Martyna Sroka, Qaim Ali Ramazan, Ingrid El-Dash, Vivian El-Dash, Wilson Ng, Daniel Watkins, Susan Thiel, Omar Ammar, and Rachel Aazzerah.

The Metabolic Melodies in the book could not have been recorded without the help of several gifted musicians. Given our non-existent musical abilities, we (and the readers of this book) are very fortunate that Liz Bacon, Heather Boren, Barbara and Neal Gladstone, Eric Hill, Tim Karplus, David Simmons and Carol Adrianne Smith were willing to help us out. We are indebted to you.

Gary Merrill and Andy Karplus, former and current heads of the Biochemistry and Biophysics department at OSU, have been steadfast supporters, throughout this project. We would also like to thank Senior Vice Provost for Academic Affairs, Becky Warner, and College of Science

Dean, Sastry Pantula, for working with the department to secure time release (for KA) to work on this project. Special thanks are due to our colleagues in the Biochemistry and Biophysics department for their friendship, collegiality and encouragement. The department, the College of Science and OSU could not have made our task any easier or more pleasant.

Finally, we would like to thank the many hundreds of students, past and present, who have inspired us to write this book. This is for you. It is a special pleasure for KA and IR to have one of you return as a co-author to help create a textbook that is truly free for all. We hope you find the book helpful in your own education.

The book is best used (currently) on iBooks (available for Macs and iPads), which allows readers to click on figures to enlarge them, watch video lectures relevant to each topic, listen to the selected songs, and link out to the internet to find more information simply by clicking on any term. Other formats, such as PDF and Kindle, allow access to all of the hyperlinks, but not all of the multimedia. If someone is interested in converting this book into a native Android format that can use all of the multimedia in the iPad version, we'd love to speak with you. If you are using the PDF version, you can download the Metabolic Melody songs at http:www.davincipress.com

We hope you find these features useful and that they help you learn biochemistry.

We would love to hear from you. Please take a few minutes after you've had a chance to use the book to tell us how the book has worked for you (email to ahernk1@gmail.com)

And join our Facebook group at https://www.facebook.com/biochemistryfreeforall/ We would really appreciate it.

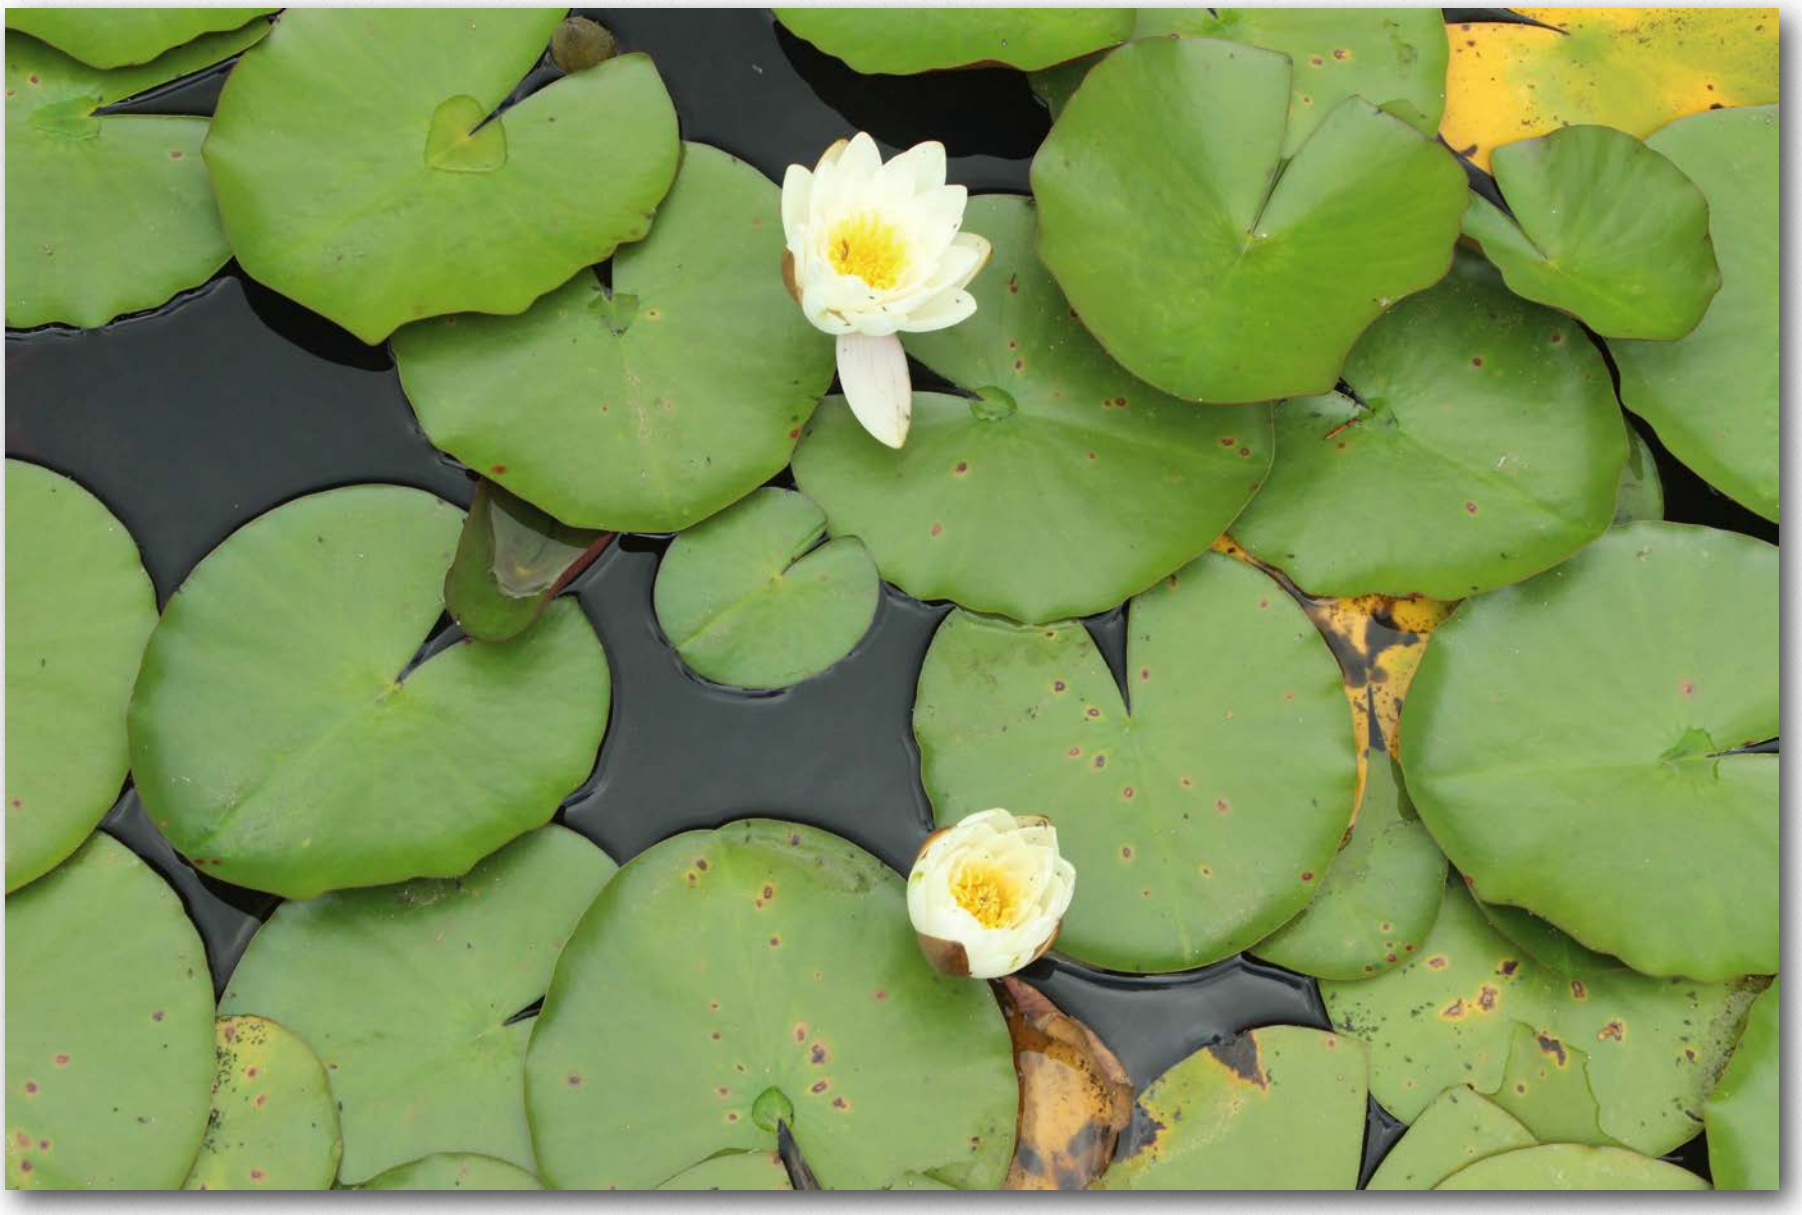
In the Beginning

"It is far better to grasp the universe as it really is than to persist in delusion, however satisfying and reassuring."

- Carl Sagan

Introduction: Basic Biology



The bio of biochemistry

The most obvious thing about living organisms is their astounding diversity. Estimates put the number of eukaryotic species at about 8.7 million, while bacteria account for anywhere between 10^7 and 10^9 different species. The number of species of archaea is still uncertain, but is expected to be very large.

These organisms, representing the three great domains of life, together occupy every environmental niche imaginable, from the human gut to the frozen expanses of the Antarctic, and from the rainforests of the Amazon basin to the acid waste washes of gold mines. Some organisms, like the tardigrades (Figure 1.1), or water bears, can withstand

incredibly harsh conditions - from a few degrees above absolute zero to 300°F, the vacuum of outer space, and pressures greater than those at the greatest depths of the ocean. In the memorable words of Dr. Ian Malcolm in the movie, Jurassic Park, “Life finds a way”.

Despite the differing demands of existence in these widely varied environments, all living things share some common characteristics. The most noticeable of these is that from hummingbirds to humpback whales, from fungi to frogs, and from bacteria to birch trees, all living things are made up of cells. This fact was first discovered by Robert Hooke, in 1665 (Figure 1.2), when he used a microscope to look at a slice of cork and found that it seemed to be made up of tiny chambers that he named cells. Subsequent examination of other living things revealed that they, too, were, without exception, made up of cells. Today, we know that organisms in all three domains of life – bacteria, archaea and eukaryotes, share this property – they are all made up of cells. For some, a single cell is the organism, while others are multicellular, like humans, wombats or weeping willows.

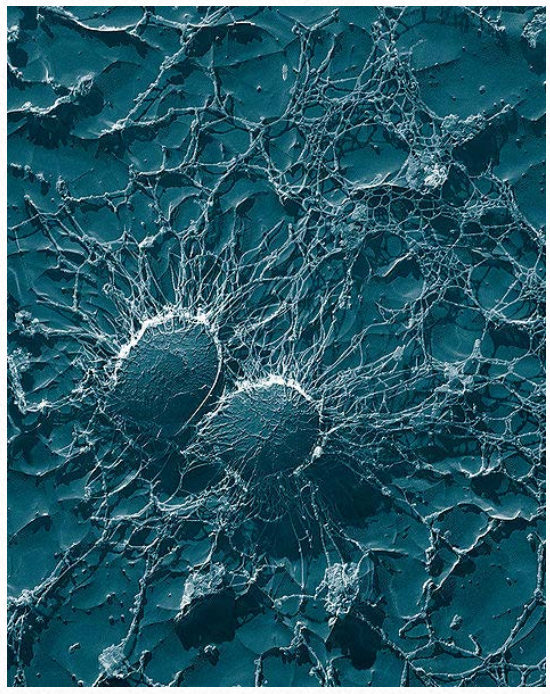

Figure 1.3 Bacterial cells
Wikipedia

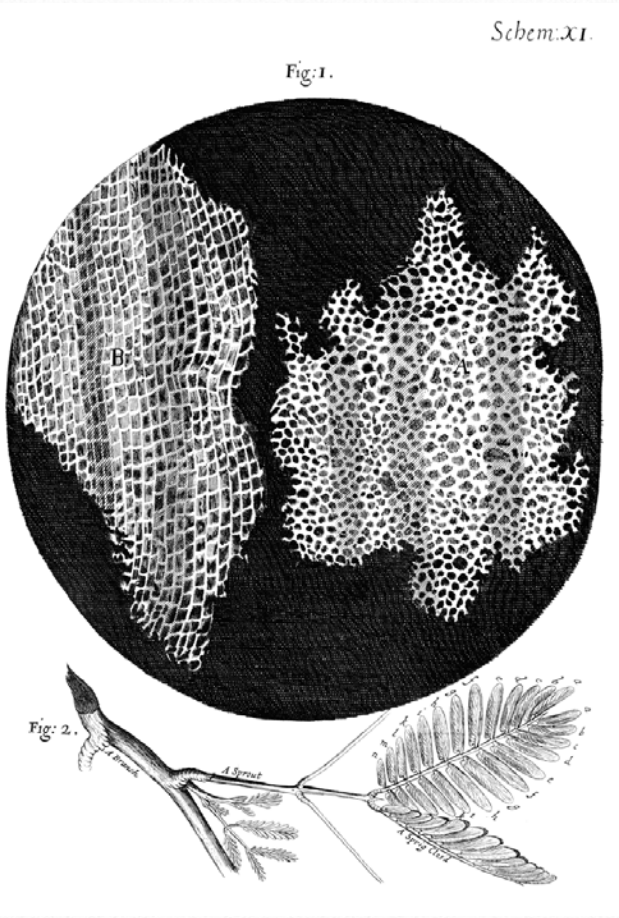

Figure 1.2 Slices of cork as seen by Hooke

The subject of this book is biochemistry, the science that explains life at the molecular level. The special characteristics of cells influence the unique chemistry of life. It is, thus fitting, to take a quick look at cells, the setting in which the molecular events of life take place.

"*There are living systems; there is no "living matter". No substance, no single molecule, extracted and isolated from a living being possess, of its own, the aforementioned paradoxical properties. They are present in living systems, only; that is to say, nowhere below the level of the cell.*" – Jacques Monod

Cells

All cells, no matter what kind, have a plasma membrane that serves as a boundary for the cell, separating it from its surroundings. They also possess a genome made up of DNA that encodes the information for making the proteins required by the cell. To translate the information in the DNA and make the proteins it encodes, all cells have the machinery for protein synthesis, namely, ribosomes and tRNAs. DNA is also the repository of information that gets copied and transmitted to the next generation, allowing living cells to reproduce.

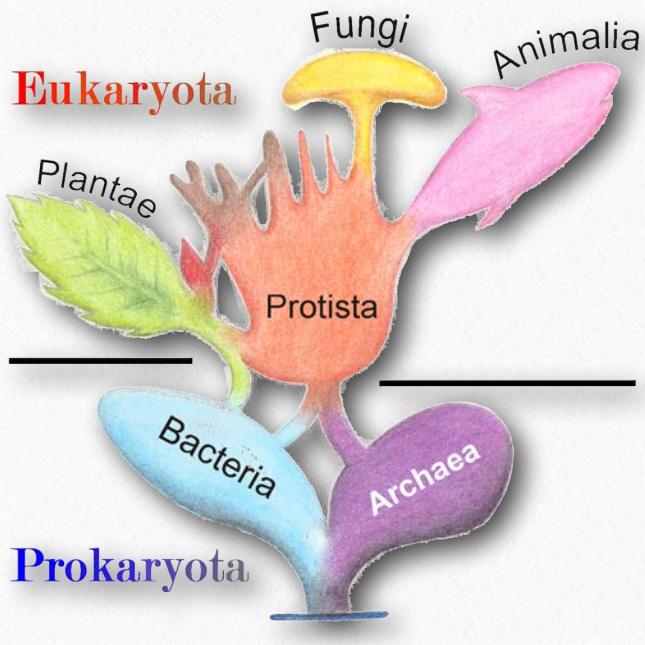

Figure 1.5 - Tree of life

Wikipedia

All cells also need to be able to obtain and use energy. The source of this energy is different in different organisms (Figure 1.4). Phototrophs are organisms that obtain metabolic energy from light, while chemotrophs get their energy from the oxidation of chemical fuels. Organisms that can capture energy from light or from chemical sources are termed autotrophs (auto=self, troph=nouris-hing). Others are heterotrophs, which use, as their energy source, the organic compounds made by other organisms. Plants, and other photosynthetic organisms are autotrophs, while animals are heterotrophs.

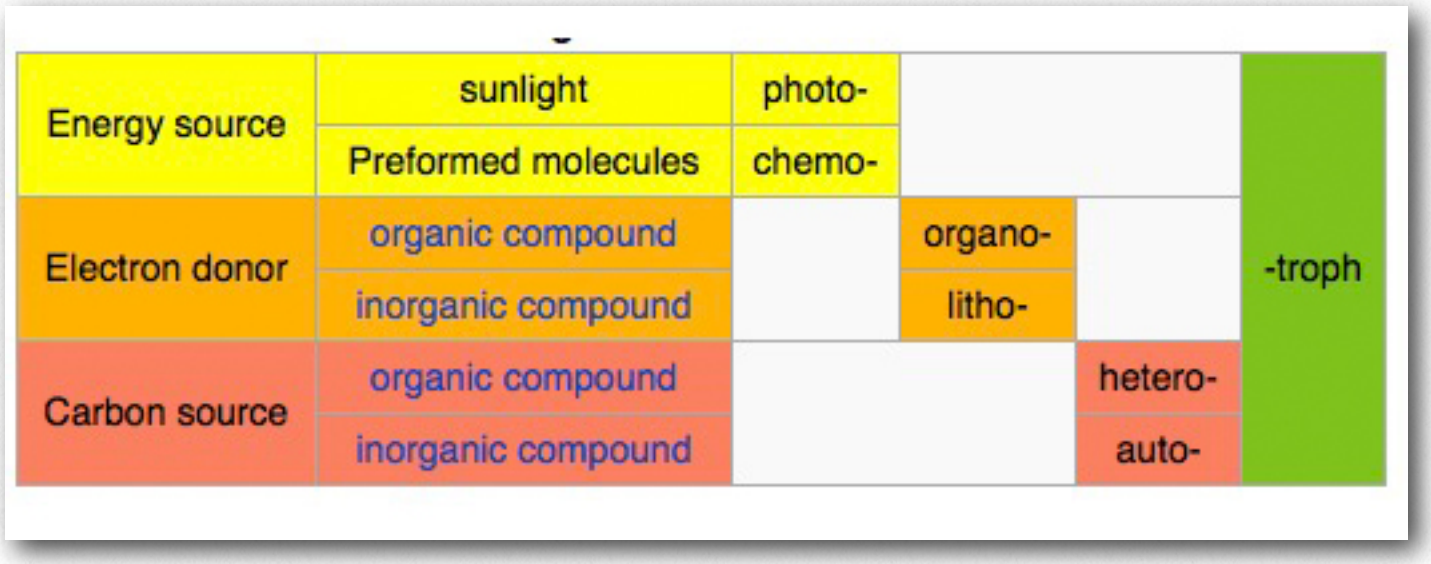

Figure 1.4 - Organization of organisms by metabolic type

Wikipedia

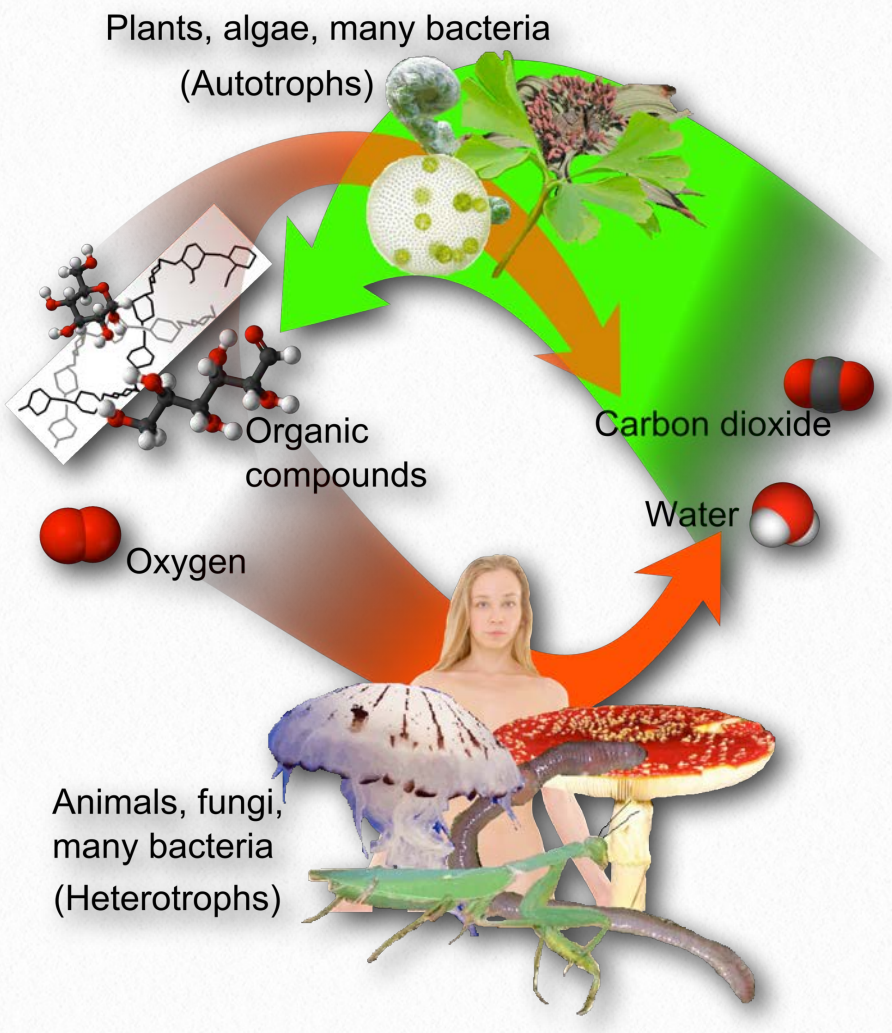

Figure 1.6 - Interplay between autotrophs and heterotrophs

Wikipedia

Cells may be aerobic (i.e., use oxygen) or anaerobic (able to live without oxygen). Some anaerobic cells are obligate anaerobes, that is, they require an environment free of oxygen.

Others are facultative anaerobes, cells that can live with, or without, oxygen.

Prokaryotic and eukaryotic cells

Organisms may be divided into two major groups, the prokaryotes and the eukaryotes. The cells of the former lack a nucleus and other organelles, while those of the latter are characterized by numerous internal, membrane-bounded compartments, including a nucleus.

Prokaryotes are unicellular and generally considerably smaller than their eukaryotic cousins, with sizes ranging from 0.5 to 5 µm in diameter. Prokaryotes typically have circular chromosomes, and may sometimes contain extra-chromosomal DNA elements (also

Table 1.1

usually circular) called plasmids. Although the DNA in prokaryotes is not wrapped around histones, as is the case for eukaryotes, prokaryotes have proteins associated with their DNA. The DNA-protein complexes in prokaryotes create a structure called a nucleoid, which is different from the eukaryotic nucleus in not being enclosed by a nuclear envelope (Figure 1.7). The proteins associated with the DNA in *Archaea* resemble eukaryotic histones, while those in bacteria are different from both eukaryotic and archaeal DNA packaging proteins.

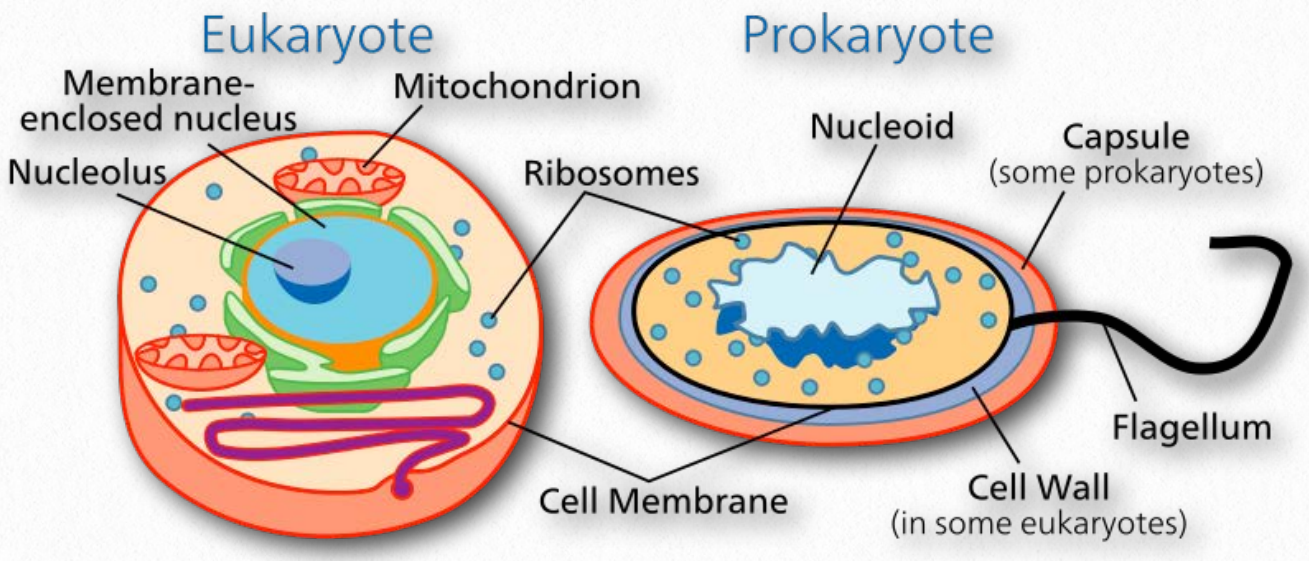

Figure 1.7 - Prokaryotic vs. eukaryotic cell structures (not to scale)

Prokaryotes may be divided into two broad categories, bacteria and archaea. These single-celled organisms are both ancient and widespread. Archaea were once thought to be a subgroup of bacteria, but have subsequently been shown to be a completely different group of organisms that are so distinct from both bacteria and eukaryotes that they now are classified in a domain of their own.

Excuse me for feeling superia
To the life forms we call the bacteria
Students know very well
There are no organelles
To be found in their tiny interia

Bacteria

Like eukaryotic cells, bacterial cells have a plasma membrane surrounding them, but in addition, they also contain an exterior cell wall, comprised of an interlocked peptidoglycan network. On their exterior surfaces, bacteria have hair-like appendages called pili that allow them to adhere to other cells. Pili play an important role in bacterial conjugation, a process in which DNA is transferred between bacterial cells. In addition, bacterial cells may have flagella that enable them to move through their surroundings.

Interestingly, bacteria can communicate, not only with members of their own species, but also with other bacterial species, using chemical signals, in a process called quorum sens-

ing. These signaling mechanisms enable bacteria to assess conditions around them (such as the size of their population). Quorum sensing plays a role in the process of infection by bacterial pathogens as well as the formation of biofilms (mats of cells that adhere to each other tightly and protect the bacteria against environmental hazards or other harmful agents).

Archaea

The first archaeans to be studied were all found in harsh environments such as salt flats and hot springs. Because of this, they were initially believed to live only in extreme environments and were described as extremophiles (Figure 1.8). We now know that archaeans can be found in every environment, moderate or extreme. Archaea have been found in the human gut, and in such huge numbers in marine plankton that it has been suggested that they may be the most abundant organisms on earth.

Figure 1.8 - Archaeans growing in acid mine waste

YouTube Lectures by Kevin HERE & HERE

While they are unicellular, and superficially resemble bacteria, archaea are in some respects more similar to eukaryotes. Their transcriptional machinery, promoter sequences and ribosomes are much more like those of eukaryotes than of prokaryotes.

Archaea are also unique among living organisms in their use of ether linkages to join the lipids used in their plasma membranes to glycerol. Not only are the ether linkages different from the ester linkages in all other forms of life, but the lipids themselves are different. In place of the fatty acids used in both bacterial and eukaryotic membranes, archaea use long isoprene-derived chains (Figure 1.9) This difference in membrane composition and structure makes archaeal membranes highly stable and may be advantageous in extreme conditions.

Archaea, like bacteria, also have a cell wall, but the cell walls do not contain peptidoglycans. Some archaea have peptidoglycan-like

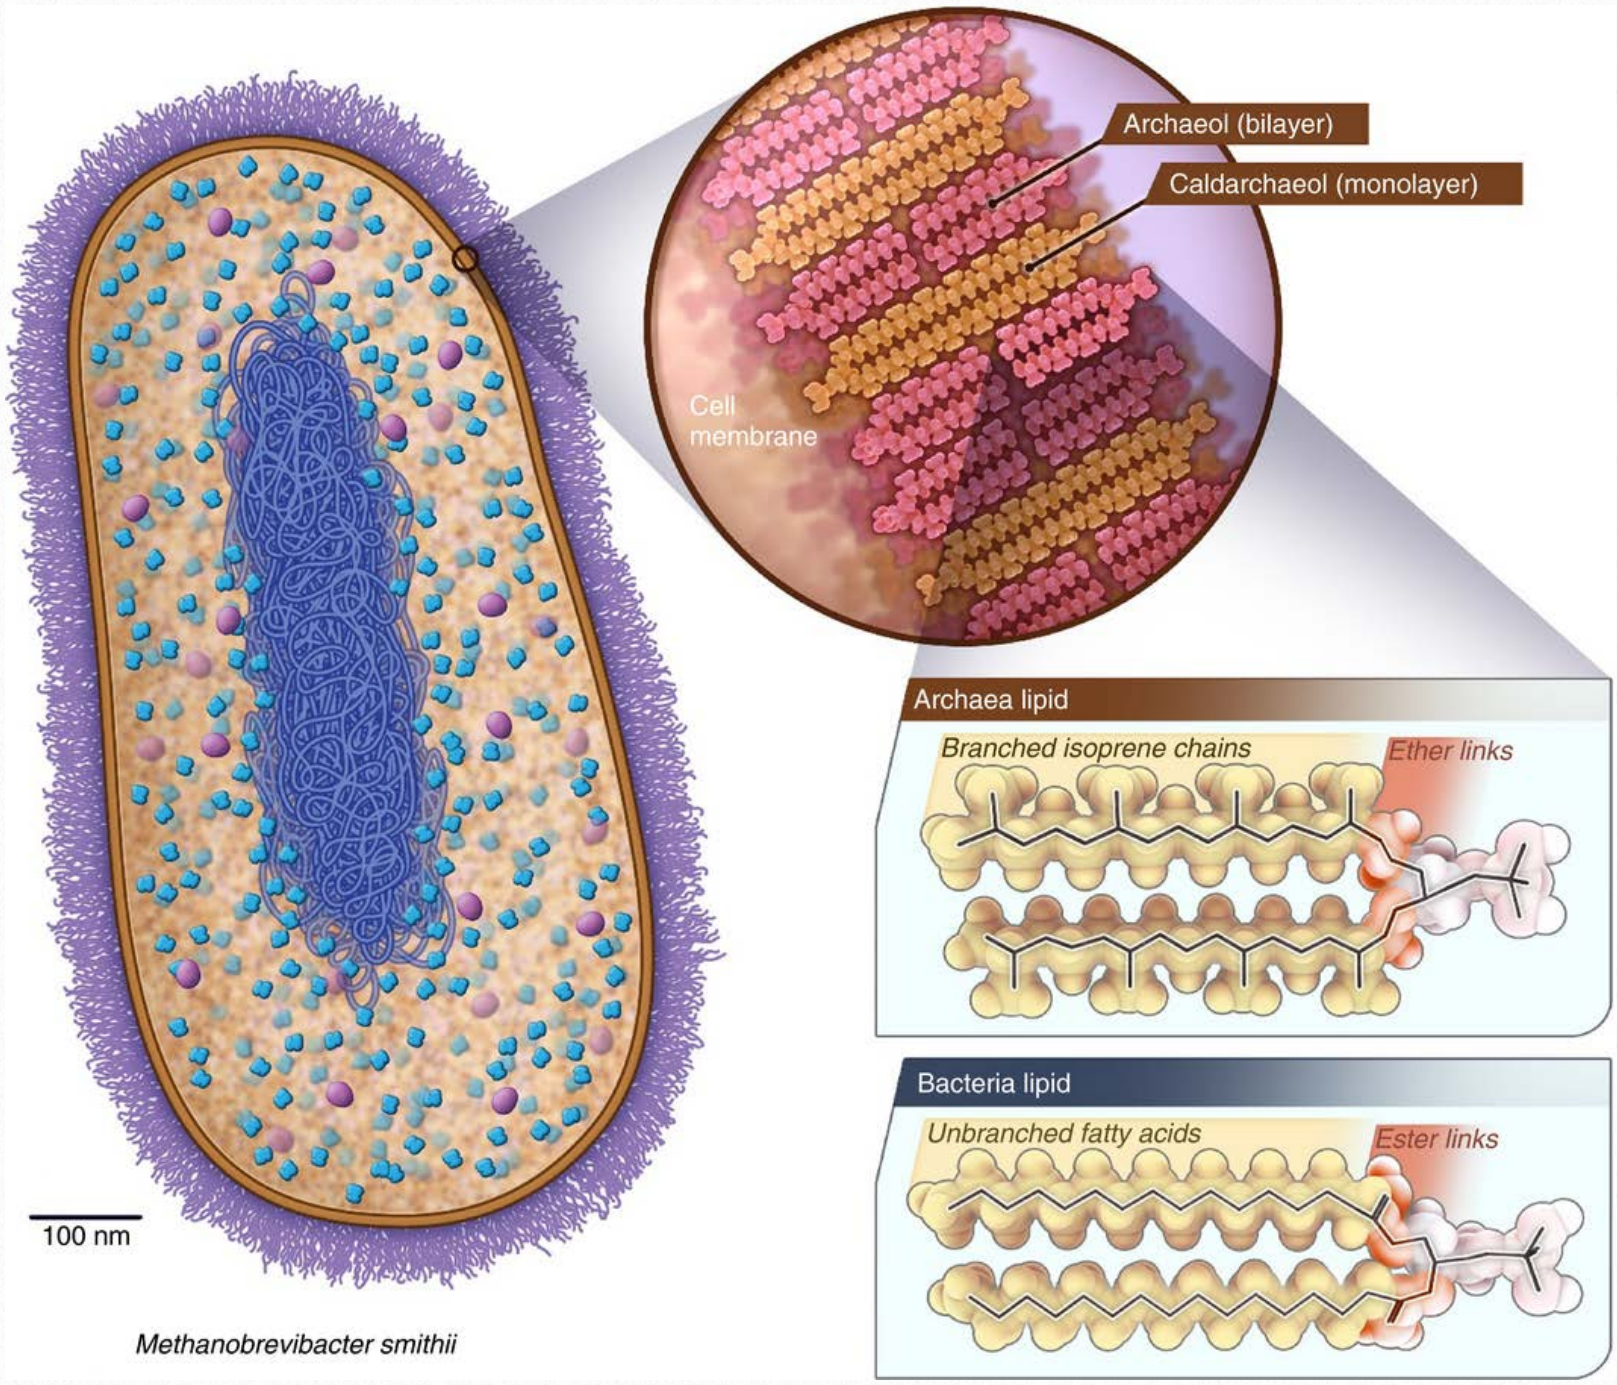

Figure 1.9 Archaeal membrane, top, showing unusual ether linkages and isoprene chains and bacterial membrane, below.

Wikipedia

molecules in their cell walls, while others build their cell walls entirely of glycoproteins and polysaccharides.

Eukaryotes

Eukaryotic cells are found in both unicellular and multicellular organizational schemes. Unicellular forms include yeast and many

Figure 1.10 Paramecium

Wikipedia

protists, familiar to students from introductory biology labs, like *Paramecium* and *Amoeba*. Multicellular eukaryotes include plants, animals, and fungi. Eukaryotic cells are surrounded by a plasma membrane. Animal cells have no cell walls, whereas plant cells use cellu-

lose, hemicellulose, and pectins to build cell walls outside their plasma membranes. Fungal cells have cell walls that are unusual in containing the polymer, chitin, which is also found in the exoskeletons of arthropods.

Eukaryotic cells are typically much larger (typically 10-100 µm) and contain considerably more DNA than prokaryotic cells. The most distinctive feature of eukaryotic cells, however, is the presence of a variety of internal membrane-bounded structures, called organelles.

Figure 1.11 - Animal cell structure

Wikipedia

Organelles

Eukaryotic cells are characterized by internal membrane-bounded compartments, or organelles. These compartments divide up the interior of the cell into discrete parts that have specialized functions.

Organelles found in eukaryotic cells include the nucleus (houses DNA), mitochondria (electron transport system/ oxidative phosphorylation for ATP synthesis), nucleolus (ribosome synthesis and assembly), endoplasmic reticulum (lipid metabolism and targeted protein synthesis and folding), the Golgi apparatus (protein modification and secretion), peroxisomes (oxidation of very long chain fatty acids), chloroplasts (plants - photosynthesis), plastids (synthesis and storage of compounds in plants), lysosomes (animals - hydrolytic enzymes), endosomes (contain endocytosed material), and vacuoles.

The presence of multiple compartments within the cell permits reactions requiring specific conditions to be carried out in isolation from the rest of the cell. For example, the for-

mation of disulfide bonds in proteins is possible in the conditions within the endoplasmic reticulum, but would not readily occur in the different environment of the cytosol. The presence of membrane-bounded compartments also allows reactants to be more concentrated because of the smaller volume of the organelle.

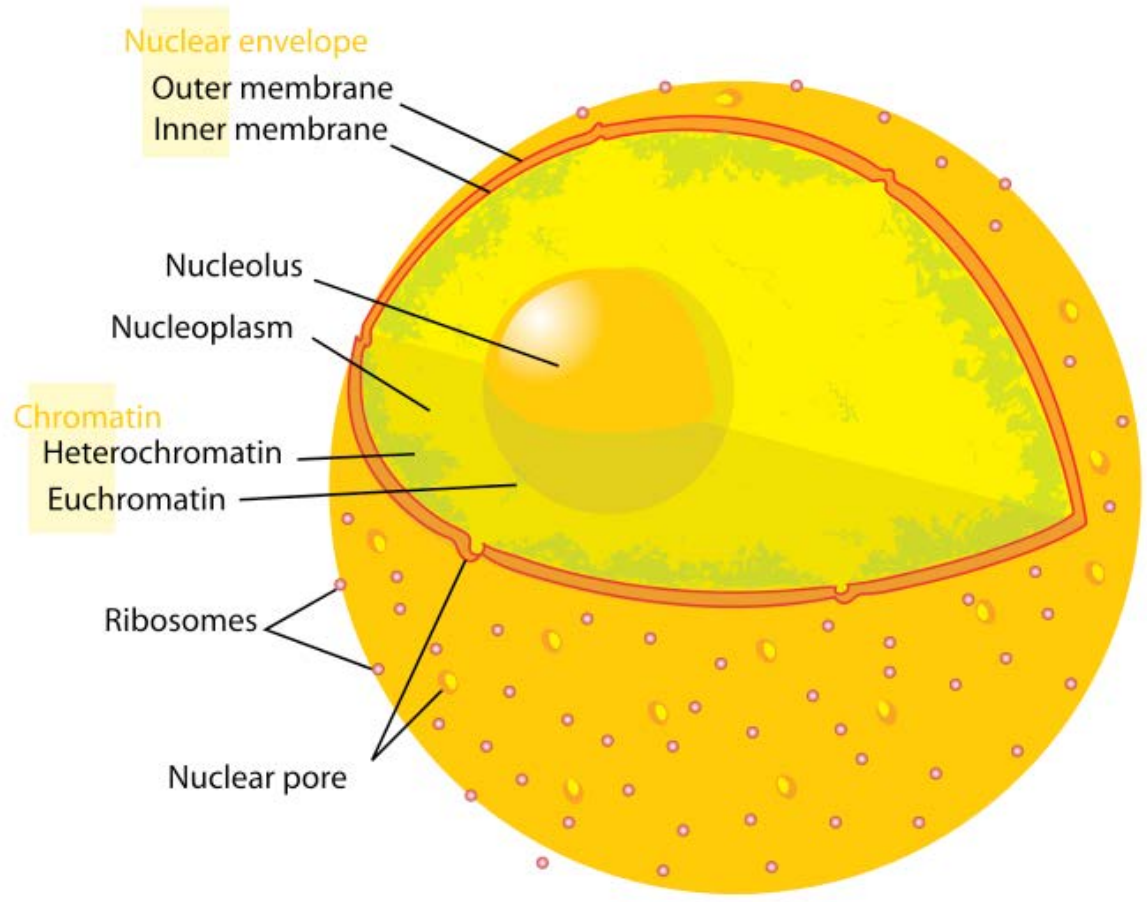

Figure 1.12 Cell nucleus

Eukaryotic DNA in a cell is divided into several linear bundles called chromosomes. Chromosomes contain the genomic DNA wrapped around cores of positively charged proteins called histones. The ends of linear eukaryotic chromosomes have telomeres, short (less than 10 bp) sequences repeated thousands of times. The role of telomeres in preventing loss of information when linear chromosomes are replicated is discussed later.

YouTube Lectures by Kevin HERE & HERE

The chromosomes in eukaryotic cells are surrounded by the nuclear envelope, a double membrane structure that encloses the nucleus (Figure 1.12). Within the nucleus, there are enzymes required for the replication and transcription of genetic information. The presence of the nuclear envelope also regulates which proteins can enter the nucleus at any given time. This, as you will see later, is an important way to control gene expression.

Mitochondria and chloroplasts have their own DNA, separate from and in addition to the nuclear DNA. This DNA is small and circular and resembles a prokaryotic chromosome. Mitochondria and chloroplasts also have their own ribosomes and tRNAs and can carry out their own protein

synthesis. This is not as odd as it seems, because these organelles are likely derived from prokaryotes that once lived as endosymbionts within ancient eukaryotic cells and eventually became integrated into their host cells.

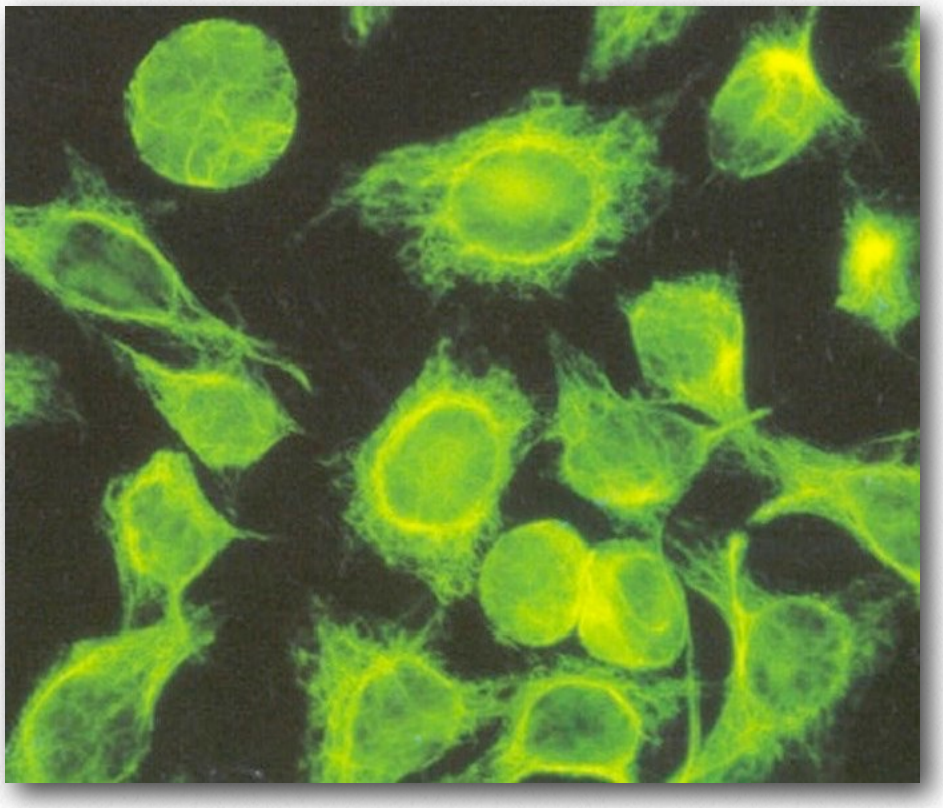

Figure 1.13 Cultured cells stained to show intermediate filaments

Wikipedia

The cytoskeleton

Another interesting feature of eukaryotic cells is the presence of an internal skeleton-like structure called a cytoskeleton. The cytoskeleton is made up of a network of interlinking protein fibers belonging to three major classes: microtubules, microfilaments, also known as actin filaments, and intermediate filaments (Figure 1.13). All eukaryotic cells have microfilaments and microtubules, but it appears that plant cells may lack intermediate filaments (It is now known that some cytoskeletal elements are present in bacteria and archaea as well, but these have been discovered relatively recently and thus, less is known about them.)

Although the word “skeleton” may suggest a rigid and fixed structure, the cytoskeleton is dynamic, with both microfilaments and microtubules disassembling and rearranging themselves on an ongoing basis, as needed. Intermediate filaments are also broken down and rebuilt, at specific times, such as during cell division. The three main classes of cytoskeletal elements are distinguished by the proteins that they are composed of, as well as the way in which those proteins assemble into the structures seen in the cell.

Intermediate filaments, for example, are made up of a variety of proteins that share a common structure, and assemble into fibers that resemble a cable made up of many individual strands of wire twisted together. This arrangement, because of its mechanical strength, makes intermediate filaments ideally suited to provide structural support to various cell structures. The nuclear envelope, for example, has a network of intermediate filaments called the nuclear lamina, just in-

side the inner membrane of the envelope in animal cells.

Microfilaments, composed of the protein actin, underlie the plasma membrane of animal cells, and give them their characteristic shapes. Remodeling of these filaments changes the shape of the cell, and is important for cell movement. In animal cells, actin also plays a role in cytokinesis, the last step in cell division, by helping to cleave the cell in two after nuclear division.

Microtubules, made up of various kinds of a protein called tubulin, also play vital roles in cell division (Figure 1.14). The spindle fibers that attach to chromosomes during metaphase, and help separate the two sets of chromosomes, are made up of microtubules. Microtubules also serve as tracks along which motor proteins, like dynein and kinesin, transport cargo to different parts of the cell.

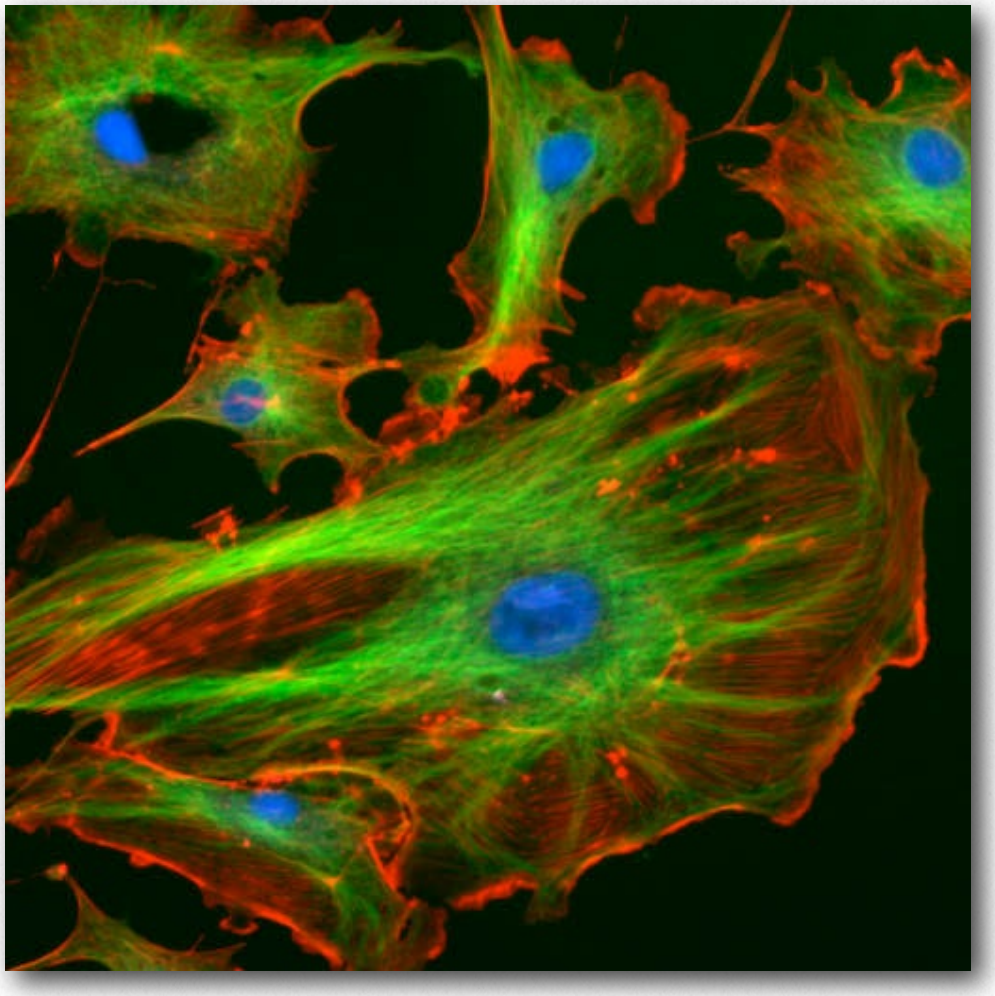

Figure 1.15 - The cytoskeleton. Actin filaments are in red, microtubules in green, nucleus in blue

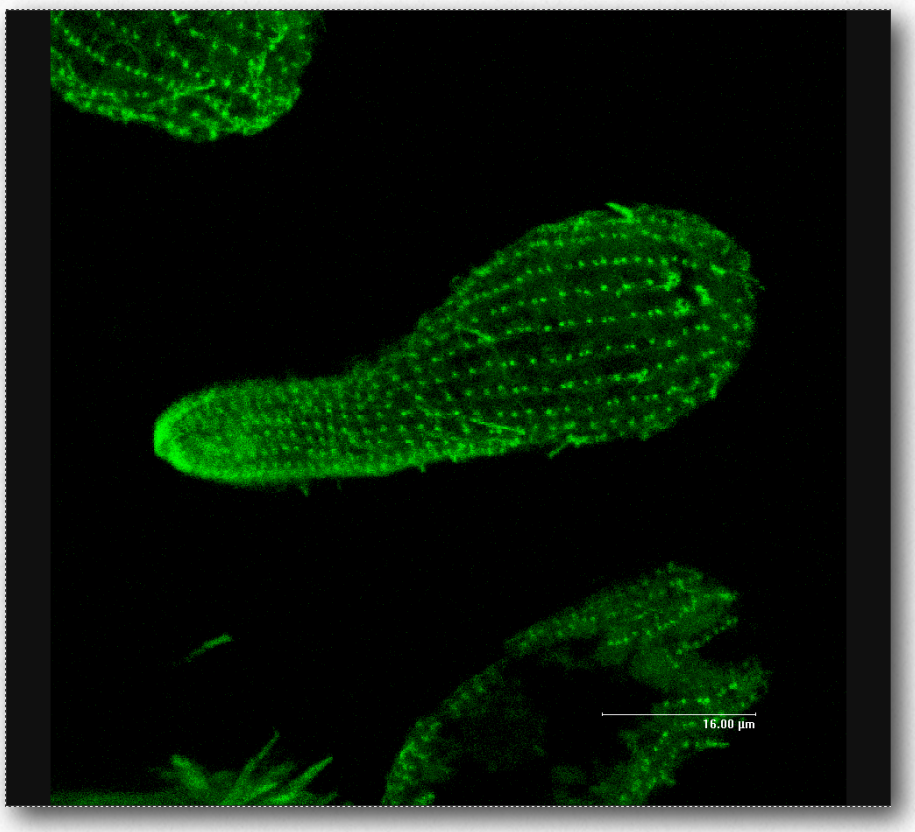

Figure 1.14 - β-tubulin in *Tetrahymena*
Wikipedia

Additional functions of the cytoskeleton include helping to organize the contents of the cell. If you ever wondered what kept organelles in an aqueous cytoplasm from floating around like beach balls in water, the answer is that organelles are anchored by attachment to the cytoskeleton. Interactions among cytoskeletal proteins and com-

ponents of the extracellular matrix are crucial in maintaining tissue structure. Membrane-associated signaling proteins are sometimes linked to components of the cytoskeleton, giving cytoskeletal proteins a role in cell signaling pathways.

Tissues

Cells in multicellular organisms are organized into tissues that play specialized roles in the body. Animals have four types of tissues in their bodies - epithelium, connective tissue, nerve tissue, and muscle tissue. The first of these, epithelial tissues line the cavities and surfaces of blood vessels and organs in the body (Figure 1.16). Epithelial cells are categorized by their shapes: squamous, columnar, and cuboidal. These can be organized in a single cell layer or in layers of two or more cells deep (referred to as stratified or layered). Glands are all comprised of epithelial cells.

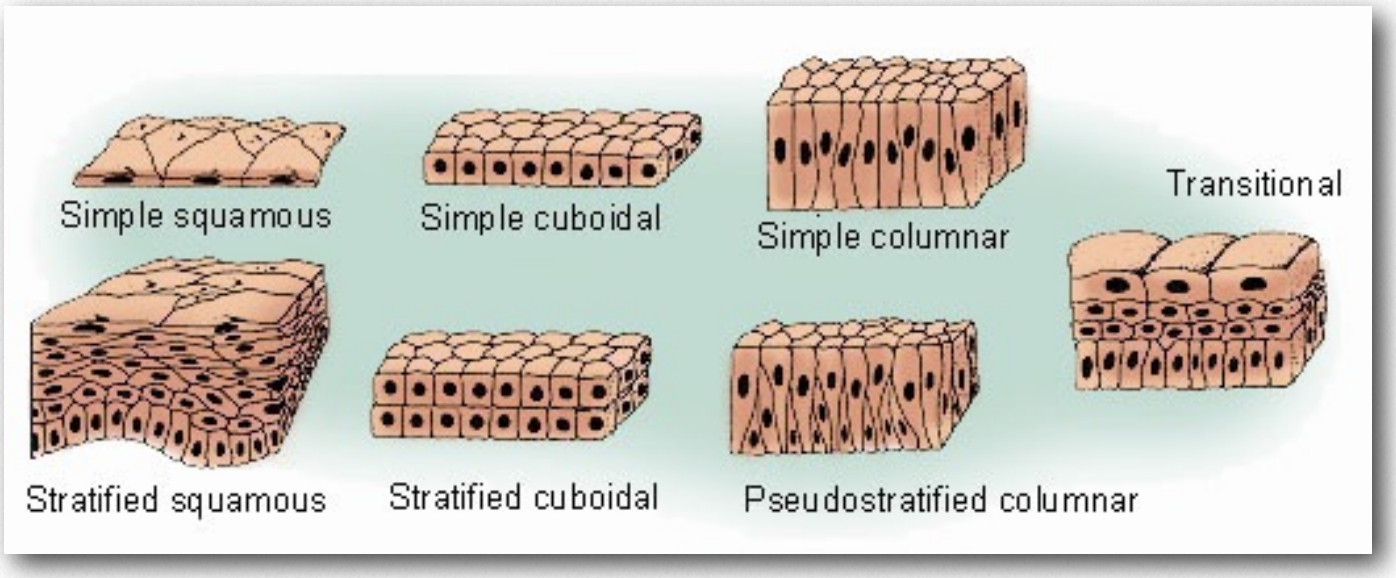

Figure 1.16 - Types of epithelial tissue

Epithelial cell functions include protection, secretion, selective absorption, transport, and sensing. Layers of epithelial cells do not contain blood vessels and must receive nutrients through the process of diffusion of materials from underlying connective tissue, through the basement membrane.

Connective tissue

Of the four animal tissues, connective tissue is the one that serves as the "glue" to hold everything together. Connective tissue fills the gaps between all the other tissues of the body, including the nervous system. In the central nervous system, for example the outer membranes, the meninges (cover of brain) and the spinal cord are composed of connective tissue. Apart from the blood and lymph, connective tissues contain three main components. They are 1) cells; 2) ground substance; and 3) fibers. Blood and lymph contain components 1 and 2, but not 3. Cell types found in connective tissue include adipocytes, fibroblasts, mast cells, macrophages, and leucocytes.

Nerve tissue

The nervous system of humans contains two main components. The brain and spinal cord comprise the central nervous system (CNS) and nerves branching from these make up the peripheral nervous system. The peripheral nervous system is responsible for regulating bodily functions and actions. In the central nervous system (CNS), the tissue types are referred to as grey matter or white matter. In the peripheral nervous system (PNS), tissue types include nerves and ganglia.

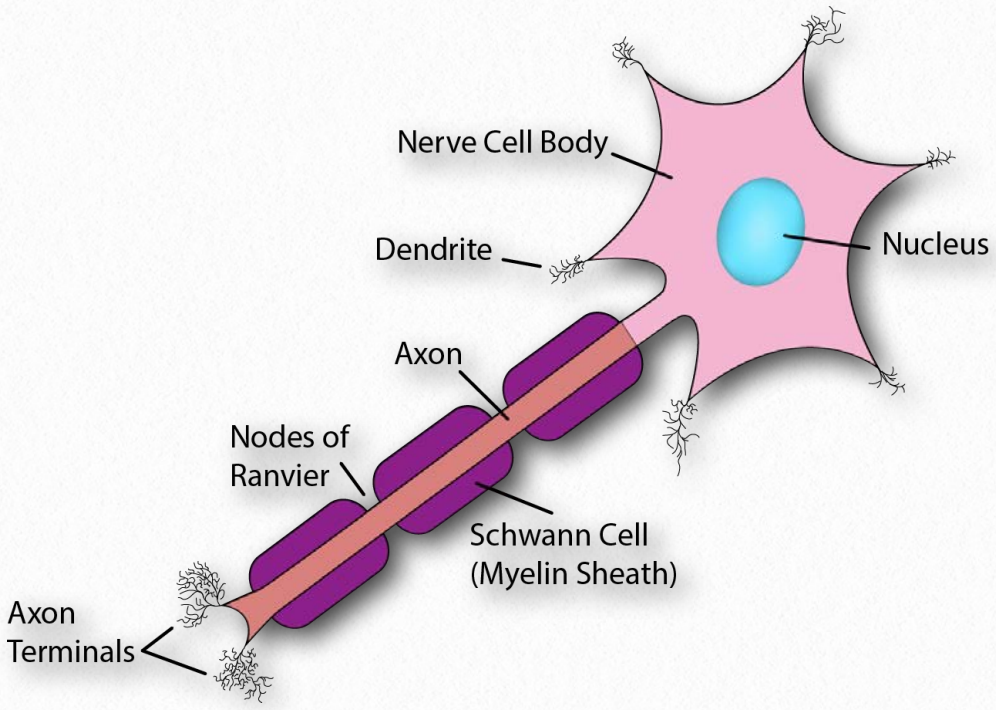

Figure 1.17 - Nerve cell anatomy

Image by Pehr Jacobson

Nerve cells are also called neurons. Neurons can transmit and receive signals. Specialized cells called glia assist in transmitting the nerve signal and also provide nutrients for the neurons. All nerve cells contain an axon (Figure 1.20) which are long fiber-like structures responsible for sending signals in the form of action potentials to adjacent cells. Nervous system functions include receiving input from senses, controlling muscles and glands, homeostasis, integration of information, and mental activity.

Muscle tissue

Muscle tissue is formed during embryonic development by a process known as myogenesis. Mammals have three types of muscle tissue - 1) skeletal/striated muscle; 2) smooth, non-striated muscle; and 3) cardiac muscle. Cardiac muscle and smooth muscle are notable for contracting involuntarily. Both can be activated through nerve stimuli from the central nervous system or by innervation from the peripheral plexus or by endocrine/hormonal activation. Striated muscles, by contrast, only contract voluntarily by (mostly) conscious action influenced by the central nervous system. Reflexive movement by striated muscles occurs non-consciously, but also arises from central nervous system stimulation.

Lyrics by Kevin Ahern

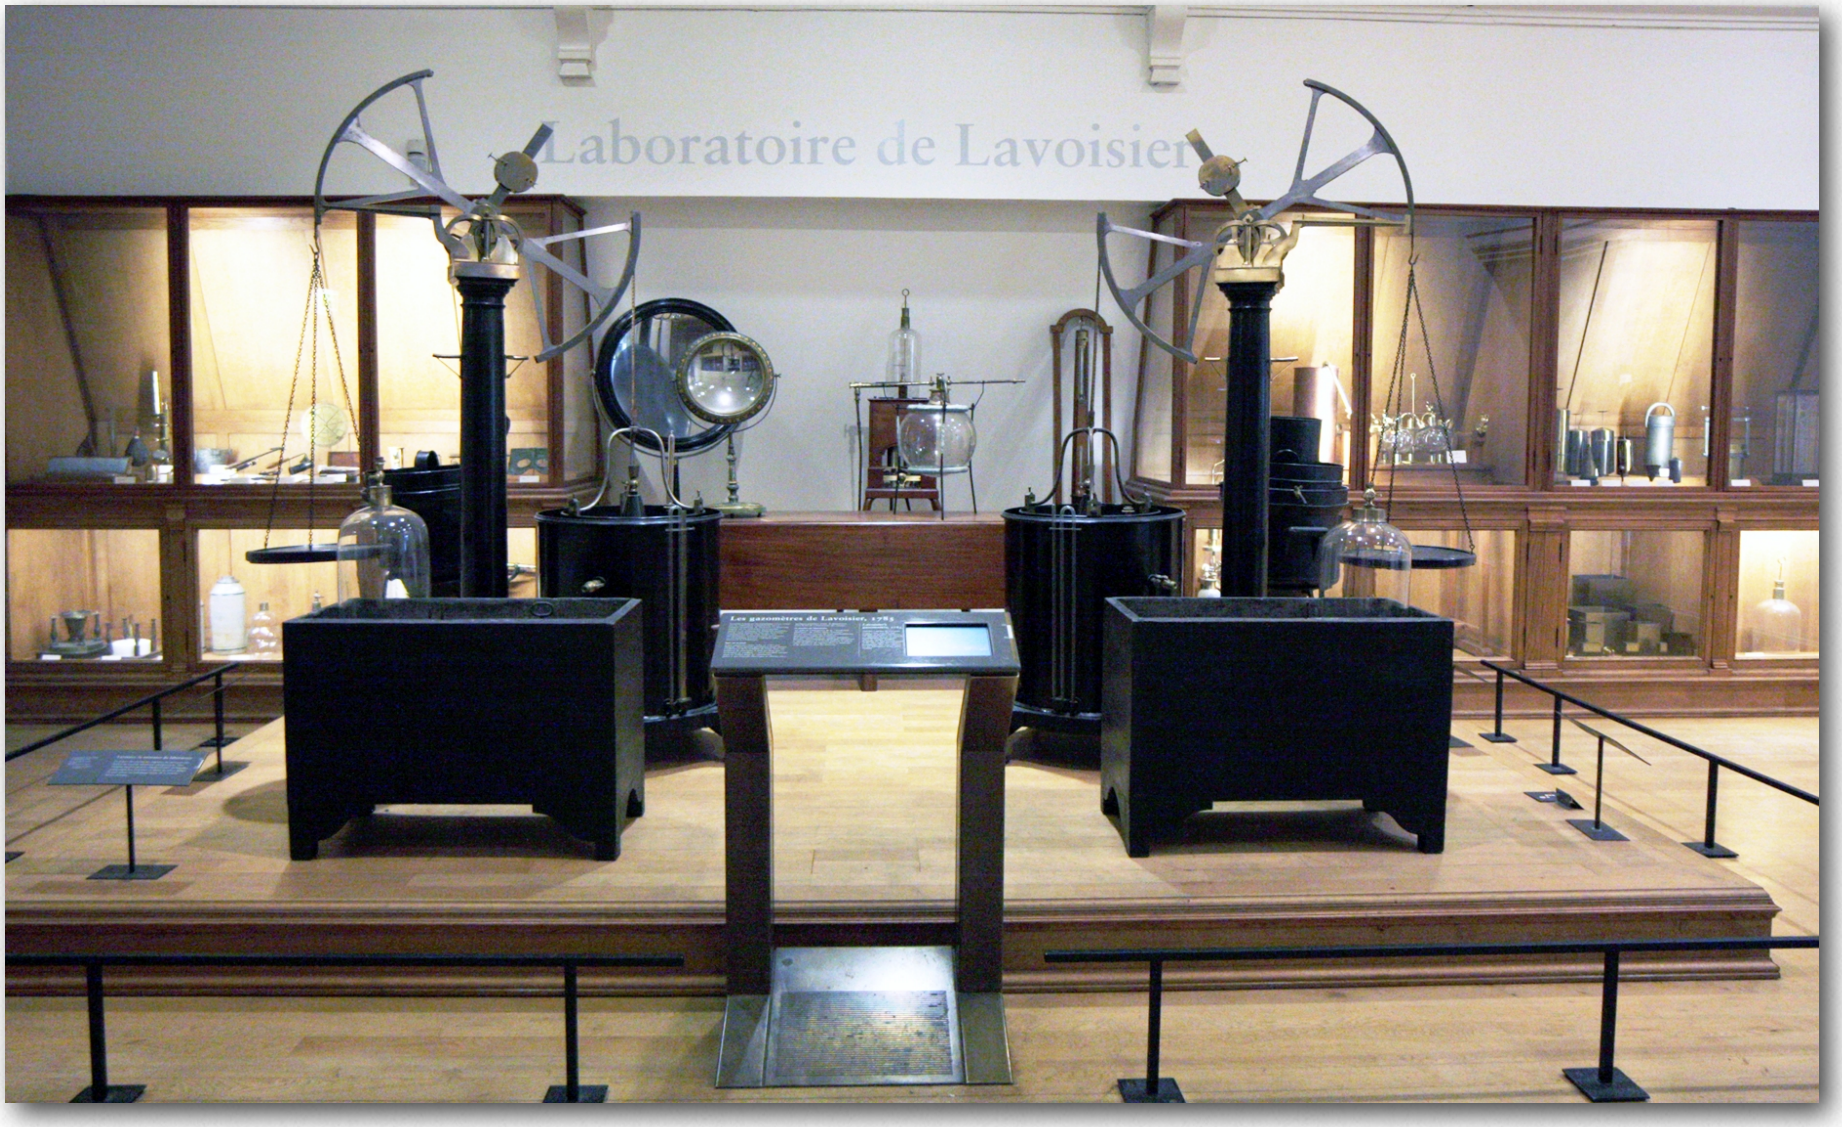
Introduction: Basic Chemistry



Certain chemistry

"Organic chemistry is the chemistry of carbon compounds. Biochemistry is the chemistry of carbon compounds that crawl"

-Michael Adams.

To understand biochemistry, one must possess at least a basic understanding of organic and general chemistry. In this brief section, we will provide a rapid review of the simple concepts necessary to understand cellular chemistry. Chemistry is chemistry, whether in a cell or outside it, but biological chemistry is a particular subset of organic chemistry that often involves enormous macromolecules, and that happens in the aqueous environment of the cell.

YouTube Lectures by Kevin HERE & HERE

Figure 1.18 shows the various organic functional groups common in biochemistry. You will encounter these functional groups as you study the biosynthetic and breakdown pathways that build and recycle the

chemical compounds of which cells are made. In addition to knowing the names and structures of these groups, students need a basic understanding of covalent and ionic bonds.

Class	General Structure	Name	Functional Group
Alkenes	RCH═CHR	Double Bond	C═C
Alcohols	ROH	Hydroxyl	—OH
Ethers	ROR	Ether	—O
Amines	RNH_2		
	R_2NH		
	R_3N	Amino	—N<
Thiols	RSH	Sulfhydryl	—SH
Aldehydes	R—C(=O)—H	Carbonyl	—C(=O)—
Ketones	R—C(=O)—R	Carbonyl	—C(=O)—
Carboxylic Acids	R—C(=O)—OH	Carboxyl	—C(=O)—OH
Amides	R—C(=O)—NR_2	Amide	—C(=O)—N<
Esters	R—C(=O)—OR′	Ester	—C(=O)—OR
Phosphoric Acid Esters	R—O—P(=O)(OH)—OH	Phosphoric Ester	—O—P(=O)(OH)—OH
Phosphoric Acid Anhydrides	R—C—P(=O)(OH)—O—P(=O)(OH)—OH	Phosphoric Anhydride	—P(=O)(OH)—O—P(=O)(OH)—

Figure 1.18 - Important functional groups in biochemistry

Image by Aleia Kim

Covalent bonds, as you know, are the result of sharing of electrons between two atoms. Ionic bonds, by contrast, are formed when one atom donates an electron to another, such as in the formation of sodium chloride.

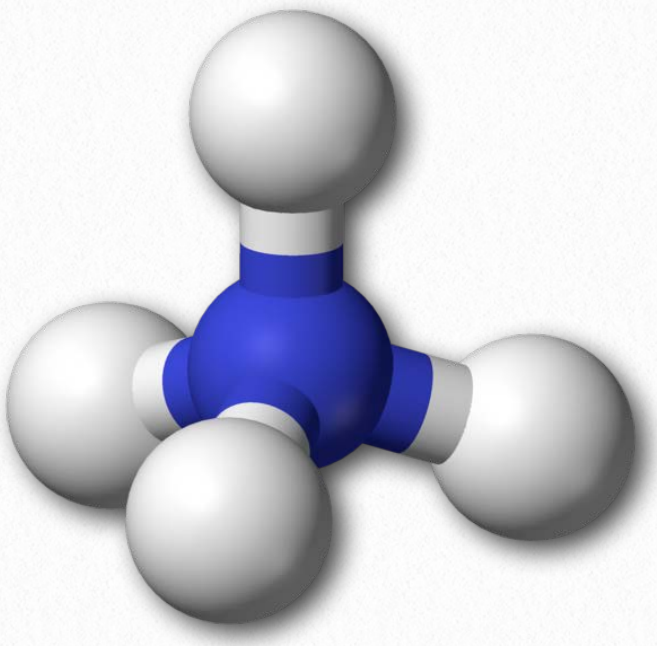


Figure 1.19 - Tetrahedral structure
Wikipedia

Single covalent bonds can rotate freely, but double bonds cannot. Single bonds around a carbon atom are arranged in a tetrahedron with bond angles of 109.5° relative to each other, with the carbon at the center (Figure 1.19). Double bonded carbons create a planar structure with bond angles typically of about 120°.

Electronegativity

Electronegativity is a measure of the affinity a nucleus has for outer shell electrons (Table 1.2). High electronegativity corresponds to high affinity. Electrons in a covalent bond are held closer to the nucleus with a greater electronegativity compared to a nucleus with lower electronegativity.

For example, in a molecule of water, with hydrogen covalently bonded to oxygen, the electrons are “pulled” toward the oxygen, which is more electronegative. Because of this, there is a slightly greater negative charge near the oxygen atom of water, compared to the hydrogen (which, correspondingly has a slightly higher positive charge). This unequal charge distribution sets up a dipole, with one side being somewhat negative and the other somewhat positive. Because of this, the molecule is described as polar.

Hydrogen bonds between water molecules are the result of the attraction of the partial positive and partial negative charges on different water molecules (Figure 1.20). Hydrogen bonds can also form between hydrogens

Table 1.2

Electronegativities of Various Atoms

Atom	Electronegativity
Oxygen	3.5
Nitrogen	3.0
Sulfur	2.6
Carbon	2.5
Phosphorous	2.2
Hydrogen	2.1

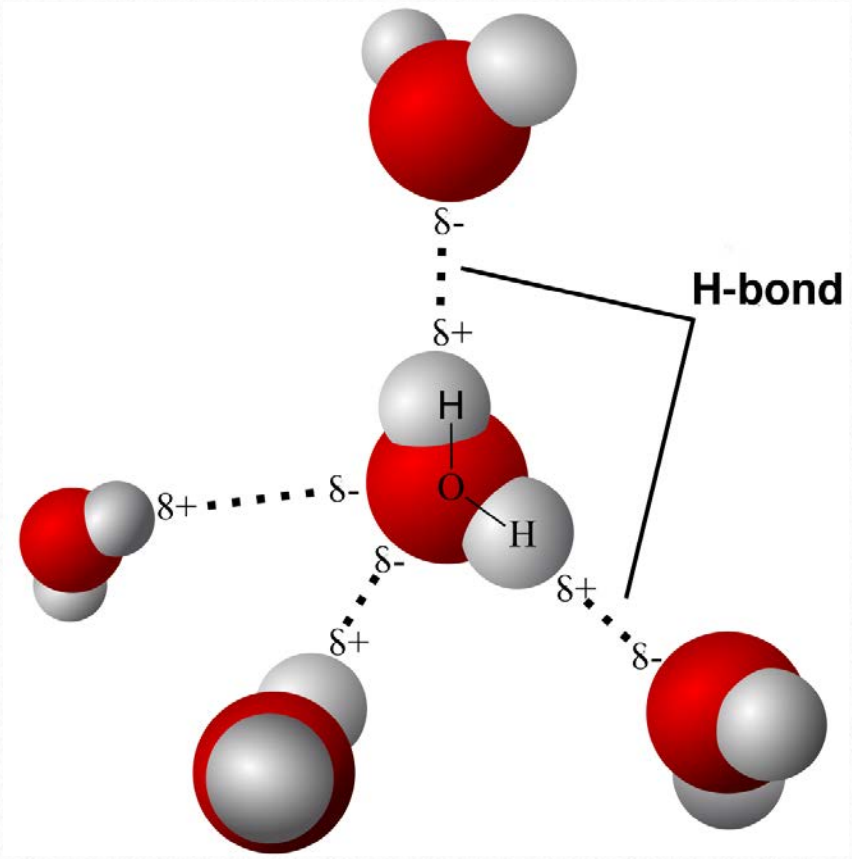

Figure 1.20 Hydrogen bonds (dotted lines) between water molecules

Wikipedia

with a partial positive charge and other strongly electronegative atoms, like nitrogen, with a partial negative charge. It is important to remember that hydrogen bonds are interactions between molecules (or parts of molecules) and are not bonds between atoms, like covalent or ionic bonds.

YouTube Lectures by Kevin HERE & HERE

Bonds between hydrogen and carbon do not form significant partial charges because the electronegativities of the two atoms are similar. Consequently, molecules containing many carbon-hydrogen bonds will not form hydrogen bonds and therefore, do not mix well with water. Such molecules are called hydrophobic. Other compounds with the ability to make hydrogen bonds are polar and can dissolve in water. They are called hydrophilic. Molecules possessing both characteristics are called amphiphilic.

Weak interactions

Hydrogen bonds are one kind of electrostatic (i.e., based on charge) interaction between dipoles. Other forms of electrostatic interactions that are important in biochemistry include weak interactions between a polar molecule and a transient dipole, or between two temporary dipoles. These temporary dipoles result from the movement of electrons in a molecule. As electrons move around, the place where they are, at a given time, becomes temporarily more negatively charged and could now attract a temporary positive charge on another molecule. Since electrons don't stay put, these dipoles are very short-lived. Thus, the attraction that depends on these dipoles fluctuates and is very weak. Weak interactions like these are sometimes called van der Waals forces. Many molecular interactions in cells depend on weak interactions. Although the individual hydrogen bonds or other dipole-dipole interactions are weak, because of their large numbers, they can result in quite strong interactions between molecules.

Oxidation/reduction

Oxidation involves loss of electrons and reduction results in gain of electrons. For

every biological oxidation, there is a corresponding reduction - one molecule loses electrons to another molecule. Oxidation reactions tend to release energy and are a source of bioenergy for chemotrophic cells.

Ionization

Ionization of biomolecules, by contrast does not involve oxidation/reduction. In ionization, a hydrogen ion (H^+) leaves behind its electron as it exits (leaving behind a negative charge) or joins a group (adding a positive charge). Biological ionizations typically involve carboxyl groups or amines, though phosphates or sulfates can also be ionized. A carboxyl group can have two ionization states - a charge of -1 corresponds to the carboxyl without its proton and a charge of zero corresponds to the charge of the carboxyl with its proton on. An amine also has two ionization states. A charge of zero corresponds to a nitrogen with three covalent bonds (usually in the form of C-NH_2) and a charge of +1 corresponds to a nitrogen making four covalent bonds (usually X-NH_3^+).

Stereochemistry

A carbon has the ability to make four single bonds (forming a tetrahedral structure) and if it bonds to four different chemical groups, their atoms can be arranged around the carbon in two different ways, giving rise to stereochemical "handedness" (Figure 1.21). Each carbon with such a property is referred to as an asymmetric center. The property of handedness *only* occurs when a carbon has four different groups bonded to it. Enzymes have very specific 3-D structures, so for biological molecules that can exist in different stereoisomeric forms, an enzyme that synthesizes it would make only one of the possible isomers. By contrast, the same molecules made chemically (not using enzymes) end up with equal amounts of both isomers, called a racemic mix.

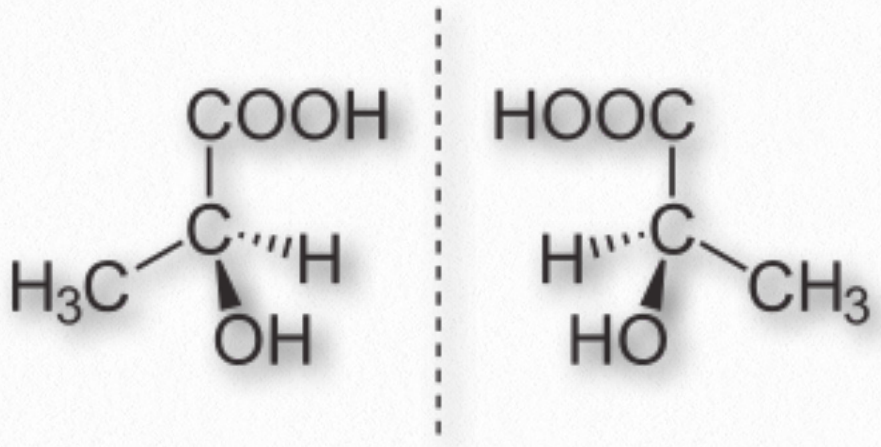

Figure 1.21 - Mirror images of lactic acid

Gibbs free energy

The Gibbs free energy calculation allows us to determine whether a reaction will be spontaneous, by taking into consideration two factors, change in enthalpy (ΔH) and change in entropy (ΔS).

The free energy content of a system is given by the Gibbs free energy (G) and is equal to the enthalpy (H) for a process minus the absolute temperature (T) times the entropy (S)

$$G = H = TS$$

For a process, the change in the Gibbs free energy ΔG is given by

$$\Delta G = \Delta H - T\Delta S$$

A ΔG that is negative corresponds to release of free energy. Reactions that release energy are exergonic, whereas those that absorb energy are called endergonic.

The biological standard Gibbs free energy change ($\Delta G°'$) corresponds to the ΔG for a process under standard conditions of temperature, pressure, and at pH = 7. For a reaction

$$aA + bB <=> cC + dD,$$

the equilibrium constant, K_{eq} is equal to

$$K_{eq} = \{[C]^c_{eq}[D]^d_{eq}]\} / \{[A]^a_{eq}[B]^b_{eq}\}$$

where a,b,c,and d are integers in the balanced equation. Large values of K_{eq} correspond to favorable reactions (more C and D produced than A and B) and small values of K_{eq} mean the opposite. At equilibrium,

$$\Delta G°' = -RT\ln K_{eq}$$

If a process has a $\Delta G = Z$ and a second process has a $\Delta G = Y$, then if the two processes are linked, ΔG and $\Delta G°'$ values for the overall reaction will be the sum of the individual ΔG and $\Delta G°'$ values.

$$\Delta G_{total} = \Delta G_1 + \Delta G_2 = Z + Y$$

$$\Delta G°'_{total} = \Delta G_1°' + \Delta G_2°'$$

Catalysis

Catalysis is an increase in the rate of a reaction induced by a substance that is, itself, unchanged by the reaction. Because catalysts remain unchanged at the end of a reaction, a single catalyst molecule can be reused for many reaction cycles. Proteins that catalyze reactions in cells are called enzymes, while ribozymes are RNA molecules that act as catalysts.

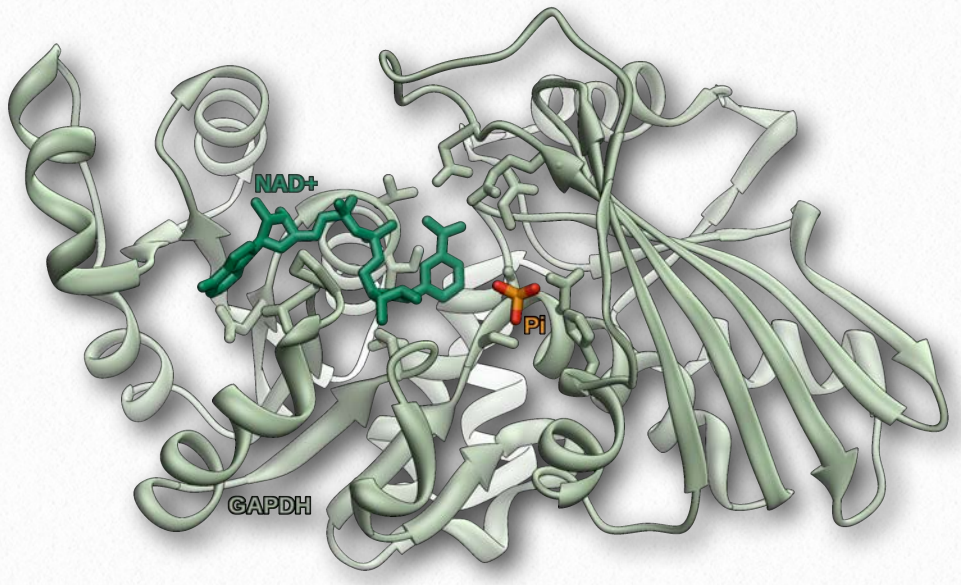

Figure 1.22 - Glyceraldehyde-3-phosphate dehydrogenase in the midst of catalysis

The Number Song

To the tune of "*Everybody Loves Somebody Sometime*"

Metabolic Melodies Website HERE

Avogadro's number is a huge one
Boltzmann's constant's rather miniscule
Values differing enormously
As we learned in school

Science numbers need to have dimensions
Size is not the most important thing
Units give the yardsticks needed
For under-STAN-ding

Bridge

It's taught in the ivory towers
By professors it's so ballyhooed
Values can have such diff'rent powers
That to know them we must have their magnitudes

One light year's a really lengthy distance
Grams define the masses high and low
The ohm can measure the resistance
If current should flow

Bridge

One set of factors you SHOULD know
The roots of seven and of three et al
Cannot be expressed as a ratio
Oh these numbers all are quite irration-al

Three point one four one five nine two six five
No end to Pi's digits it's absurd
Endlessly reminding me that I've
BEEN SO OUT-num-bered

Introduction: Water and Buffers

Water everywhere

When it comes to water, we're literally drowning in it, as water is by far the most abundant component of every cell. To understand life, we begin the discussion with the basics of water, because everything that happens in cells, even reactions buried deep inside enzymes, away from water, is influenced by water's chemistry.

YouTube Lectures by Kevin HERE & HERE

The water molecule has wide 'V' shape (the H-O-H angle is 104°) with uneven sharing of electrons between the oxygen and the hydrogen atoms (Figure 1.23). Oxygen, with its higher electronegativity, holds electrons closer to itself than the hydrogens do. The hydrogens, as a result, are described as having a partial positive charge (typically designated as δ^+) and the oxygen has a partial negative charge (written as δ^-). Thus, water is

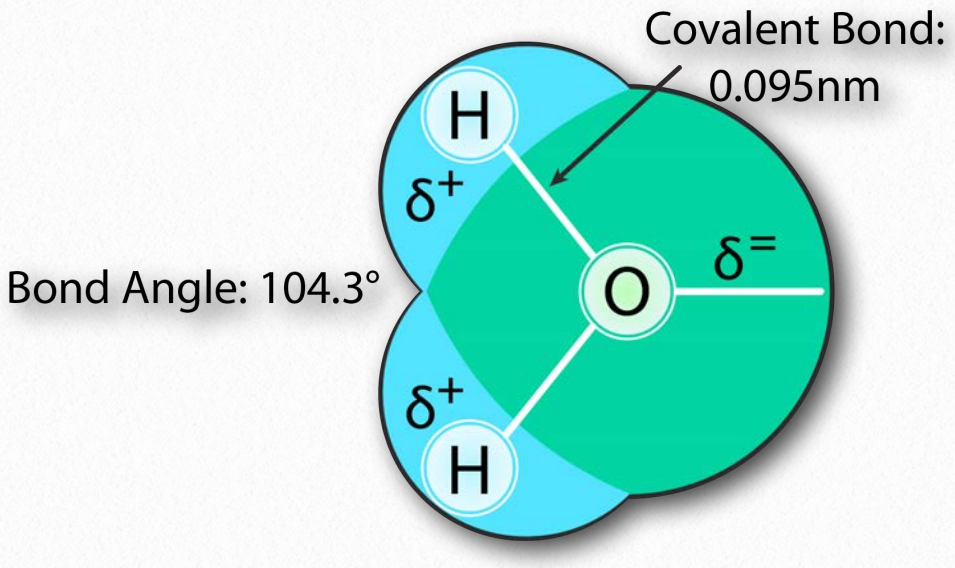

Figure 1.23 - Arrangement of atoms in water
Image by Aleia Kim

a polar molecule because charges are distributed around it unevenly, not symmetrically.

Water as a solvent

Water (Figure 1.23) is described as a solvent because of its ability to solvate (dissolve) many, but not all, molecules. Molecules that are ionic or polar dissolve readily in water, but non-polar substances dissolve poorly in water, if at all. Oil, for example, which is non-polar, separates from water when mixed with it. On the other hand, sodium chloride, which ionizes, and ethanol, which is polar, are able to form hydrogen bonds, so both dissolve in water. Ethanol's solubility in water is crucial for brewers, winemakers, and distillers – but for this property, there would be no wine, beer or spirits. As explained in an earlier section, we use the term hydrophilic to describe substances that interact well with water and dissolve in it and the term hydrophobic to refer to materials that are non-polar and do not dissolve in water. Table 1.3 illustrates some polar and non-polar substances. A third term, amphiphilic, refers to compounds that have both properties. Soaps, for example are amphiphilic, containing a long, non-polar aliphatic tail and a head that ionizes.

Solubility

The solubility of materials in water is based in free energy changes, as measured by ΔG. Re-

Table 1.3

Hydrophilic vs Hydrophobic Compounds

Hydrophobic	Hydrophilic
Nonpolar hydrocarbons (hexane)	Ionic compounds (NaCl)
Lipids (fats and cholesterol)	Polar organic compounds (alcohols, ketones or carbonyls)
	Weak acids (phosphates, amino acids)
	Sugars/carbohydrates

member, from chemistry, that H is the enthalpy (heat at constant pressure) and S is entropy. Given this,

$$\Delta G = \Delta H - T\Delta S,$$

where T is the temperature in Kelvin. For a process to be favorable, the ΔG for it must be less than zero.

From the equation, lowered ΔG values will be favored with decreases in enthalpy and/or increases in entropy. Let us first consider why non-polar materials do not dissolve in water. We could imagine a situation where the process of dissolving involves the "surrounding" of each molecule of the non-polar solute in water, just like each sodium and each chloride ion gets surrounded by water molecules as salt dissolves.

Water organization

There is a significant difference, though between surrounding a non-polar molecule with water molecules and surrounding ions (or polar compounds) with water molecules.

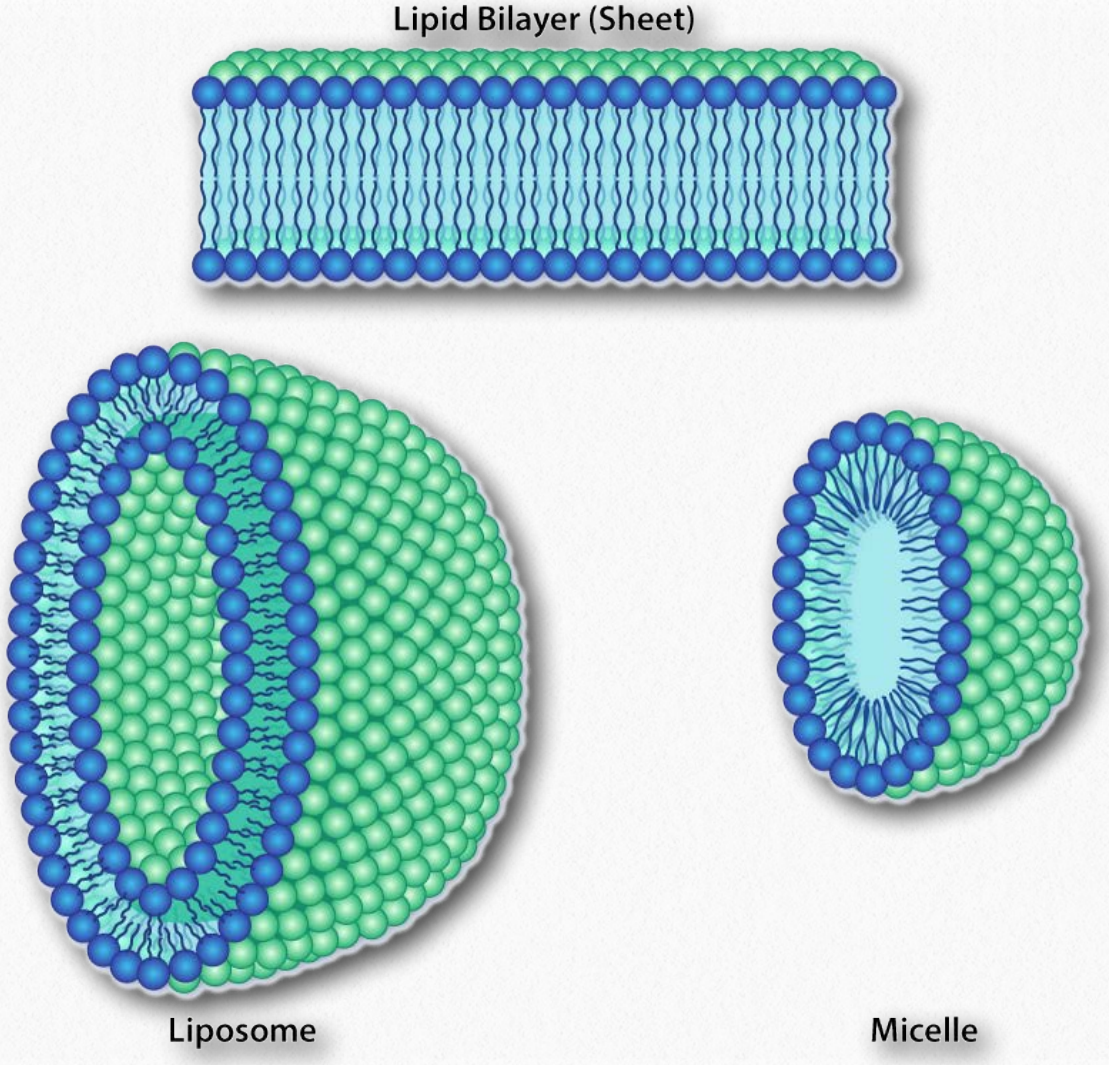

Figure 1.25 - Structures formed by amphiphilic substances in water.

Image by Aleia Kim

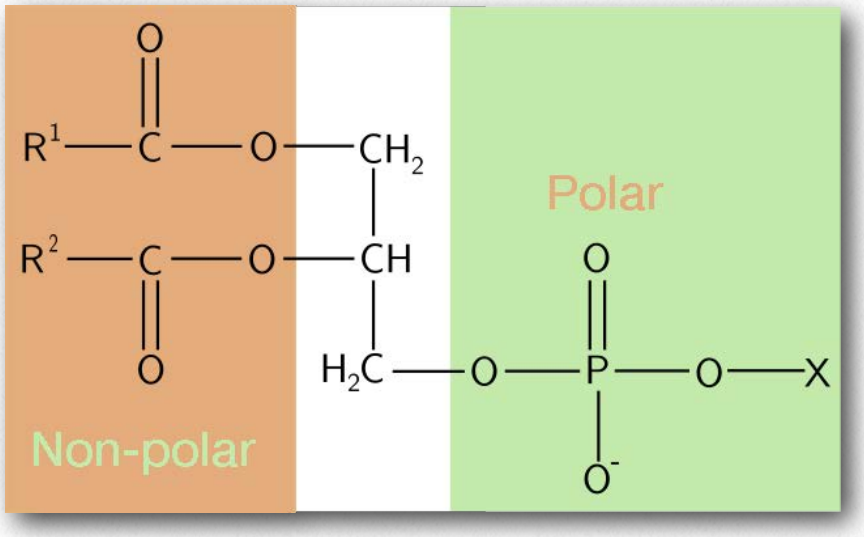

Figure 1.26 - A phospholipid - an amphiphilic substance

Since mixing a non-polar substance with water doesn't generally have any significant heat component, the ΔG is positive. This means, then, that dissolving a non-polar compound in water is not favorable and does not occur to any significant extent. Further, when the non-polar material associates with itself and not water, then the water molecules are free to mix, without being ordered, resulting in an increase of entropy. Entropy therefore drives the separation of non-polar substances from aqueous solutions.

The difference is that since non-polar molecules don't really interact with water, the water behaves very differently than it does with ions or molecules that form hydrogen bonds. In fact, around each non-polar molecule, water gets *very* organized, aligning itself regularly. As any freshman chemistry student probably remembers, entropy is a measure of disorder, so when something becomes ordered, entropy decreases, meaning the ΔS is negative, so the $T\Delta S$ term in the equation is positive (negative of a negative).

Figure 1.27 - Vinegar (black) and oil (yellow) A mix of polar and nonpolar compounds
Wikipedia

Amphiphilic substances

Next, we consider mixing of an amphiphilic substance, such as a soap, with water (Figure 1.24). The sodium ions attached to the fatty acids in soap readily come off in aqueous solution, leaving behind a negatively charged molecule at one end and a non-polar region at the other end. The ionization of the soap causes in an increase in entropy - two particles instead of one. The non-polar portion of the negatively charged soap ion is problematic - if exposed to water, it will cause

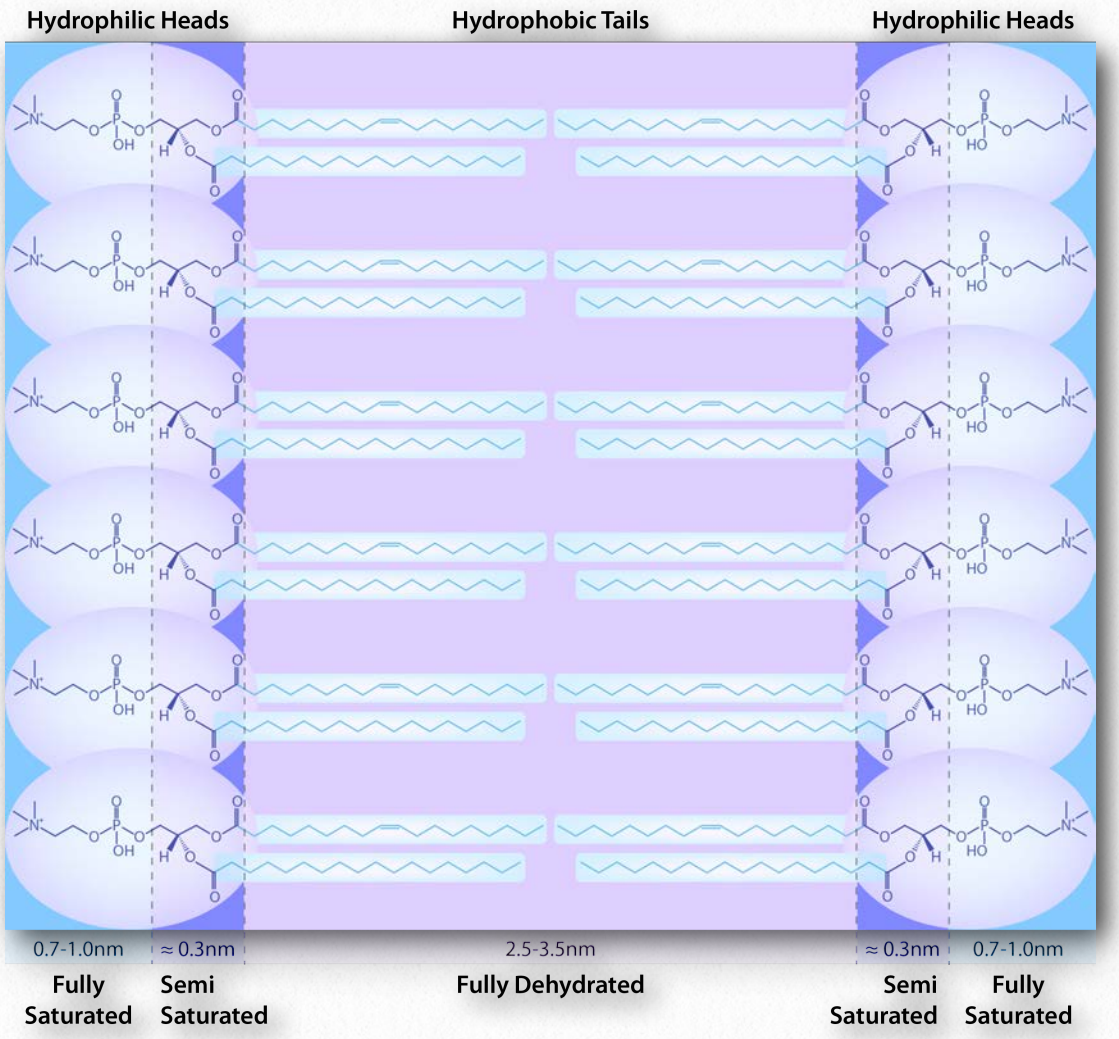

Figure 1.28 - Environment of a lipid bilayer. Water is concentrated away from the hydrophobic center, being saturated on the outside, semi-saturated near the head-tail junction and fully dehydrated in the middle.

Image by Aleia Kim

water to organize and result in a decrease of entropy and a positive ΔG.

Since we know fatty acids dissolve in water, there must be something else at play. There is. Just like the non-polar molecules in the first example associated with each other and not water, so too do the non-polar portions of the soap ions associate with each other and exclude water. The result is that the soap ions arrange themselves as micelles (Figure 1.25) with the non-polar portions on the interior of the structure away from water and the polar portions on the outside interacting with water.

The interaction of the polar heads with water returns the water to its more disordered state. This increase in disorder, or entropy, drives the formation of micelles. As will be seen in the discussion of the lipid bilayer, the same forces drive glycerophospholipids and sphingolipids to spontaneously form bilayers where the non-polar portions of the molecules interact with each other to exclude water and the polar portions arrange themselves on the outsides of the bilayer (Figure 1.28).

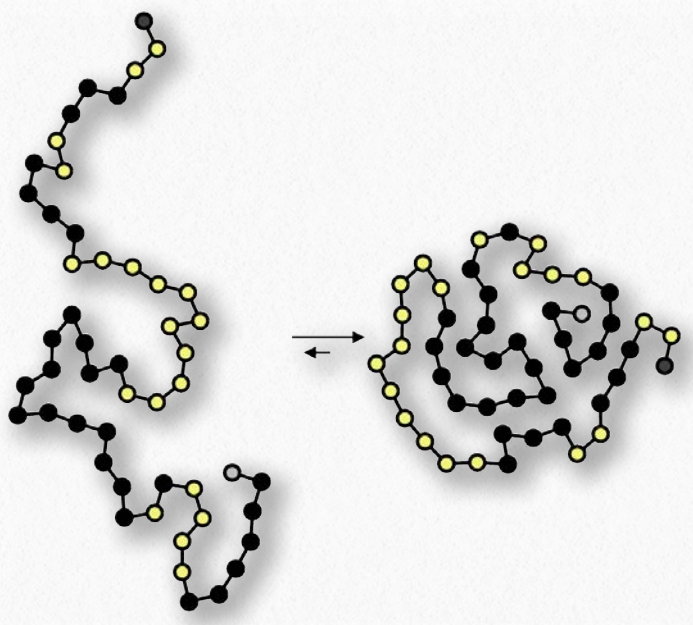

Figure 1.29 - Protein folding arranges hydrophobic amino acids (black dots) inside the protein

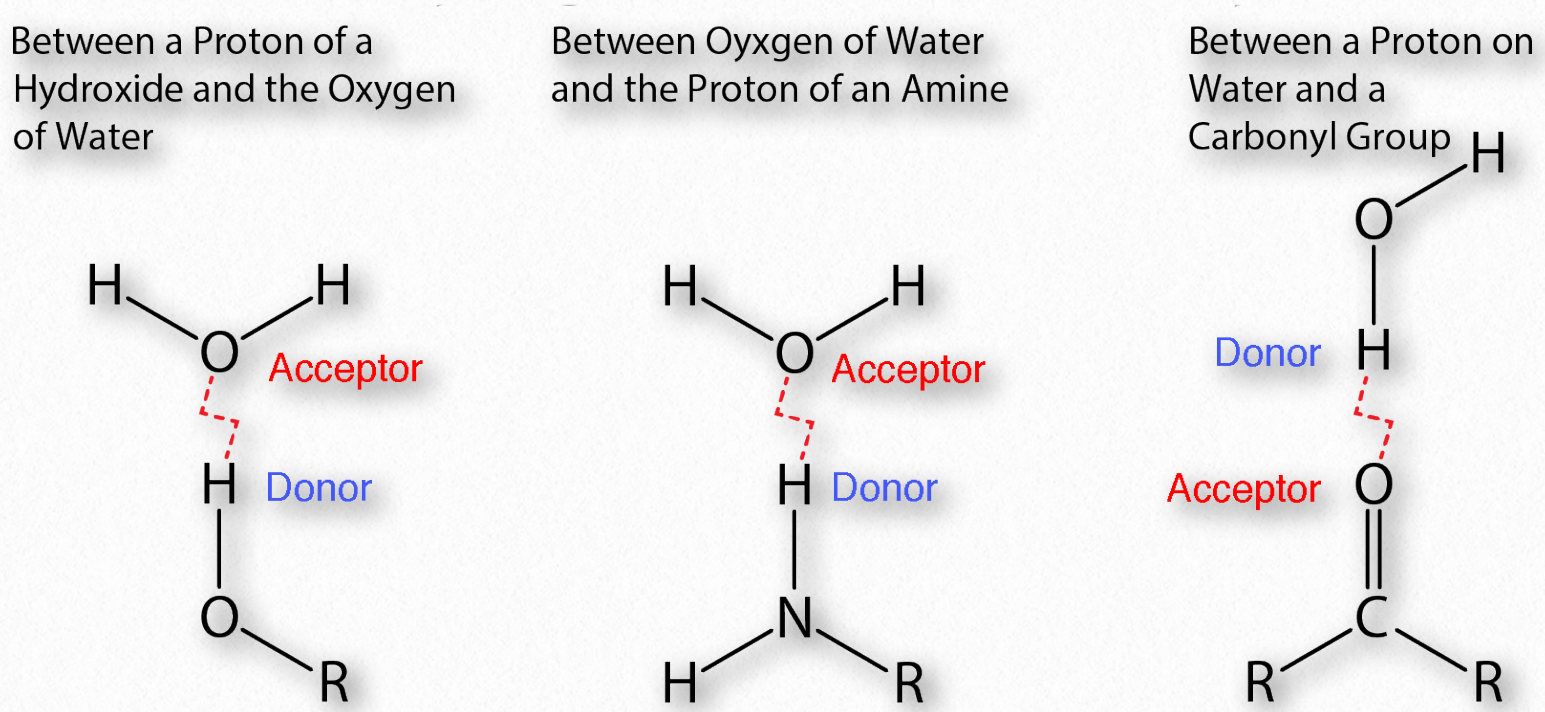

Figure 1.30 - Common hydrogen bonds in biochemistry

Image by Aleia Kim

Yet another example is seen in the folding of globular proteins in the cytoplasm. Non-polar amino acids are found in the interior portion of the protein (water excluded). Interaction of the non-polar amino acids turns out to be a driving force for the folding of proteins as they are being made in an aqueous solution.

Hydrogen bonds

The importance of hydrogen bonds in biochemistry (Figure 1.30) is hard to overstate. Linus Pauling himself said,

" . . . . *I believe that as the methods of structural chemistry are further applied to physiological problems it will be found that the significance of the hydrogen bond for physiology is greater than that of any other single structural feature.*"

In 2011, an IUPAC task group gave an evidence-based definition of hydrogen bonding that states,

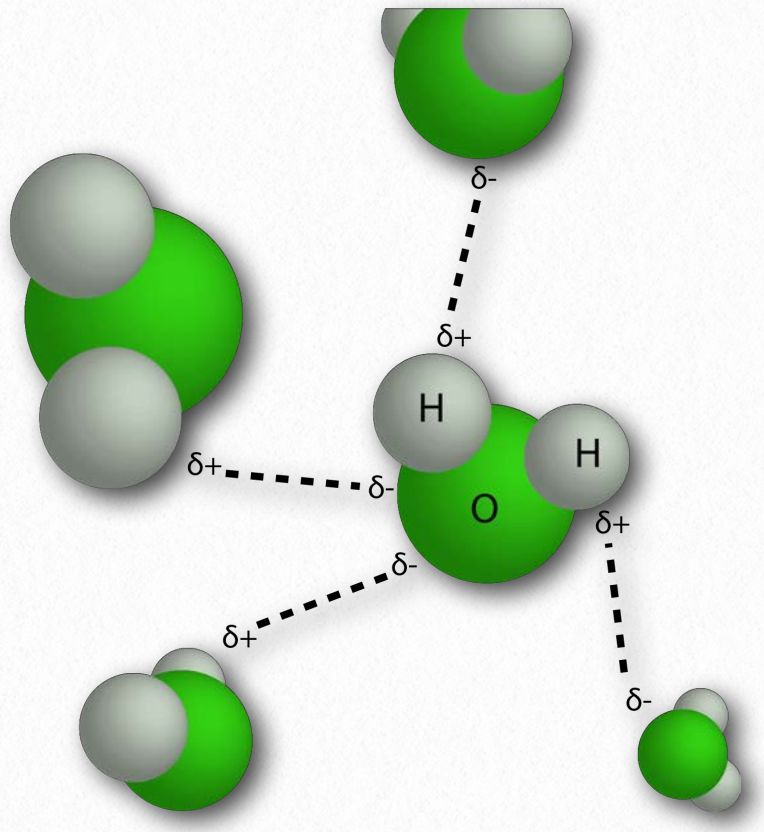

Figure 1.31 - Hydrogen bonds between water molecules

Image by Pehr Jacobson

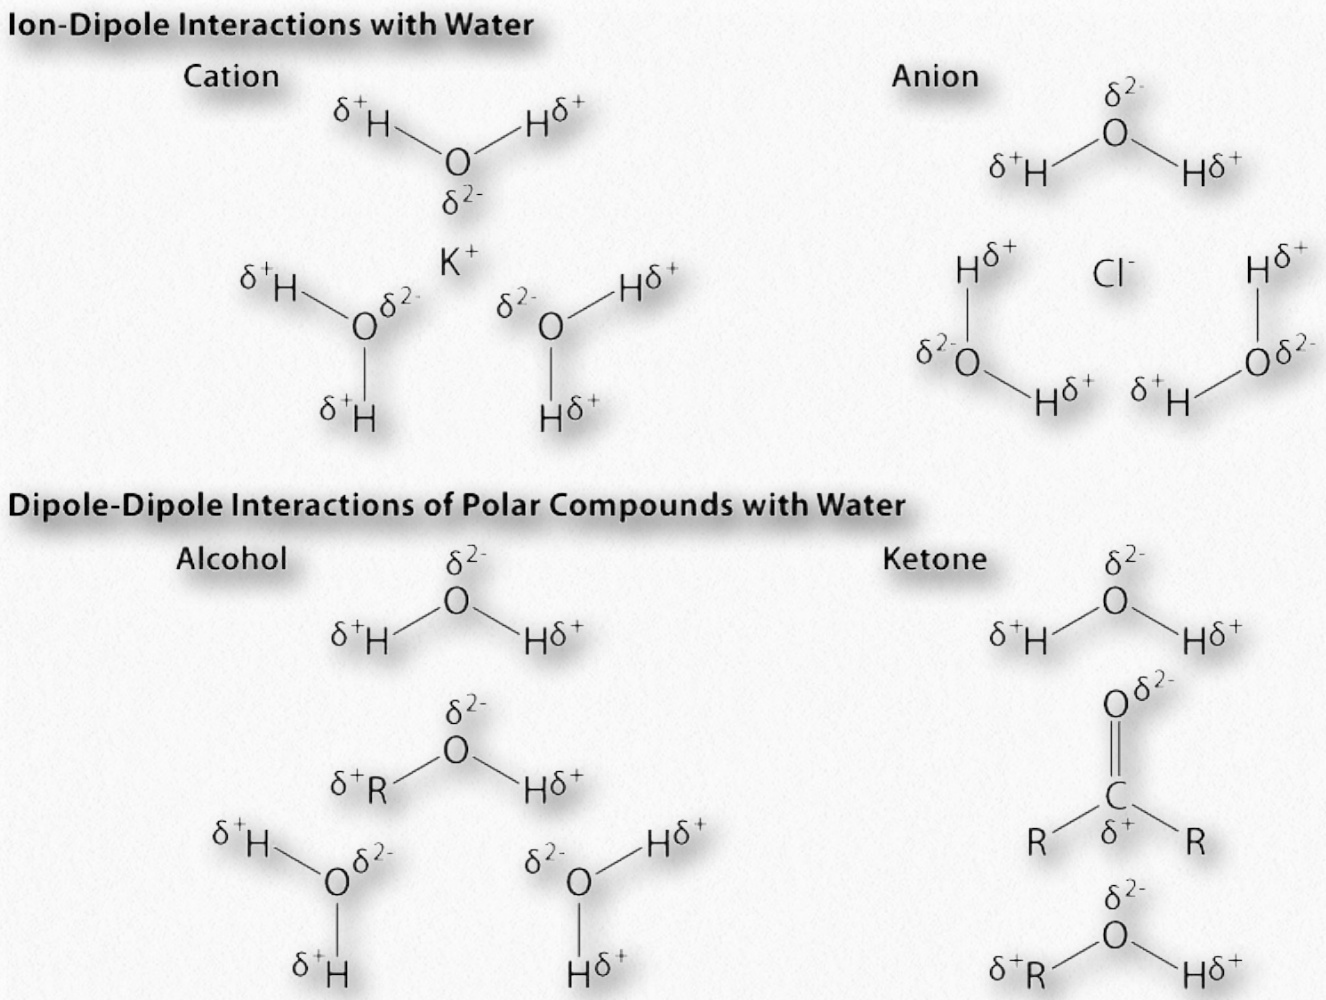

Figure 1.32 - Example dipole interactions in biochemistry
Image by Aleia Kim

"*The hydrogen bond is an attractive interaction between a hydrogen atom from a molecule or a molecular fragment X–H in which X is more electronegative than H, and an atom or a group of atoms in the same or a different molecule, in which there is evidence of bond formation.*"

YouTube Lectures by Kevin HERE & HERE

Partial charges

The difference in electronegativity between hydrogen and the molecule to which it is covalently bound give rise to partial charges as described above. These tiny charges (δ^+ and δ^-) result in formation of hydrogen bonds, which occur when the partial positive charge of a hydrogen atom is attracted to the partial negative of another molecule. In water, that means the hydrogen of one water molecule is attracted to the oxygen of another (Figure 1.31). Since water is an asymmetrical molecule, it means also that the charges are asymmetrical. Such an uneven distribution is what makes a dipole. Dipolar molecules are important for interactions with other dipolar molecules and for dissolving ionic substances (Figure 1.32).

Hydrogen bonds are not exclusive to water. In fact, they are important forces holding together macromolecules that include proteins and nucleic acids. Hydrogen bonds occur within and between macromolecules.

The complementary pairing that occurs between bases in opposite strands of DNA, for example, is based on hydrogen bonds.

Table 1.4

Bond Energies

	Type of Bond	Bond Energy (kJ/mol)
Covalent Bonds	C—H	413
	O—H	460
Noncovalent Bonds	Hydrophobic Interaction	4-12
	Hydrogen Bond	20
	Ion-dipole Interaction	20

Image by Aleia Kim

Each hydrogen bond is relatively weak (compared to a covalent bond, for example - Table 1.4), but collectively they can be quite strong.

Benefits of weak interactions

Their weakness, however, is actually quite beneficial for cells, particularly as regards nucleic acids (Figure 1.33). The strands of DNA, for example, must be separated over short stretches in the processes of replication and the synthesis of RNA. Since only a few base pairs at a time need to be separated, the energy required to do this is small and the enzymes involved in the processes can readily take them apart, as needed. Hydrogen bonds also play roles in binding of substrates to enzymes, catalysis, and protein-protein interaction, as well as other kinds of binding, such as protein-DNA, or antibody-antigen.

As noted, hydrogen bonds are weaker than covalent bonds (Table 1.4) and their strength varies from very weak (1-2 kJ/mol) to fairly strong (29 kJ/mol). Hydrogen bonds only occur over relatively short distances (2.2 to

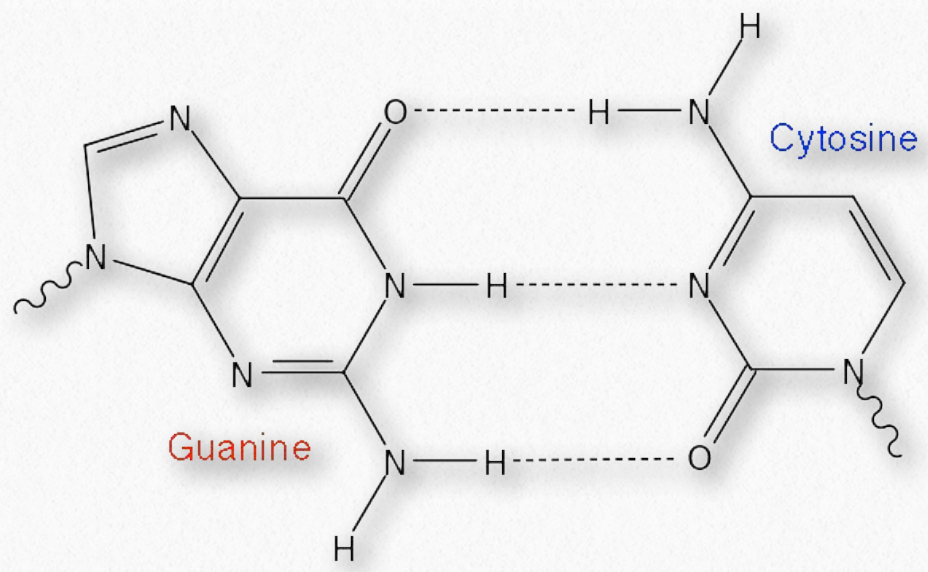

Figure 1.33 - Hydrogen bonds in a base pair of DNA

Image by Aleia Kim

4.0 Å). The farther apart the hydrogen bond distance is, the weaker the bond is.

The strength of the bond in kJ/mol represents the amount of heat that must be put into the system to break the bond - the larger the number, the greater the strength of the bond. Hydrogen bonds are readily broken using heat. The boiling of water, for example, requires breaking of H-bonds. When a biological structure, such as a protein or a DNA molecule, is stabilized by hydrogen bonds, breaking those bonds destabilizes the structure and can result in denaturation of the substance - loss of structure. It is partly for this reason that most proteins and all DNAs lose their native, or folded, structures when heated to boiling.

For DNA molecules, denaturation results in complete separation of the strands from each other. For most proteins, this means loss of

Table 1.5

Image by Aleia Kim

their characteristic three-dimensional structure and with it, loss of the function they performed. Though a few proteins can readily reassume their original structure when the solution they are in is cooled, most can't. This is one of the reasons that we cook our food. Proteins are essential for life, so denaturation of bacterial proteins results in death of any microorganisms contaminating the food.

YouTube Lectures by Kevin HERE & HERE

The importance of buffers

Water can ionize to a slight extent (10^{-7} M) to form H^+ (proton) and OH^- (hydroxide). We measure the proton concentration of a solution with pH, which is the negative log of the proton concentration.

$$pH = -Log[H^+]$$

If the proton concentration, $[H^+]= 10^{-7}$ M, then the pH is 7. We could just as easily measure the hydroxide concentration with the pOH by the parallel equation,

$$pOH = -Log[OH^-]$$

In pure water, dissociation of a proton simultaneously creates a hydroxide, so the pOH of pure water is 7, as well. This also means that

$$pH + pOH = 14$$

Now, because protons and hydroxides can combine to form water, a large amount of one will cause there to be a small amount of the other. Why is this the case? In simple terms, if I dump 0.1 moles of H^+ into a pure water solution, the high proton concentration will react with the relatively small amount of hydroxides to create water, thus reducing hydroxide concentration. Similarly, if I dump excess hydroxide (as NaOH, for example) into pure water, the proton concentration falls for the same reason.

Acids vs bases

Chemists use the term "acid" to refer to a substance which has protons that can dissociate (come off) when dissolved in water. They use the term "base" to refer to a substance that can absorb protons when dissolved in water. Both acids and bases come in strong and weak forms. (Examples of weak acids are shown in Table 1.5.)

Strong acids, such as HCl, dissociate completely in water. If we add 0.1 moles ($6.02x10^{22}$ molecules) of HCl to a solution to make a liter, it will have 0.1 moles of H^+ and

I confess I am pleased to possess
In my buffers a strong UPS
Giving H's when needed
Grabbing same when exceeded
So my cells don't get proton distressed

Clearing Confusion - Students are often puzzled and expect that

$$[H^+] = [A^-]$$

because the dissociation equation shows one of each from HA. This is, in fact, true ONLY when HA is allowed to dissociate in pure water. Usually the HA is placed into solution that has protons and hydroxides to affect things. Those protons and /or hydroxides change the H^+ and A^- concentration unequally, since A^- can absorb some of the protons and/or HA can release H^+ when influenced by the OH^- in the solution. Therefore, one must calculate the proton concentration from the pH using the Henderson Hasselbalch equation.

$$pH = pK_a + \log([Ac^-]/[HAc])$$

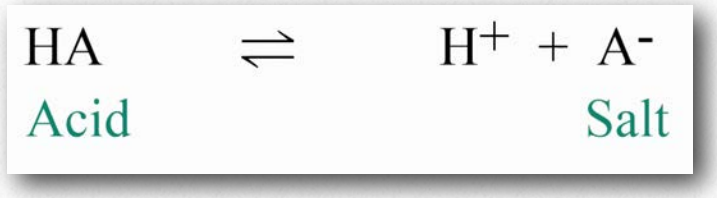

Figure 1.34 - Dissociation of a weak acid

Image by Aleia Kim

0.1 moles of Cl^- or $6.02x10^{22}$ molecules of each . There will be no remaining HCl when this happens. A strong base like NaOH also dissociates completely into Na^+ and OH^-.

Weak acids

Weak acids and bases differ from their strong counterparts. When you put one mole of acetic acid (HAc) into pure water, only a tiny percentage of the HAc molecules dissociate into H^+ and Ac^-. Clearly, weak acids are very different from strong acids. Weak bases behave similarly, except that they accept protons, rather than donate them. Since we can view everything as a form of a weak acid, we will not use the term weak base here.

You may wonder why we care about weak acids. You may never have thought much of weak acids when you were in General Chemistry. Your instructor described them as buffers and you probably dutifully memorized the fact that “buffers are substances that resist change in pH” without really learning what

Table 1.6

Salt/Acid Ratio as a Function of pK_as

pH	[Salt]/[Acid]
$pK_a + 3$	1000
$pK_a + 2$	100
$pK_a + 1$	10
pK_a	1
$pK_a - 1$	1/10
$pK_a - 2$	1/100
$pK_a - 3$	1/1000

Image by Aleia Kim

this meant. Buffers are much too important to be thought of in this way.

UPS

Weak acids are critical for life because their affinity for protons causes them to behave like a UPS. We're not referring to the UPS that is the United Parcel Service®, but instead, to the encased battery backup systems for computers called Uninterruptible Power Supplies that kick on to keep a computer running during a power failure. The battery in a laptop computer is a UPS, for example.

We can think of weak acids as Uninterruptible Proton Suppliers within certain pH ranges,

> On this chemical fact we must dwell
> H-A-C's just not like H-C-L
> It always negotiates
> Before it dissociates
> To bid every proton farewell

providing (or absorbing) protons as needed. Weak acids thus help to keep the H^+ concentration (and thus the pH) of the solution they are in relatively constant.

Consider the bicarbonate/carbonic acid system. Figure 1.35 shows what happens when H_2CO_3 dissociates. Adding hydroxide ions (by adding a strong base like NaOH) to the solution causes the H^+ ions to react with OH^- ions to make water. Consequently, the concentration of H^+ ions would go down and the pH would go up.

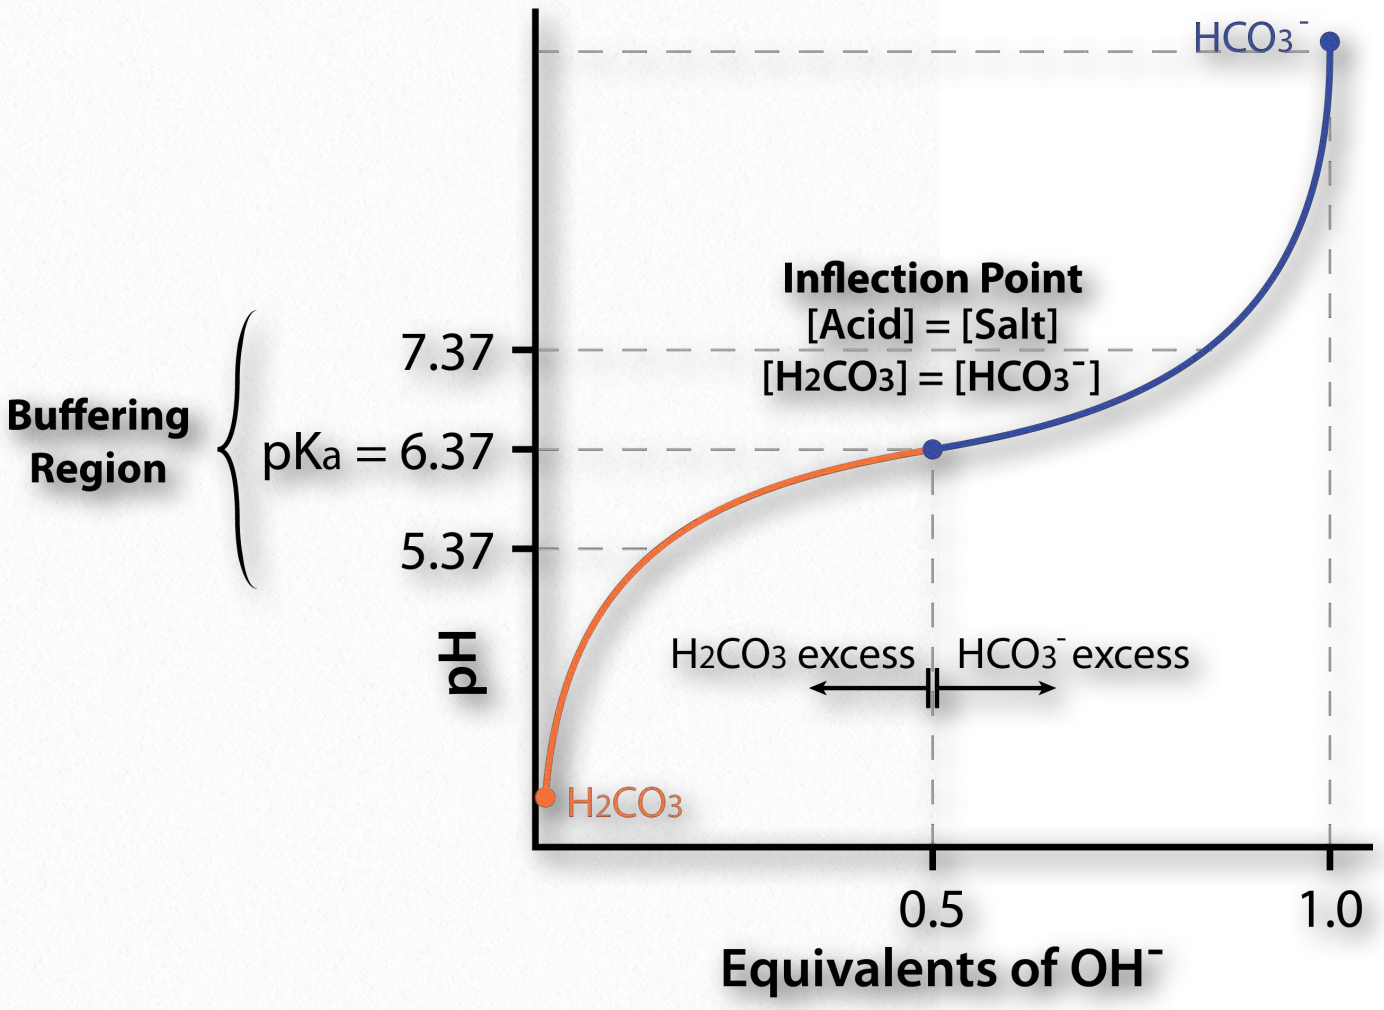

Figure 1.35 - Titration curve for carbonic acid

Image by Aleia Kim

However, in contrast to the situation with a solution of pure water, there is a backup source of H^+ available in the form of H_2CO_3. Here is where the UPS function kicks

in. As protons are taken away by the added hydroxyl ions (making water), they are partly replaced by protons from the H_2CO_3. This is why a weak acid is a buffer. It resists changes in pH by releasing protons to compensate for those "used up" in reacting with the hydroxyl ions.

Why do we care about pH? Because biological molecules can, in some cases, be exquisitely sensitive to changes in it. As the pH of a solution changes, the charges of molecules in the solution can change, as you will see. Changing charges on biological molecules, especially proteins, can drastically affect how they work and even whether they work at all.

Henderson-Hasselbalch

It is useful to be able to predict the response of the H_2CO_3 system to changes in H^+ concentration. The Henderson-Hasselbalch equation defines the relationship between pH and the ratio of HCO_3^- and H_2CO_3. It is

$$pH = pKa + \log([HCO3^-]/[H_2CO_3])$$

This simple equation defines the relationship between the pH of a solution and the ratio of $HCO3^-$ and H_2CO_3 in it. The new term, called the pK_a, is defined as

$$pK_a = -\text{Log } K_a,$$

just as

$$pH = -\text{Log } [H^+].$$

The K_a is the acid dissociation constant and is a measure of the strength of an acid. For a general acid, HA, which dissociates as

$$HA \rightleftarrows H^+ + A^-,$$

$$K_a = [H^+][A^-]/[HA]$$

Thus, the stronger the acid, the more protons that will dissociate from it when added to water and the larger the value its K_a will have. Large values of K_a translate to lower values of pK_a. As a result, the lower the pKa value is for a given acid, the stronger the weak acid is.

YouTube Lectures by Kevin
HERE & HERE

Constant pK_a

Please note that pK_a is a constant for a given acid. The pK_a for carbonic acid is 6.37. By comparison, the pK_a for formic acid is 3.75. Formic acid is therefore a stronger acid than acetic acid. A stronger acid will have more protons dissociated at a given pH than a weaker acid.

Now, how does this translate into stabilizing pH? Figure 1.35 shows a titration curve. In this curve, the titration begins with the conditions at the lower left (very low pH). At this pH, the H_2CO_3 form predominates, but as more and more OH^- is added (moving to the

right), the pH goes up, the amount of $HCO3^-$ goes up and (correspondingly), the amount of H_2CO_3 goes down. Notice that the curve "flattens" near the pK_a (6.37).

Buffering region

Flattening of the curve tells us is that the pH is not changing much (not going up as fast) as it did earlier when the same amount of hydroxide was added. The system is resisting a change in pH (not stopping the change, but slowing it) in the region of about one pH unit above and one pH unit below the pK_a. Thus, the buffering region of the carbonic acid/bicarbonate buffer is from about 5.37 to 7.37. It is maximally strong at a pH of 6.37.

Now it starts to become apparent how the buffer works. HA can donate protons when extras are needed (such as when OH^- is added to the solution by the addition of NaOH). Similarly, A^- can accept protons when extra H^+ are added to the solution (adding HCl, for example). The maximum ability to donate or accept protons comes when

$$[A^-] = [HA]$$

This is consistent with the Henderson Hasselbalch equation and the titration curve. When $[A^-] = [HA]$, pH = 6.37 + Log(1). Since Log(1) = 0, pH = 6.37 = pKa for carbonic acid. Thus for any buffer, the buffer will have maximum strength and display flattening of its titration curve when $[A^-] = [HA]$ and when pH = pK_a. If a buffer has more than one pK_a (Figure 1.36), then each pK_a region will display the behavior.

Buffered vs non-buffered

To understand how well a buffer protects against changes in pH, consider the effect of adding .01 moles of HCl to 1.0 liter of pure water (no volume change) at pH 7, compared to adding it to 1.0 liter of a 1M acetate buffer at pH 4.76. Since HCl completely dissociates, in 0.01M (10^{-2} M) HCl you will have 0.01M H^+. For the pure water, the pH drops from 7.0 down to 2.0 (pH = -log(0.01M)).

By contrast, the acetate buffer's pH after adding the same amount of HCl is 4.74. Thus, the pure water solution sees its pH fall from 7 to 2 (5 pH units), whereas the buffered solution saw its pH drop from 4.76 to 4.74 (0.02 pH units). Clearly, the buffer minimizes the impact of the added protons compared to the pure water.

Buffer capacity

It is important to note that buffers have capacities limited by their concentration. Let's imagine that in the previous paragraph, we had added the 0.01 moles HCl to an acetate buffer that had a concentration of 0.01M and equal amounts of Ac^- and HAc. When we try to do the math in parallel to the previous calculation, we see that there are 0.01M protons, but only 0.005M A^- to absorb them. We could imagine that 0.005M of the protons would be

absorbed, but that would still leave 0.005M of protons unbuffered. Thus, the pH of this solution would be approximately

$$pH = -\log(0.005M) = 2.30$$

Exceeding buffer capacity dropped the pH significantly compared to adding the same amount of protons to a 1M acetate buffer. Consequently, when considering buffers, it is important to recognize that their concentration sets their limits. Another limit is the pH range in which one hopes to control proton concentration.

Multiple ionizable groups

Now, what happens if a molecule has two (or more) ionizable groups? It turns out, not surprisingly, that each group will have its own pK_a and, as a consequence, will have multiple regions of buffering.

Figure 1.36 shows the titration curve for the amino acid aspartic acid. Note that in-

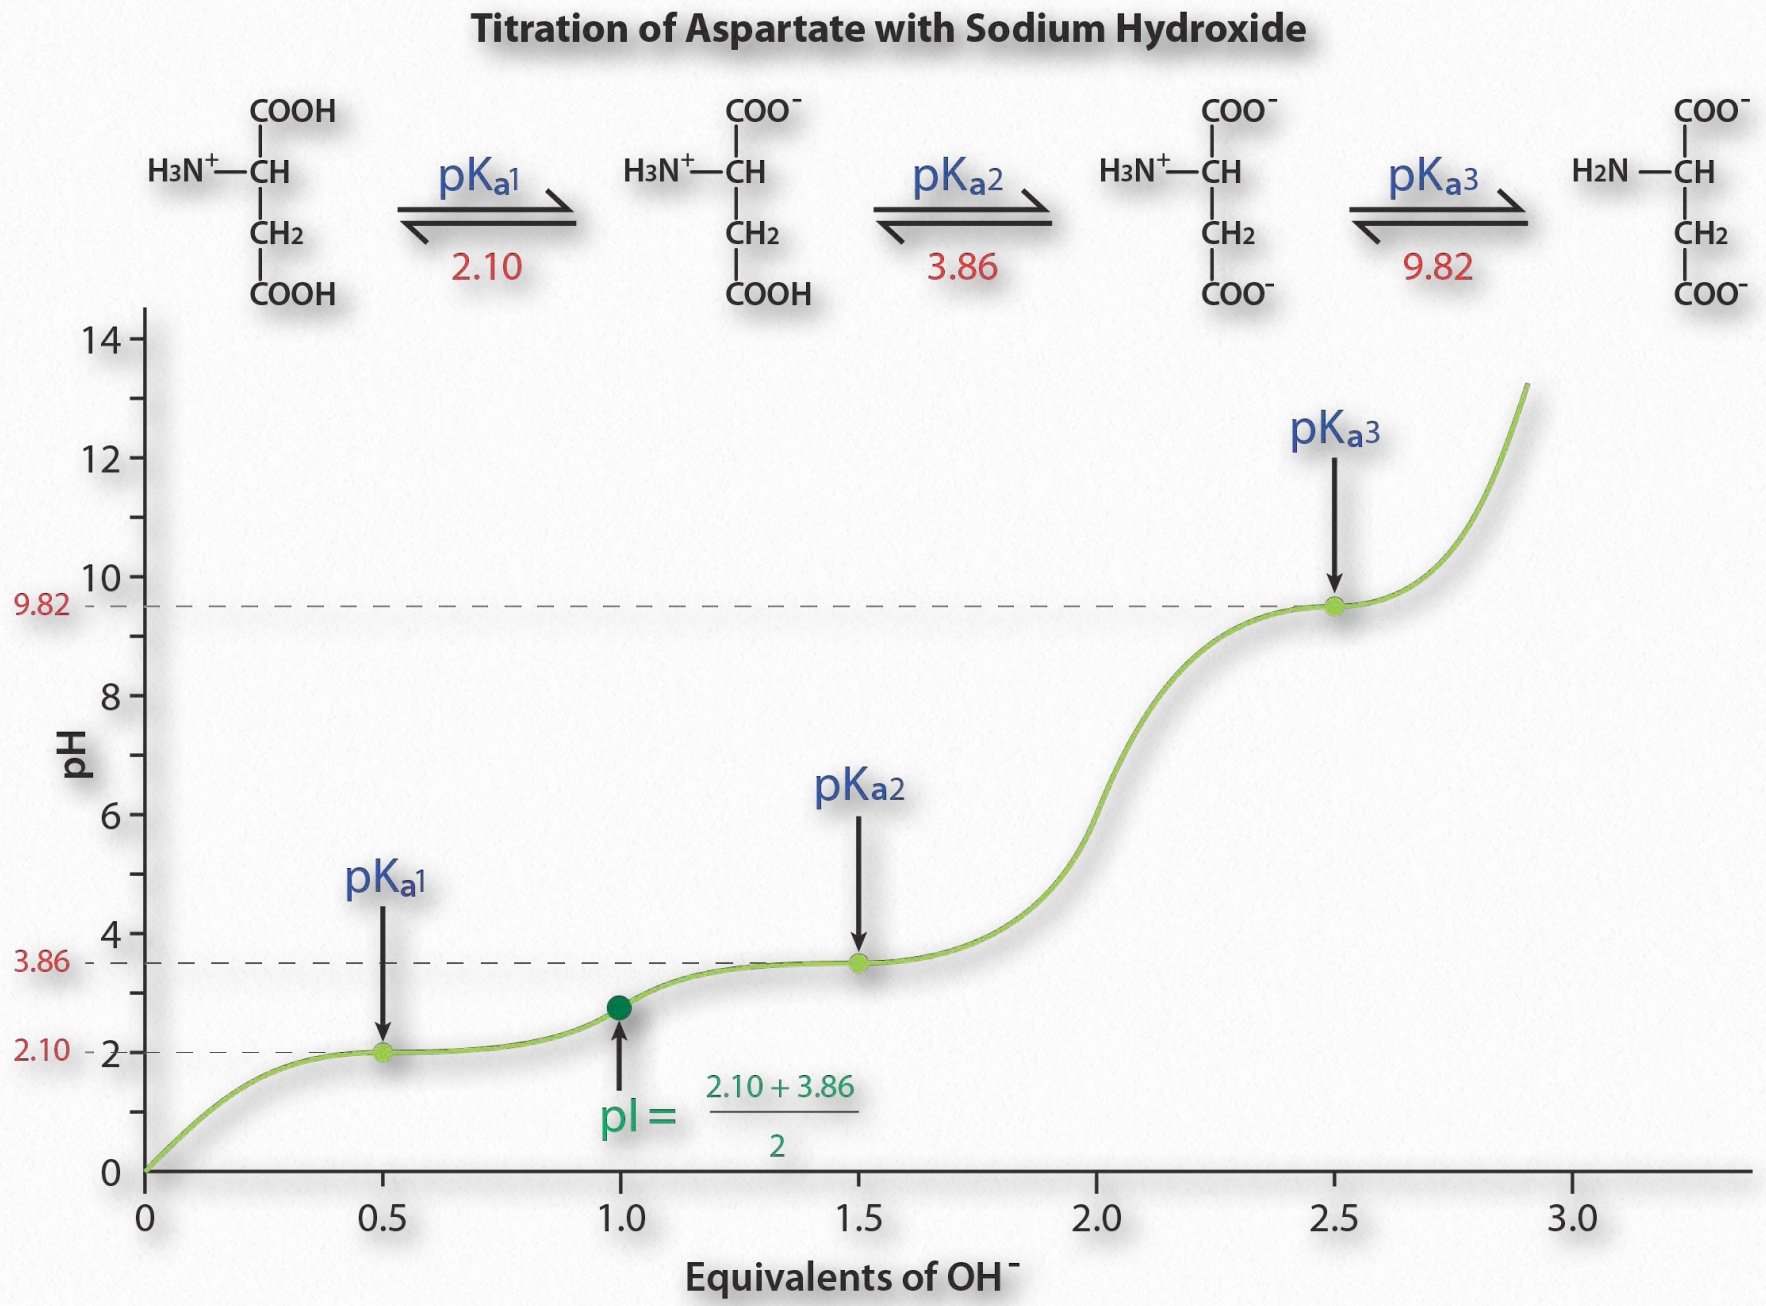

Figure 1.36 - Titration of an acidic amino acid

Image by Aleia Kim

stead of a single flattening of the curve, as was seen for acetic acid, aspartic acid's titration curve displays three such regions. These are individual buffering regions, each centered on the respective pK_a values for the carboxyl group and the amine group.

Aspartic acid has four possible charges: +1 (α-carboxyl group, α-amino group, and R-group carboxyl each has a proton), 0 (α-carboxyl group missing proton, α- amino group has a proton, R-group carboxyl has a proton), -1 (α-carboxyl group and R-group carboxyl each lack a proton, α-amino group retains a proton), -2 (α-carboxyl, R-group carboxyl, and α-amino groups all lack extra proton).

Prediction

How does one predict the charge for an amino acid at a given pH? A good rule of thumb for estimating charge is that if the pH is more than one unit below the pK_a for a group (carboxyl or amino), the proton is on. If the pH is more than one unit above the pK_a for the group, the proton is off. If the pH is NOT more than one or less than one pH unit from the pK_a, this simple assumption will not work.

Further, it is important to recognize that these rules of thumb are estimates only. The pI (pH at which the charge of a molecule is zero) is an exact value calculated as the average of the two pK_a values on either side of the zero region. It is calculated at the average of the two pKa values around the point where the charge of the molecule is zero. For aspartic acid, this corresponds to pK_{a1} and pK_{a2}.

Henderson Hasselbalch

To the tune of "*My Country 'Tis of Thee*

Metabolic Melodies Website HERE

Henderson Hasselbalch
You put my brain in shock
Oh woe is me
The pKa's can make
Me lie in bed awake
They give me really bad headaches
Oh hear my plea

Salt - acid RA-ti-os
Help keep the pH froze
By buf-fer-ING
They show tenacity
Complete audacity
If used within capacity
To maintain things

I know when H's fly
A buffer will defy
Them actively
Those protons cannot waltz
When they get bound to salts
With this the change in pH halts
All praise to thee

Thus now that I've addressed
This topic for the test
I've got know-how
The pH I can say
Equals the pK_a
In sum with log of S o'er A
I know it now

Recorded by David Simmons
Lyrics by Kevin Ahern and Indira Rajagopal

Ode to Bicarbonate

To the tune of "*Song Sung Blue*"
Metabolic Melodies Website HERE

H-2-O
Ionizes slowly
You should know
Its behavior wholly

It presides - in cells' insides - a solvent great
But mix it with an oil and shake it up
You'll see 'em separate
See 'em separate

C-O-2
Made in oxidation
Inside you
Decarboxylation

So divine – when it combines up with the H-2-Os
Bonding together makes bicarbonates
To ease the pH woes

Bicarbonate – can conjugate and take protons out
Restoring a balance inside of the blood
Of this there is no doubt

Thus it's so
Thanks to bicarb buffer
In blood flow
You don't have to suffer

Bicarbonate – will conjugate to take the protons out
Restoring a balance inside of the blood
Of this there is no doubt

Protons stow
In the bicarb buffer
Never grow

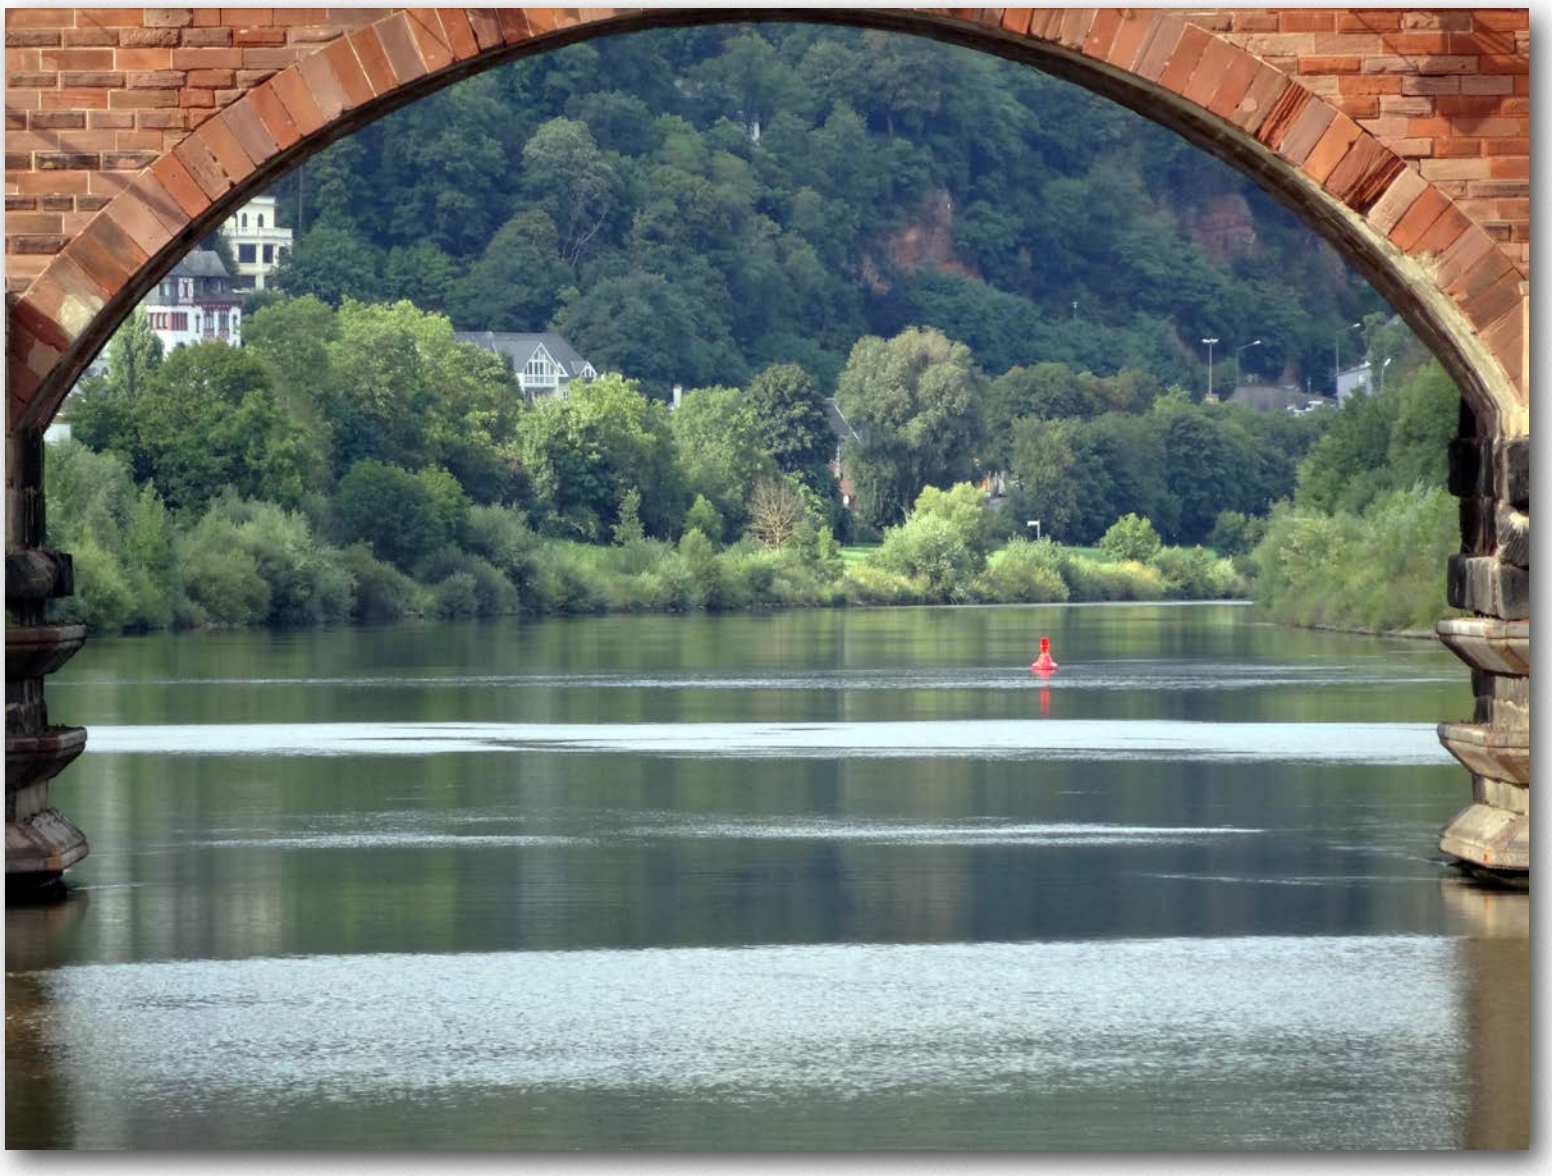
Structure & Function

"The man who does not read good books has no advantage over the man who cannot read them."

Mark Twain



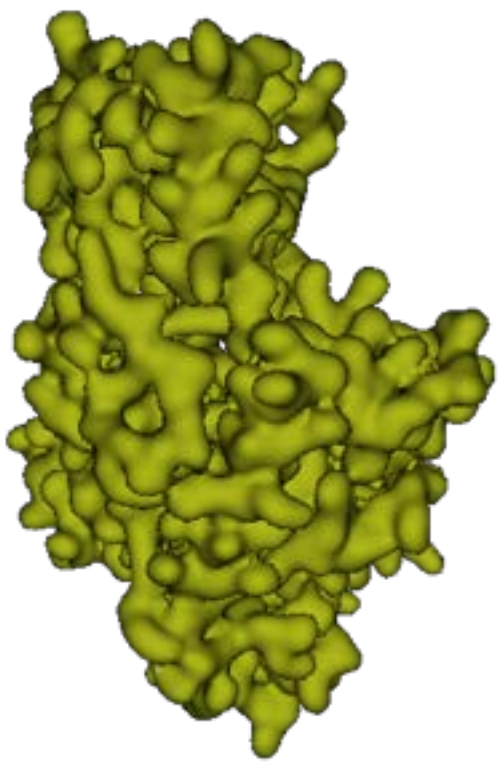
Introduction

When we study life at the molecular level, it becomes apparent that the structures of biological molecules are inseparable from their functions. The molecular interactions that underlie life are dependent on the structures of the molecules we are made of.

"*It is structure that we look for, whenever we try to understand anything. All science is built upon this search. We like to understand, and to explain, observed facts in terms of structure.*

- Linus Pauling

In this chapter, we will examine the structures of the major classes of biomolecules, with an eye to understanding how these structures relate to function.



Interactive 2.1 - The enzyme Hexokinase: as for all enzymes, the activity of hexokinase depends on its structure.

Protein Database (PDB)

Biological molecules

As noted earlier, water is the most abundant molecule in cells, and provides the aqueous environment in which cellular chemistry happens. Dissolved in this water are inorganic ions like sodium, potassium and calcium. But the distinctiveness of biochemistry derives from the vast numbers of complex, large, carbon compounds, that are made by living cells. You have probably learned that the major classes of biological molecules are proteins, nucleic acids, carbohydrates and lipids. The first three of these major groups are macromolecules that are built as long polymers made up of smaller subunits or monomers, like strings of beads. The lipids, while not chains of monomers, also have smaller subunits that are assembled in various ways to make the lipid components of cells, including membranes. The chemical properties and three dimensional conformations of these molecules determine all the molecular interactions upon which life depends. Whether building structures within cells, transferring information, or catalyzing reactions, the activities of biomolecules are governed by their structures. The properties and shapes of macromolecules, in turn, depend on the subunits of which they are built.

Building blocks

We will next examine the major groups of biological macromolecules: proteins, polysaccharides, nucleic acids, and lipids. The building blocks of the first three, respectively, are amino acids, monosaccharides (sugars), and nucleotides. Acetyl-CoA is the most common building block of lipids.

Structure & Function: Amino Acids

"It is one of the more striking generalizations of biochemistry ...that the twenty amino acids and the four bases, are, with minor reservations, the same throughout Nature."

- Francis Crick

Building blocks of protein

All of the proteins on the face of the earth are made up of the same 20 amino acids. Linked together in long chains called polypeptides, amino acids are the building blocks for the vast assortment of proteins found in all living cells.

YouTube Lectures by Kevin HERE & HERE

All amino acids have the same basic structure, which is shown in Figure 2.1. At the “center” of each amino acid is a carbon called the **α** carbon and attached to it are four groups - a hydrogen, an **α**-carboxyl group, an **α**-amine group, and an R-group, sometimes referred to as a side chain. The α carbon, carboxyl, and amino groups are common to all amino acids, so the

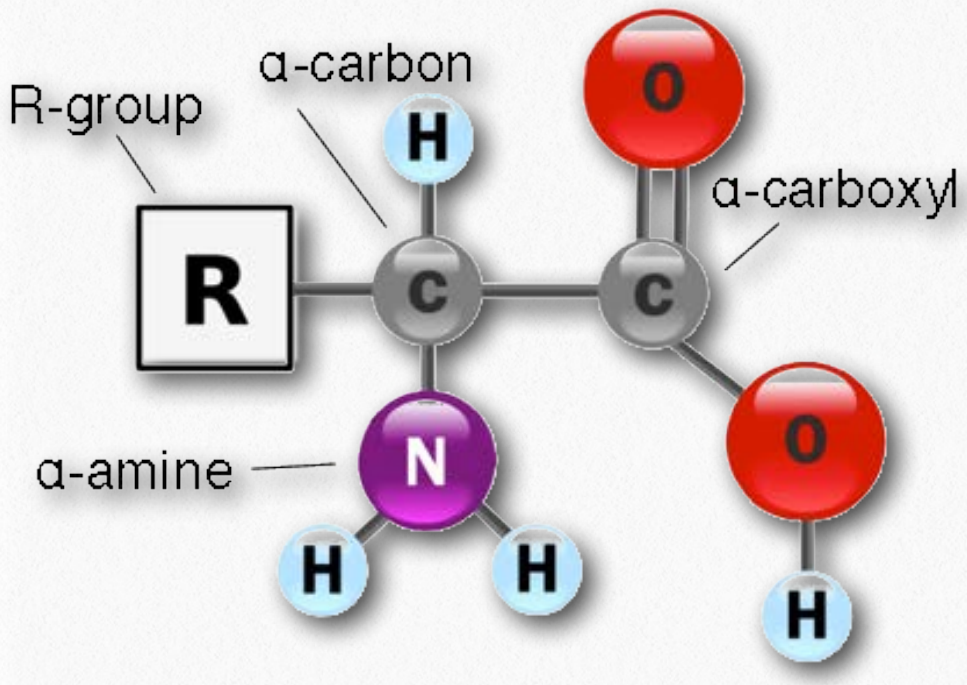


Figure 2.1 - General amino acid structure

R-group is the only unique feature in each amino acid. (A minor exception to this structure is that of proline, in which the end of the R-group is attached to the α-amine.) With the exception of glycine, which has an R-group consisting of a hydrogen atom, all of the amino acids in proteins have four different groups attached to them and consequently can exist in two mirror image forms, L and D. With only very minor exceptions, every amino acid found in cells and in proteins is in the L configuration.

There are 22 amino acids that are found in proteins and of these, only 20 are specified by the universal genetic code. The others, selenocysteine and pyrrolysine use tRNAs that are able to base pair with stop codons in the mRNA during translation. When this happens, these unusual amino acids can be incorporated into proteins. Enzymes containing selenocysteine, for example, include glutathione peroxidases, tetraiodothyronine 5' deiodinases, thioredoxin reductases, formate dehydrogenases, glycine reductases, and selenophosphate synthetase. Pyrrolysine-containing proteins are much rarer and are mostly confined to archaea.

Essential	Non-Essential
Histidine	Alanine
Isoleucine	Arginine
Leucine	Asparagine
Lysine	Aspartic acid
Methionine	Cysteine
Phenylalanine	Glutamic acid
Threonine	Glutamine
Tryptophan	Glycine
Valine	Proline
	Selenocysteine
	Serine
	Tyrosine

Table 2.1 - Essential and non-essential amino acids

Non-Polar	Carboxyl	Amine	Aromatic	Hydroxyl	Other
Alanine	Aspartic Acid	Arginine	Phenylalanine	Serine	Asparagine
Glycine	Glutamic Acid	Histidine	Tryptophan	Threonine	Cysteine
Isoleucine		Lysine	Tyrosine	Tyrosine	Glutamine
Leucine					Selenocysteine
Methionine					Pyrrolysine
Proline					
Valine					

Table 2.2 - Amino acid categories (based on R-group properties)

Essential and non-essential

Nutritionists divide amino acids into two groups - essential amino acids (must be in the diet because cells can't synthesize them) and non-essential amino acids (can be made by cells). This classification of amino acids has little to do with the structure of amino acids. Essential amino acids vary considerable from one organism to another and even differ in humans, depending on whether they are adults or children. Table 2.1 shows essential and non-essential amino acids in humans.

Some amino acids that are normally non-essential, may need to be obtained from the diet in certain cases. Individuals who do not synthesize sufficient amounts of arginine, cysteine, glutamine, proline, selenocysteine, serine, and tyrosine, due to illness, for example, may need dietary supplements containing these amino acids.

Non-protein amino acids

There are also α-amino acids found in cells that are not incorporated into proteins. Common ones include ornithine and citrulline. Both of these compounds are intermediates in the urea cycle. Ornithine is a metabolic precursor of arginine and citrulline can be produced by the breakdown of arginine. The latter reaction produces nitric oxide, an important signaling molecule. Citrulline is the metabolic byproduct. It is sometimes used as a dietary supplement to reduce muscle fatigue.

R-group chemistry

We separate the amino acids into categories based on the chemistry of their R-groups. If you compare groupings of amino acids in different textbooks, you will see different names for the categories and (sometimes) the same amino acid being categorized differently by different authors. Indeed, we categorize ty-

Amino acid	Short	Abbrev.	Side chain	Hydro-phobic	pKa	Polar	pH	Small	Tiny	Aromatic or Aliphatic	van der Waals volume

Figure 2.2 - Amino acid side chain properties

Wikipedia

rosine both as an aromatic amino acid and as a hydroxyl amino acid. It is useful to classify amino acids based on their R-groups, because it is these side chains that give each amino acid its characteristic properties. Thus, amino acids with (chemically) similar side groups can be expected to function in similar ways, for example, during protein folding.

YouTube Lectures by Kevin HERE & HERE

Non-polar amino acids

Alanine (Ala/A) is one of the most abundant amino acids found in proteins, ranking second only to leucine in occurrence. A D-form of the amino acid is also found in bacterial cell walls. Alanine is non-essential, being readily synthesized from pyruvate. It is coded for by GCU, GCC, GCA, and GCG. Wikipedia link HERE.

Glycine (Gly/G) is the amino acid with the shortest side chain, having an R-group consistent only of a single hydrogen. As a result, glycine is the only amino acid that is not chiral. Its small side chain allows it to readily fit into both hydrophobic and hydrophilic environments.

Glycine is specified in the genetic code by GGU, GGC, GGA, and GGG. It is non-essential to humans. Wikipedia link HERE.

Isoleucine (Ile/I) is an essential amino acid encoded by AUU, AUC, and AUA. It has a hydrophobic side chain and is also chiral in its side chain. Wikipedia link HERE.

Leucine (Leu/L) is a branched-chain amino acid that is hydrophobic and essential.

Leucine is encoded by six codons: UUA,UUG, CUU, CUC, CUA, CUG. Wikipedia link HERE.

Methionine (Met/M) is an essential amino acid that is one of two sulfur-containing amino acids - cysteine is the other. Methionine is non-polar and encoded solely by the AUG codon. It is the "initiator" amino acid in protein synthesis, being the first one incorporated into protein chains. In prokaryotic cells, the first methionine in a protein is formylated. Wikipedia link HERE.

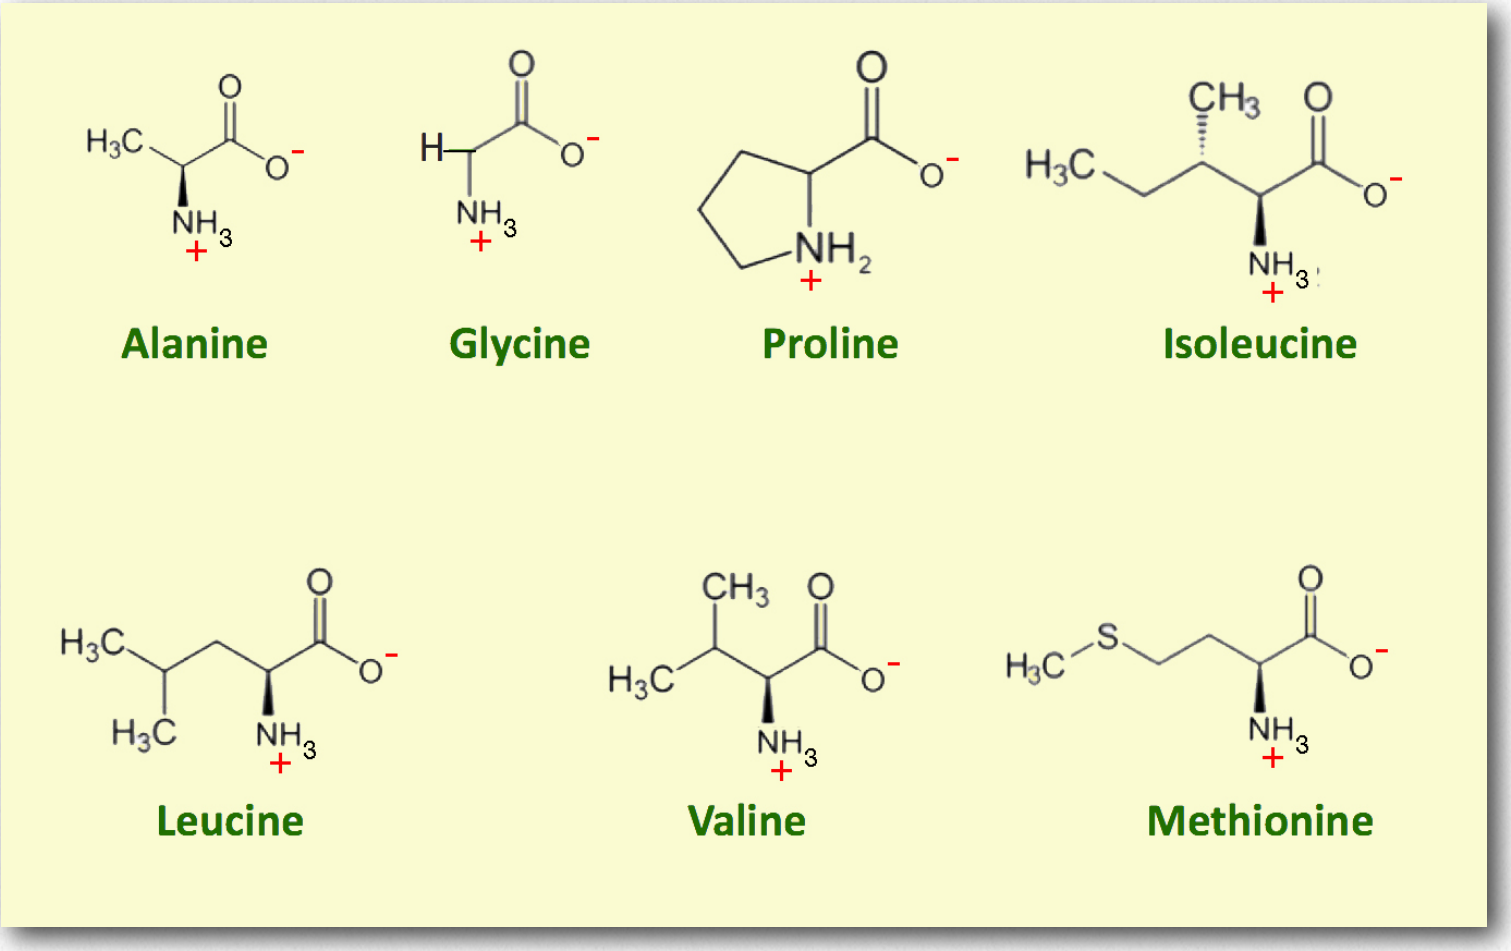

Figure 2.3 - Non-polar amino acids

Proline (Pro/P) is the only amino acid found in proteins with an R-group that joins with its own α-amino group, making a secondary amine and a ring. Proline is a non-essential amino acid and is coded by CCU, CCC, CCA, and CCG. It is the least flexible of the protein amino acids and thus gives conformational rigidity when present in

Leucine is the only dietary amino acid reported to directly stimulate protein synthesis in muscle, but caution is in order, as 1) there are conflicting studies and 2) leucine toxicity is dangerous, resulting in "the four D's": diarrhea, dermatitis, dementia and death .

a protein. Proline's presence in a protein affects its secondary structure. It is a disrupter of α-helices and β-strands. Proline is often hydroxylated in collagen (the reaction requires Vitamin C - ascorbate) and this has the effect of increasing the protein's conformational stability. Proline hydroxylation of hypoxia-inducible factor (HIF) serves as a sensor of oxygen levels and targets HIF for destruction when oxygen is plentiful. Wikipedia link HERE.

Valine (Val/V) is an essential, non-polar amino acid synthesized in plants. It is noteworthy in hemoglobin, for when it replaces glutamic acid at position number six, it causes hemoglobin to aggregate abnormally under low oxygen conditions, resulting in sickle cell disease. Valine is coded in the genetic code by GUU, GUC, GUA, and GUG. Wikipedia link HERE.

Carboxyl amino acids

Aspartic acid (Asp/D) is a non-essential amino acid with a carboxyl group in its R-group. It is readily produced by transamination of oxaloacetate. With a pK_a of 3.9, aspartic acid's side chain is negatively charged at physiological pH. Aspartic acid is specified in the genetic code by the codons GAU and GAC. Wikipedia link HERE.

Glutamic acid (Glu/E), which is coded by GAA and GAG, is a non-essential amino acid readily made by transamination of α-ketoglutarate. It is a neurotransmitter and has an R-group with a carboxyl group that readily ionizes (pK_a = 4.1) at physiological pH. Wikipedia link HERE.

Amine amino acids

Arginine (Arg/R) is an amino acid that is, in some cases, essential, but non-essential in others. Premature infants cannot synthesize arginine. In addition, surgical trauma, sepsis, and burns increase demand for arginine. Most people, however, do not need arginine supplements. Arginine's side chain contains a complex guanidinium group with a pK_a of over 12, making it positively charged at cellular pH. It is coded for by six codons - CGU, CGC, CGA, CGG, AGA, and AGG. Wikipedia link HERE.

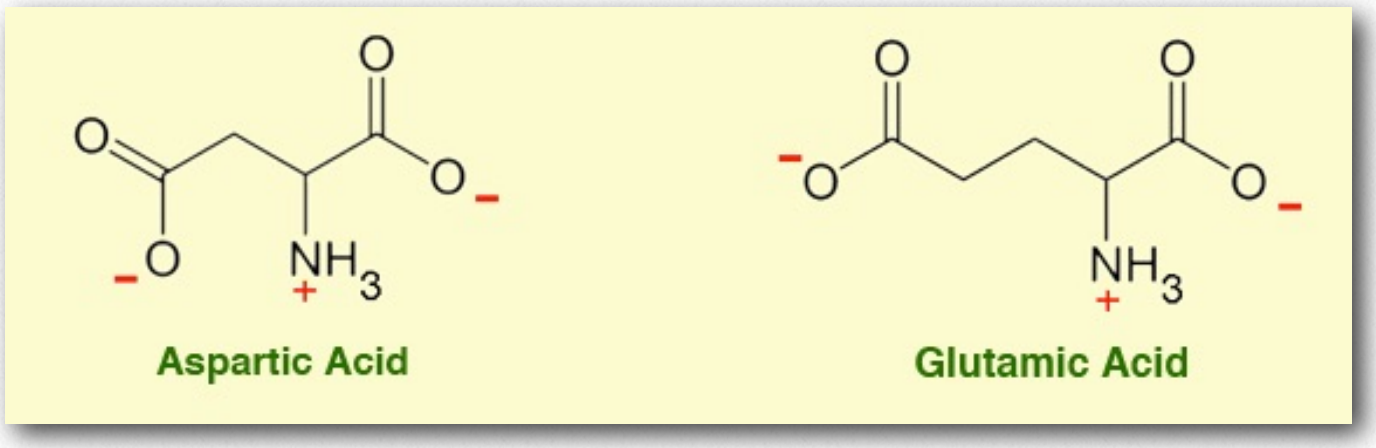

Figure 2.4 - Carboxyl amino acids

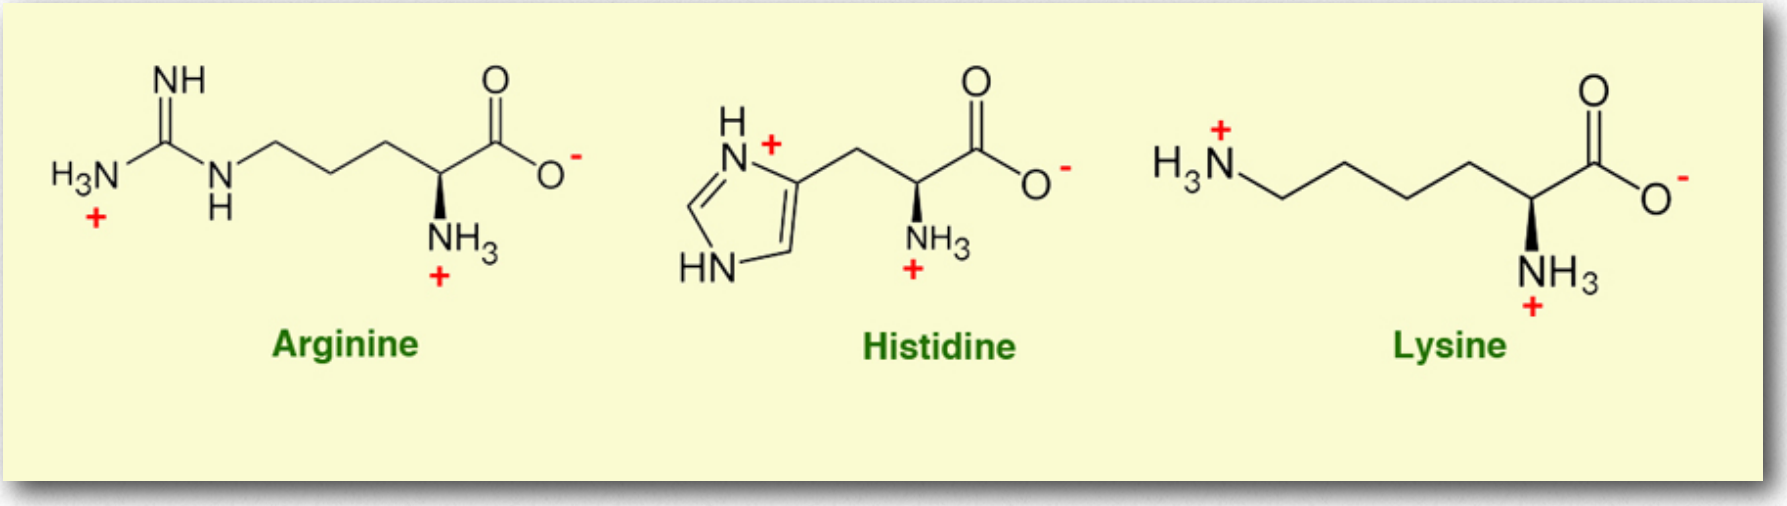

Figure 2.5 - Amine amino acids

Histidine (His/H) is the only one of the proteinaceous amino acids to contain an imidazole functional group. It is an essential amino acid in humans and other mammals. With a side chain pK_a of 6, it can easily have its charge changed by a slight change in pH. Protonation of the ring results in two NH structures which can be drawn as two equally important resonant structures. Wikipedia link HERE.

Lysine (Lys/K) is an essential amino acid encoded by AAA and AAG. It has an R-group that can readily ionize with a charge of +1 at physiological pH and can be post-translationally modified to form acetyllysine, hydroxylysine, and methyllysine. It can also be ubiquitinated, sumoylated, neddylated, biotinylated, carboxylated, and pupylated, and. O-Glycosylation of hydroxylysine is used to flag proteins for export from the cell. Lysine is often added to animal feed because it is a limiting amino acid and is necessary for optimizing growth of pigs and chickens. Wikipedia link HERE.

Aromatic amino acids

Phenylalanine (Phe/ F) is a non-polar, essential amino acid coded by UUU and UUC. It is a metabolic precursor of tyrosine. Inability to metabolize phenylalanine arises from the genetic disorder known as phenylketonuria. Phenylalanine is a component of the aspartame artificial sweetener. Wikipedia link HERE.

Tryptophan (Trp/W) is an essential amino acid containing an indole functional group. It is a metabolic precursor of serotonin, niacin, and (in plants) the auxin phytohormone. Though reputed to serve as a sleep aid, there are no clear research results indicating this. Wikipedia link HERE.

Tyrosine (Tyr/Y) is a non-essential amino acid coded by UAC and UAU. It is a target for phosphorylation in proteins by tyrosine protein kinases and plays a role

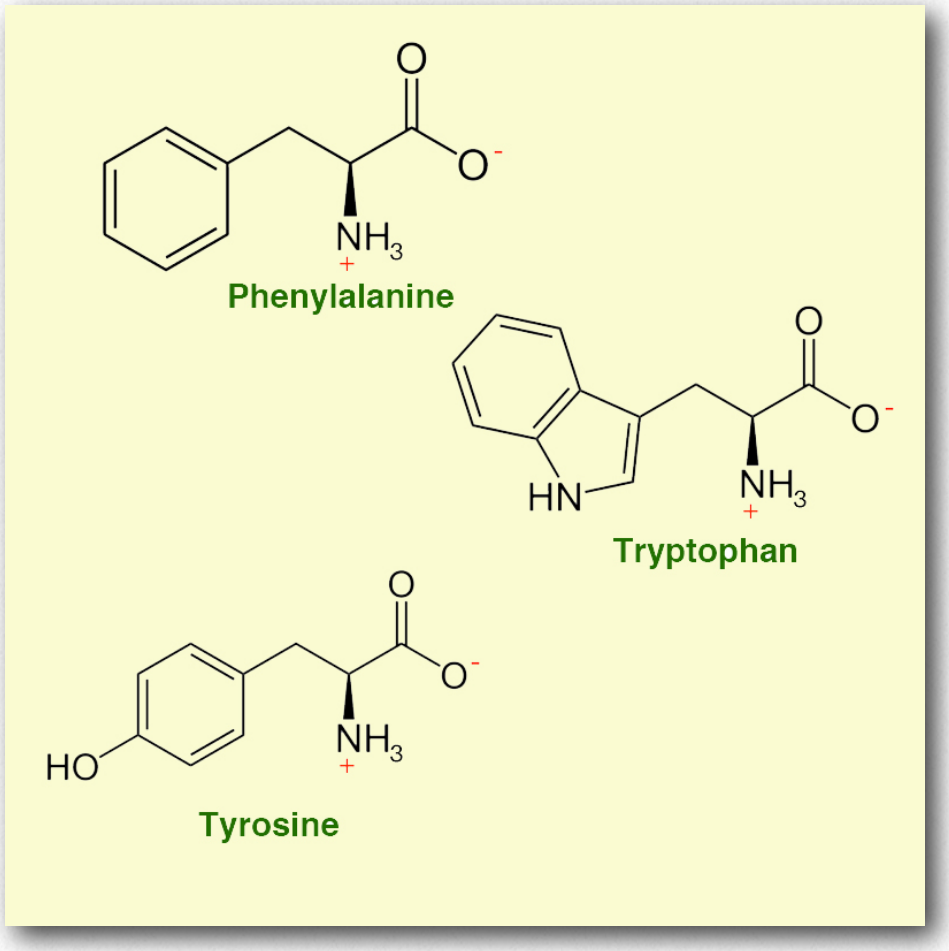

Figure 2.6 - **Aromatic amino acids**

in signaling processes. In dopaminergic cells of the brain, tyrosine hydroxylase converts tyrosine to l-dopa, an immediate precursor of dopamine. Dopamine, in turn, is a precursor of norepinephrine and epinephrine. Tyrosine is also a precursor of thyroid hormones and melanin. Wikipedia link HERE.

Hydroxyl amino acids

Serine (Ser/S) is one of three amino acids having an R-group with a hydroxyl in it (threonine and tyrosine are the others). It is coded by UCU, UCC, UCA, UGC, AGU, and AGC. Being able to hydrogen bond with water, it is classified as a polar amino acid. It is not essential for humans. Serine is precursor of many important cellular compounds, including purines, pyrimidines, sphingolipids, folate, and of the amino acids glycine, cysteine, and tryptophan. The hydroxyl group of serine in proteins is a target for phosphorylation by certain protein kinases. Serine is also a part of the catalytic triad of serine proteases. Wikipedia link HERE.

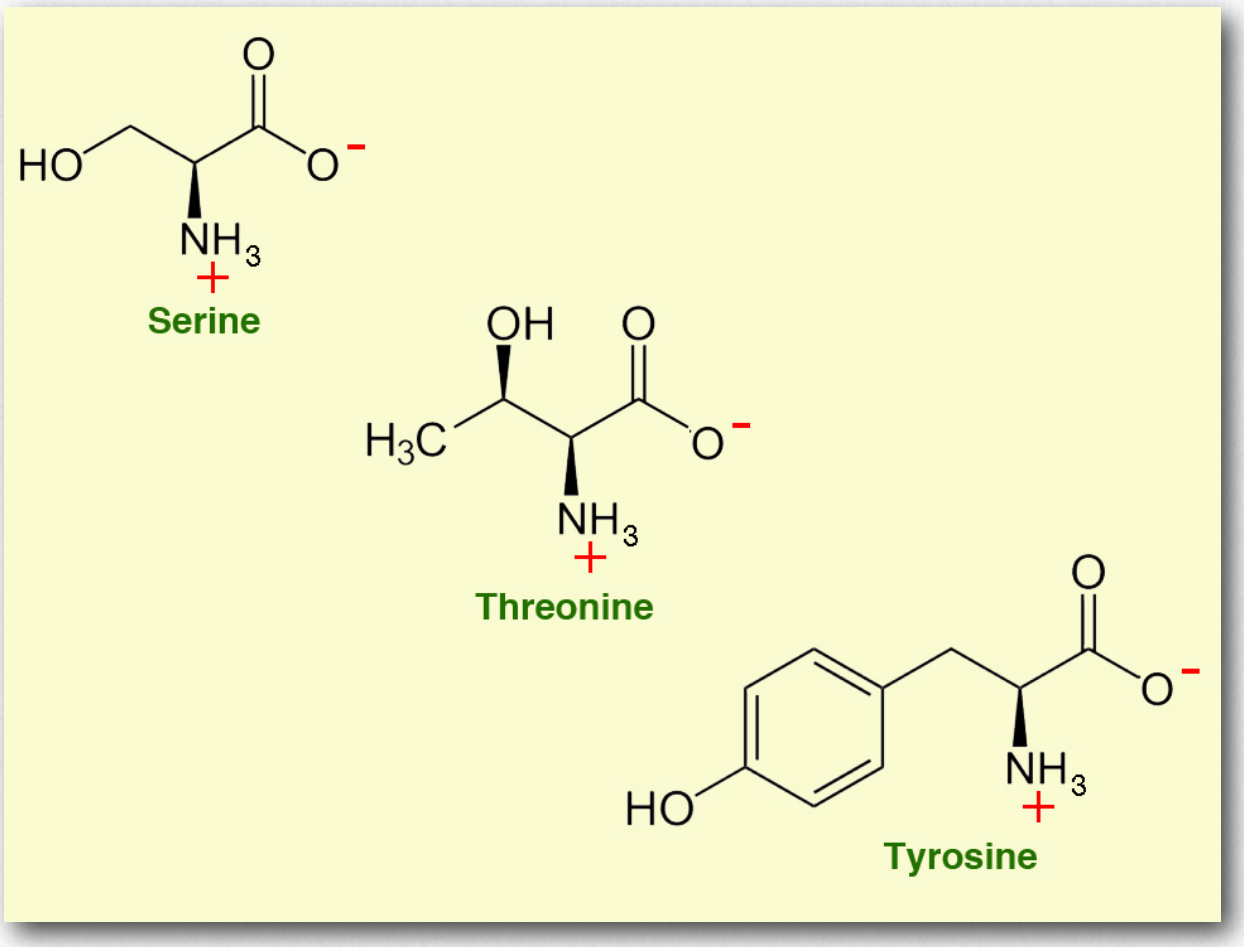

Figure 2.7 - **Hydroxyl amino acids**

Amino acid	Short	Abbrev.	Avg. mass (Da)	pI	pK_1 (α-COOH)	pK_2 (α-$^+NH_3$)

Figure 2.8 - Amino acid properties

Wikipedia

Threonine (Thr/T) is a polar amino acid that is essential. It is one of three amino acids bearing a hydroxyl group (serine and tyrosine are the others) and, as such, is a tar-

get for phosphorylation in proteins. It is also a target for O-glycosylation of proteins. Threonine proteases use the hydroxyl group of the amino acid in their catalysis and it is a precursor in one biosynthetic pathway for making glycine. In some applications, it is used as a pro-drug to increase brain glycine levels. Threonine is encoded in the genetic code by ACU, ACC, ACA, and ACG. Wikipedia link HERE.

Tyrosine - see HERE.

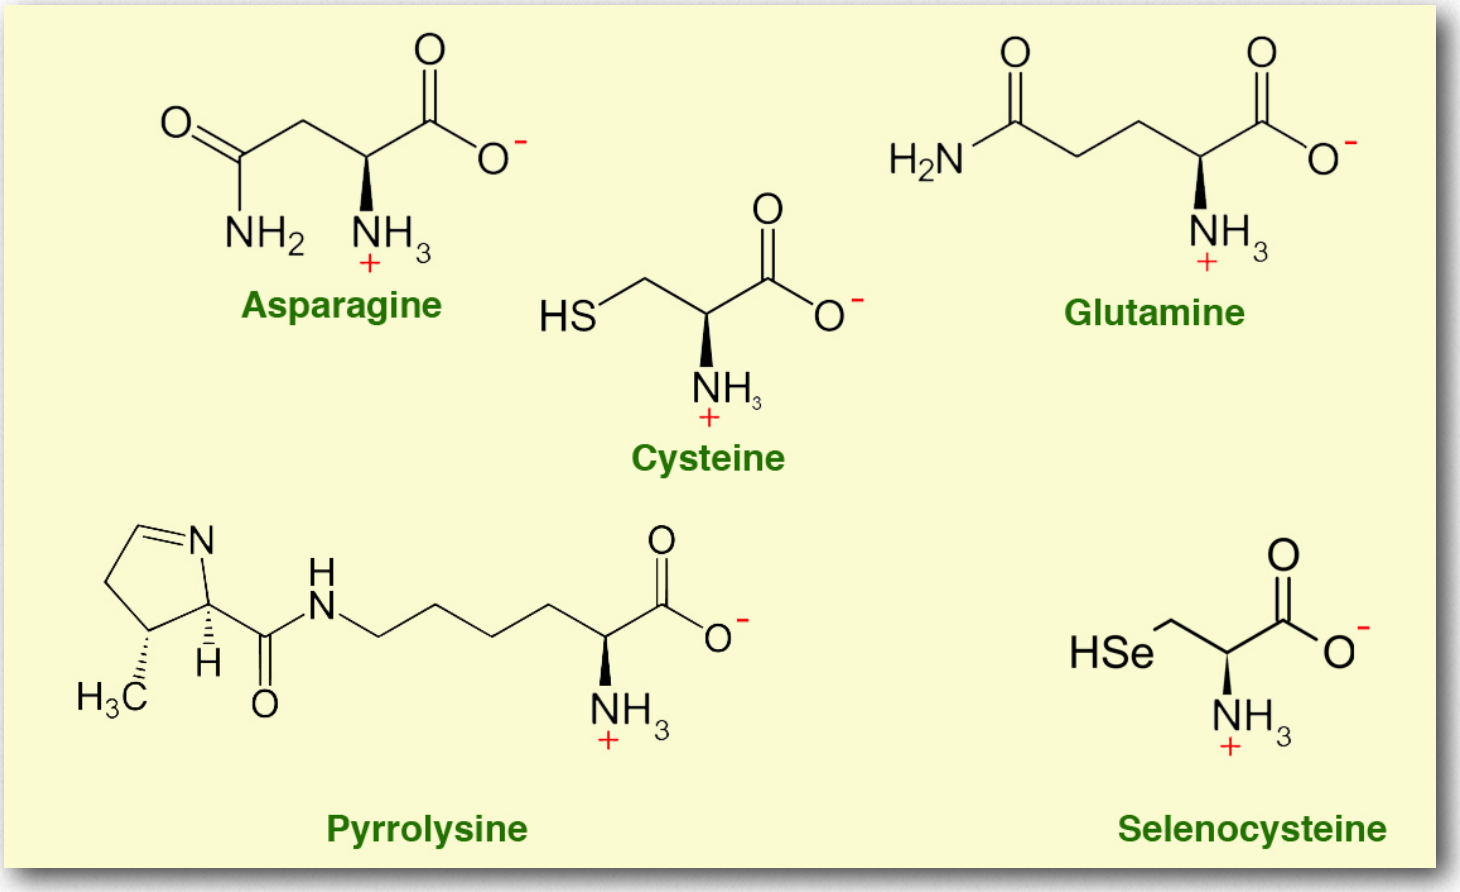

Figure 2.9 - Other amino acids

Other amino acids

Asparagine (Asn/N) is a non-essential amino acid coded by AAU and AAC. Its carboxyamide in the R-group gives it polarity. Asparagine is implicated in formation of acrylamide in foods cooked at high temperatures (deep frying) when it reacts with carbonyl groups. Asparagine can be made in the body from aspartate by an amidation reaction with an amine from glutamine. Breakdown of asparagine produces malate, which can be oxidized in the citric acid cycle. Wikipedia link HERE.

YouTube Lectures by Kevin HERE & HERE

Cysteine (Cys/C) is the only amino acid with a sulfhydryl group in its side chain. It is non-essential for most humans, but may be essential in infants, the elderly and individuals who suffer from certain metabolic diseases. Cysteine's sulfhydryl group is readily oxidized to a disulfide when reacted with another one. In addition to being found in proteins, cysteine is also a component of the tripeptide, glutathione. Cysteine is specified by the codons UGU and UGC. Wikipedia link HERE.

Glutamine (Gln/Q) is an amino acid that is not normally essential in humans, but may be in individuals undergoing intensive athletic training or with gastrointestinal disorders. It has a carboxyamide side chain which does not normally ionize under physiological pHs, but which gives polarity to the side chain. Glutamine is coded for by CAA and CAG and is readily made by amidation of glutamate. Glutamine is the most abundant amino acid in circulating blood and is one of only a few amino acids that can cross the blood-brain barrier. Wikipedia link HERE.

Selenocysteine (Sec/U) is a component of selenoproteins found in all kingdoms of life. It is a component in several enzymes, including glutathione peroxidases and thioredoxin reductases. Selenocysteine is incorporated into proteins in an unusual scheme involving the stop codon UGA. Cells grown in the absence of selenium terminate protein synthesis at UGAs. However, when selenium is present, certain mRNAs which contain a selenocysteine insertion sequence (SECIS), insert selenocysteine when UGA is encountered. The SECIS element has characteristic nucleotide sequences and secondary structure base-pairing patterns. Twenty five human proteins contain selenocysteine. Wikipedia link HERE.

Pyrrolysine (Pyl/O) is a twenty second amino acid, but is rarely found in proteins. Like selenocysteine, it is not coded for in the genetic code and must be incorporated by unusual means. This occurs at UAG stop codons. Pyrrolysine is found in methanogenic archaean organisms and at least one methane-producing bacterium. Pyrrolysine is a component of methane-producing enzymes. Wikipedia link HERE.

Ionizing groups

pK_a values for amino acid side chains are very dependent upon the chemical environment in which they are present. For example, the R-group carboxyl found in aspartic acid has a pK_a value of 3.9 when free in solution, but can be as high as 14 when in certain environments inside of proteins, though that is unusual and extreme. Each amino acid has at least one ionizable amine group (α-amine) and one ionizable carboxyl group (α-carboxyl). When these are bound in a peptide bond, they no longer ionize. Some, but not all amino acids have R-groups that can ionize. The charge of a protein then arises from the charges of the α-amine group, the α-carboxyl group. and the sum of the charges of the ionized R-groups. Titration/ionization of aspartic acid is depicted in Figure 2.10. Ionization (or deionization) within a protein's structure can have significant effect on the overall conformation of the protein and, since structure is related to function, a major impact on the activity of a protein. Most proteins have relatively narrow ranges of optimal

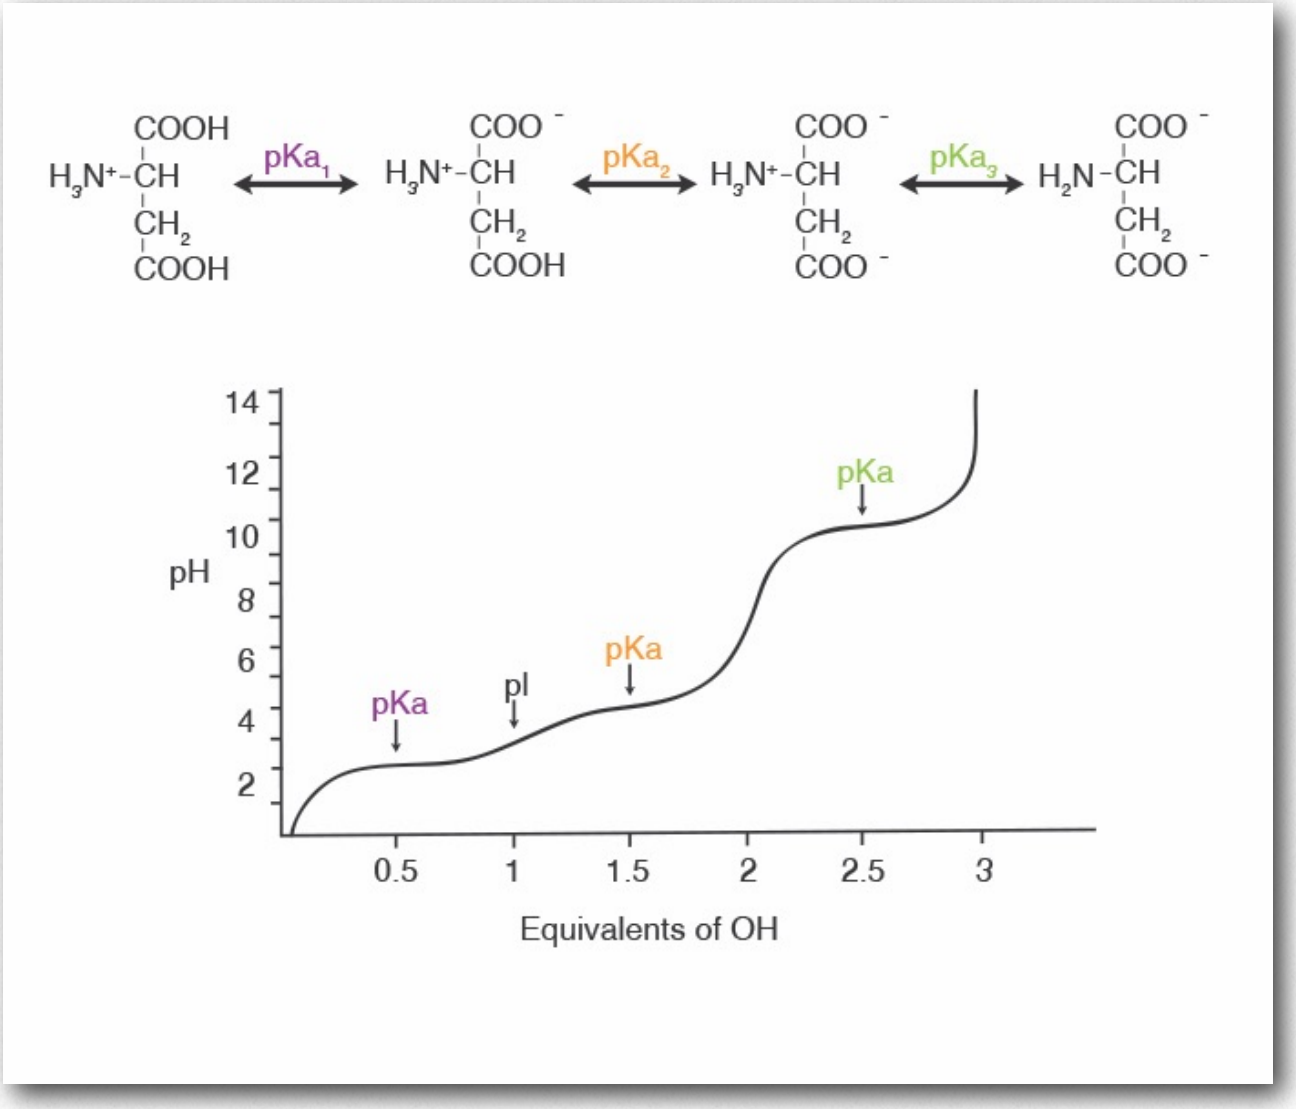

Figure 2.10 - Titration curve for aspartic acid

Image by Penelope Irving

activity that typically correspond to the environments in which they are found (Figure 2.11). It is worth noting that formation of peptide bonds between amino acids removes ionizable hydrogens from both the α-amine and α-carboxyl groups of amino acids. Thus, ionization/deionization in a protein arises only from 1) the amino terminus; 2) carboxyl terminus; 3) R-groups; or 4) other functional groups (such as sulfates or phosphates) added to amino acids post-translationally - see below.

Carnitine

Not all amino acids in a cell are found in proteins. The most common examples include ornithine (arginine metabolism), citrulline (urea cycle), and carnitine (Figure 2.12). When fatty acids destined for oxidation are moved into the mitochondrion for that purpose, they travel across the inner membrane attached to carnitine. Of the two stereoisomeric forms, the L form is the active one. The molecule is

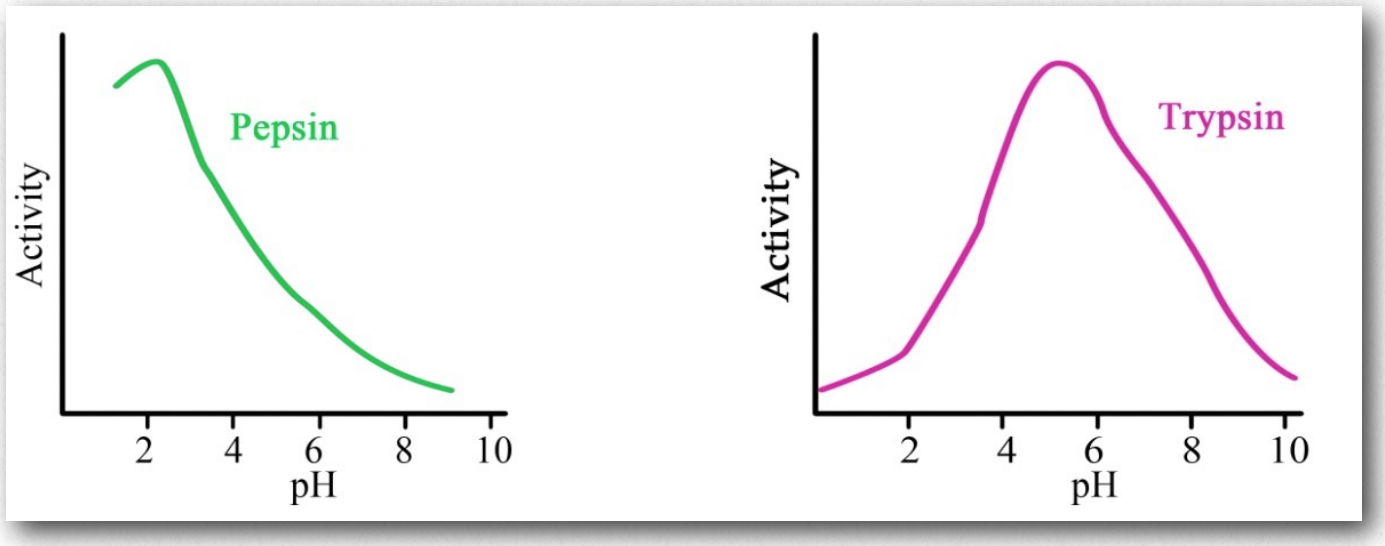

Figure 2.11 - Enzyme activity changes as pH changes

Image by Aleia Kim

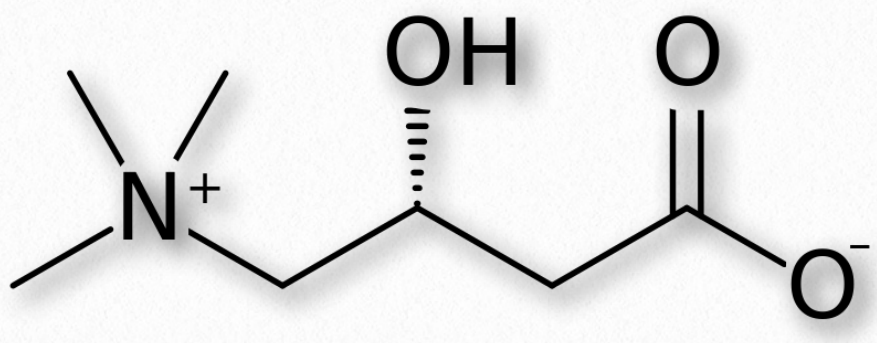

Figure 2.12 - L-Carnitine

synthesized in the liver from lysine and methionine. From exogenous sources, fatty acids must be activated upon entry into the cytoplasm by being joined to coenzyme A. The CoA portion of the molecule is replaced by carnitine in the intermembrane space of the mitochondrion in a reaction catalyzed by carnitine acyltransferase I. The resulting acylcarnitine molecule is transferred across the inner mitochondrial membrane by the carnitine-acylcarnitine translocase and then in the matrix of the mitochondrion, carnitine acyltransferase II replaces the carnitine with coenzyme A (Figure 6.88).

Catabolism of amino acids

We categorize amino acids as essential or non-essential based on whether or not an organism can synthesize them. All of the amino acids, however, can be broken down by all organisms. They are, in fact, a source of energy for cells, particularly during times of starvation or for people on diets containing very low amounts of carbohydrate. From a perspective of breakdown (catabolism), amino acids are categorized as glucogenic if they produce intermediates that can be made into glucose

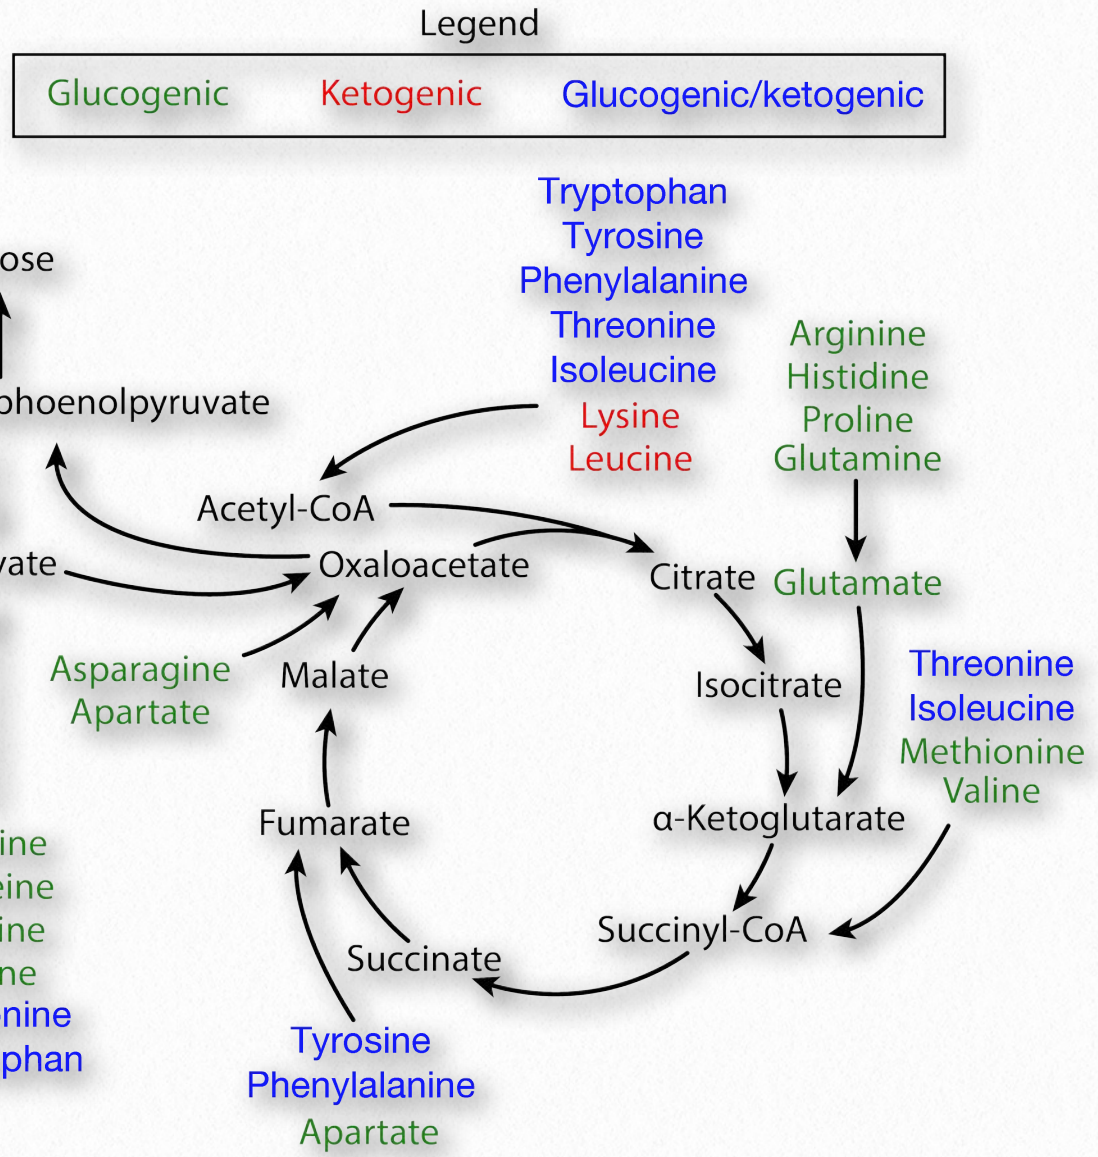

Figure 2.13 - Catabolism of amino acids. Some have more than one path.

Image by Pehr Jacobson

or ketogenic if their intermediates are made into acetyl-CoA. Figure 2.13 shows the metabolic fates of catabolism of each of the amino acids. Note that some amino acids are both glucogenic and ketogenic.

Post-translational modifications

After a protein is synthesized, amino acid side chains within it can be chemically modified, giving rise to more diversity of structure and function (Figure 2.14). Common alterations include phosphorylation of hydroxyl groups of serine, threonine, or tyrosine. Lysine, proline, and histidine can have hydroxyls added to amines in their R-groups. Other modifications to amino acids in proteins include addition of fatty acids (myristic acid or palmitic acid), isoprenoid groups, acetyl groups, methyl groups, iodine, carboxyl groups, or sulfates. These can have the effects of ionization (addition of phosphates/sulfates), deionization (addition of acetyl group to the R-group amine of lysine), or have no effect on charge at all. In addition, N-linked- and O-linked-glycoproteins have carbohydrates covalently attached to side chains of asparagine and threonine or serine, respectively.

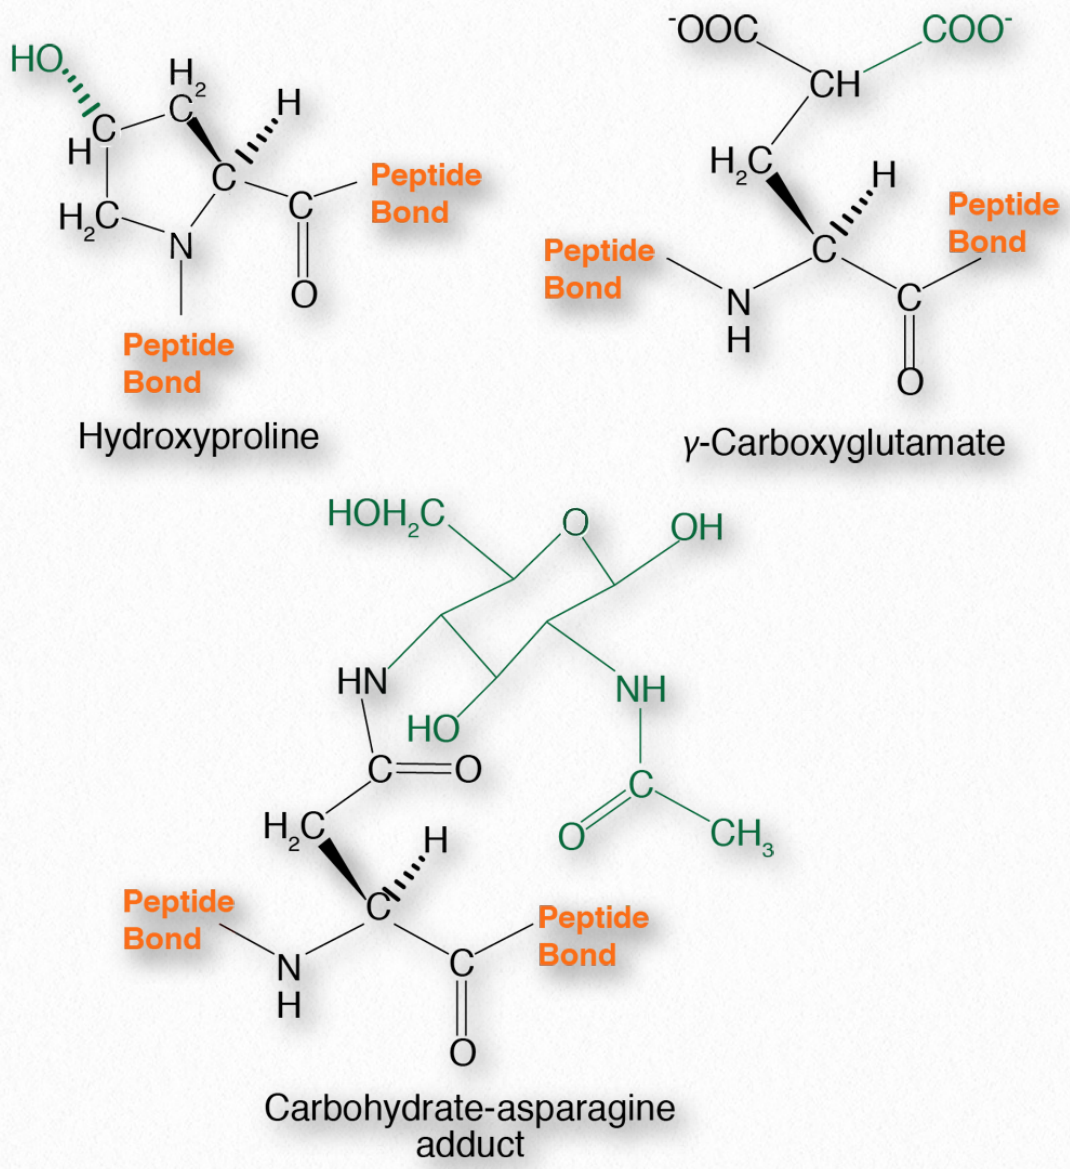

Figure 2.14 - Post-translationally modified amino acids. Modifications shown in green.

Image by Penelope Irving

Some amino acids are precursors of important compounds in the body. Examples include epinephrine, thyroid hormones, L-dopa, and dopamine (all from tyrosine), serotonin (from tryptophan), and histamine (from histidine).

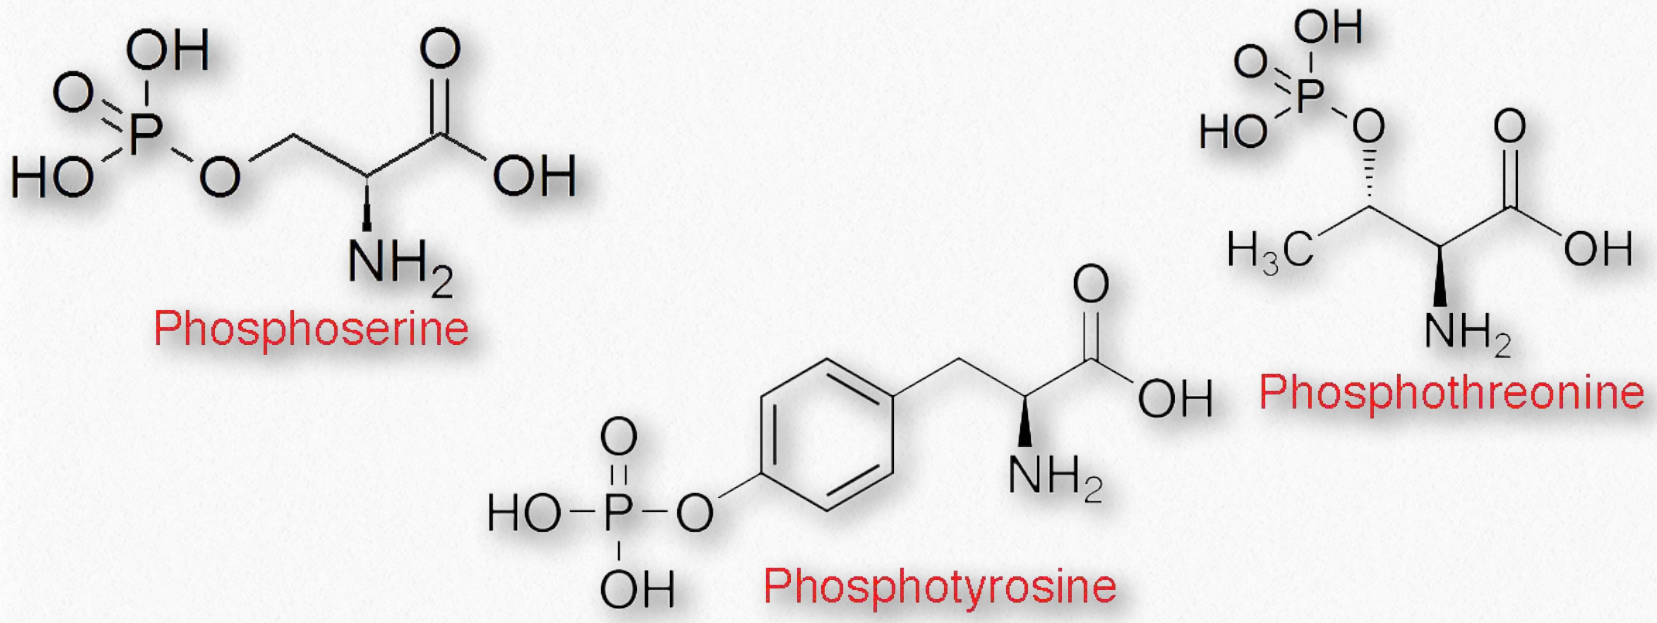

Figure 2.15 - **Phosphorylated amino acids**

Building polypeptides

Although amino acids serve other functions in cells, their most important role is as constituents of proteins. Proteins, as we noted earlier, are polymers of amino acids.

Amino acids are linked to each other by peptide bonds, in which the carboxyl group of one amino acid is joined to the amino group of the next, with the loss of a molecule of water. Additional amino acids are added in the same way, by formation of peptide bonds between the free carboxyl on the end of the growing chain and the amino group of the next amino acid in the sequence. A chain made up of just a few amino acids linked together is called an oligopeptide (oligo=few) while a typi-

YouTube Lectures by Kevin HERE & HERE

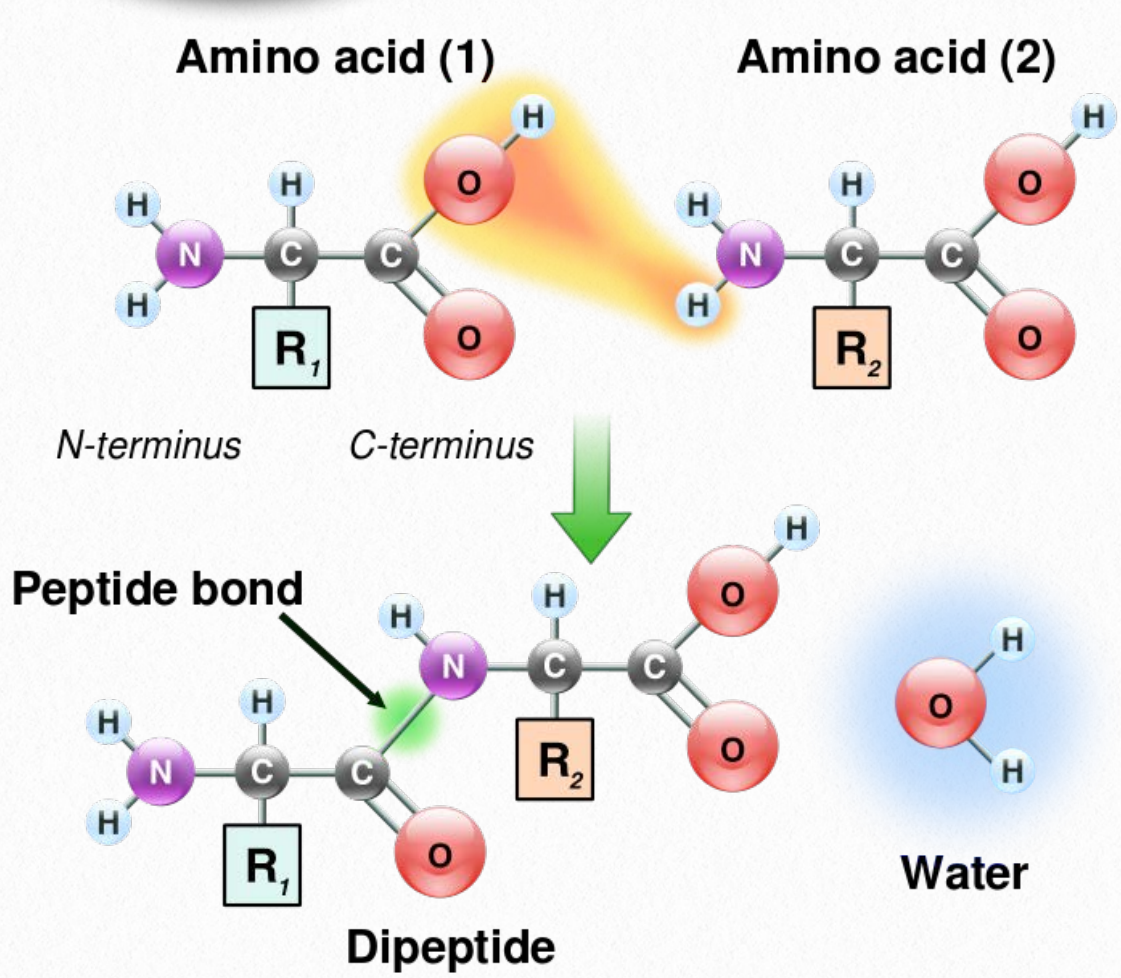

Figure 2.16 **Formation of a peptide bond**

cal protein, which is made up of many amino acids is called a polypeptide (poly=many). The end of the peptide that has a free amino group is called the N-terminus (for NH2), while the end with the free carboxyl is termed the C-terminus (for carboxyl).

As we've noted before, function is dependent on structure, and the string of amino acids must fold into a specific 3-D shape, or conformation, in order to make a functional protein. The folding of polypeptides into their functional forms is the topic of the next section.

Lyrics by Kevin Ahern

You're Cysteine

To the tune of "*You're Sixteen*"
Metabolic Melodies Website HERE

You're in every protein
That I've ever seen
There's no need to debate
You're cysteine, a building block, and you're great

You give the hair waves
It's something we crave
Makes the food on my plate
You're cysteine, a building block, and you're great

Bridge
That sulfhydryl in your chain
Can oxidize, but I don't complain
It gives support to all peptides
So proteins need to have disulfides

You're an acid it seems
And have an amine
Please don't ever mutate
You're cysteine, a building block, and you're great

Bridge
A U-G-U or U-G-C
In secret code at the cell's decree
You're in my skin and in my bone
And even in my glutathione

You're in every protein
That I've ever seen
There's no need to debate
You're cysteine, a building block, and you're great

Structure & Function: Proteins I

Protein diversity

Proteins are the workhorses of the cell. Virtually everything that goes on inside of cells happens as a result of the actions of proteins. Among other things, protein enzymes catalyze the vast majority of cellular reactions, mediate signaling, give structure both to cells and to multicellular organisms, and exert control over the expression of genes. Life, as we know it, would not exist if there were no proteins. The versatility of proteins arises because of their varied structures.

YouTube Lectures by Kevin HERE & HERE

Proteins are made by linking together amino acids, with each protein having a characteristic and unique amino acid sequence.

To get a sense for the diversity of proteins that can be made using 20 different amino acids, consider that the number of different combinations possible with 20 amino acids is 20^n, where n=the number of amino acids in the chain. It becomes apparent that even a dipeptide made of just two amino acids joined together gives us $20^2 = 400$ different combinations. If we do the calculation for a

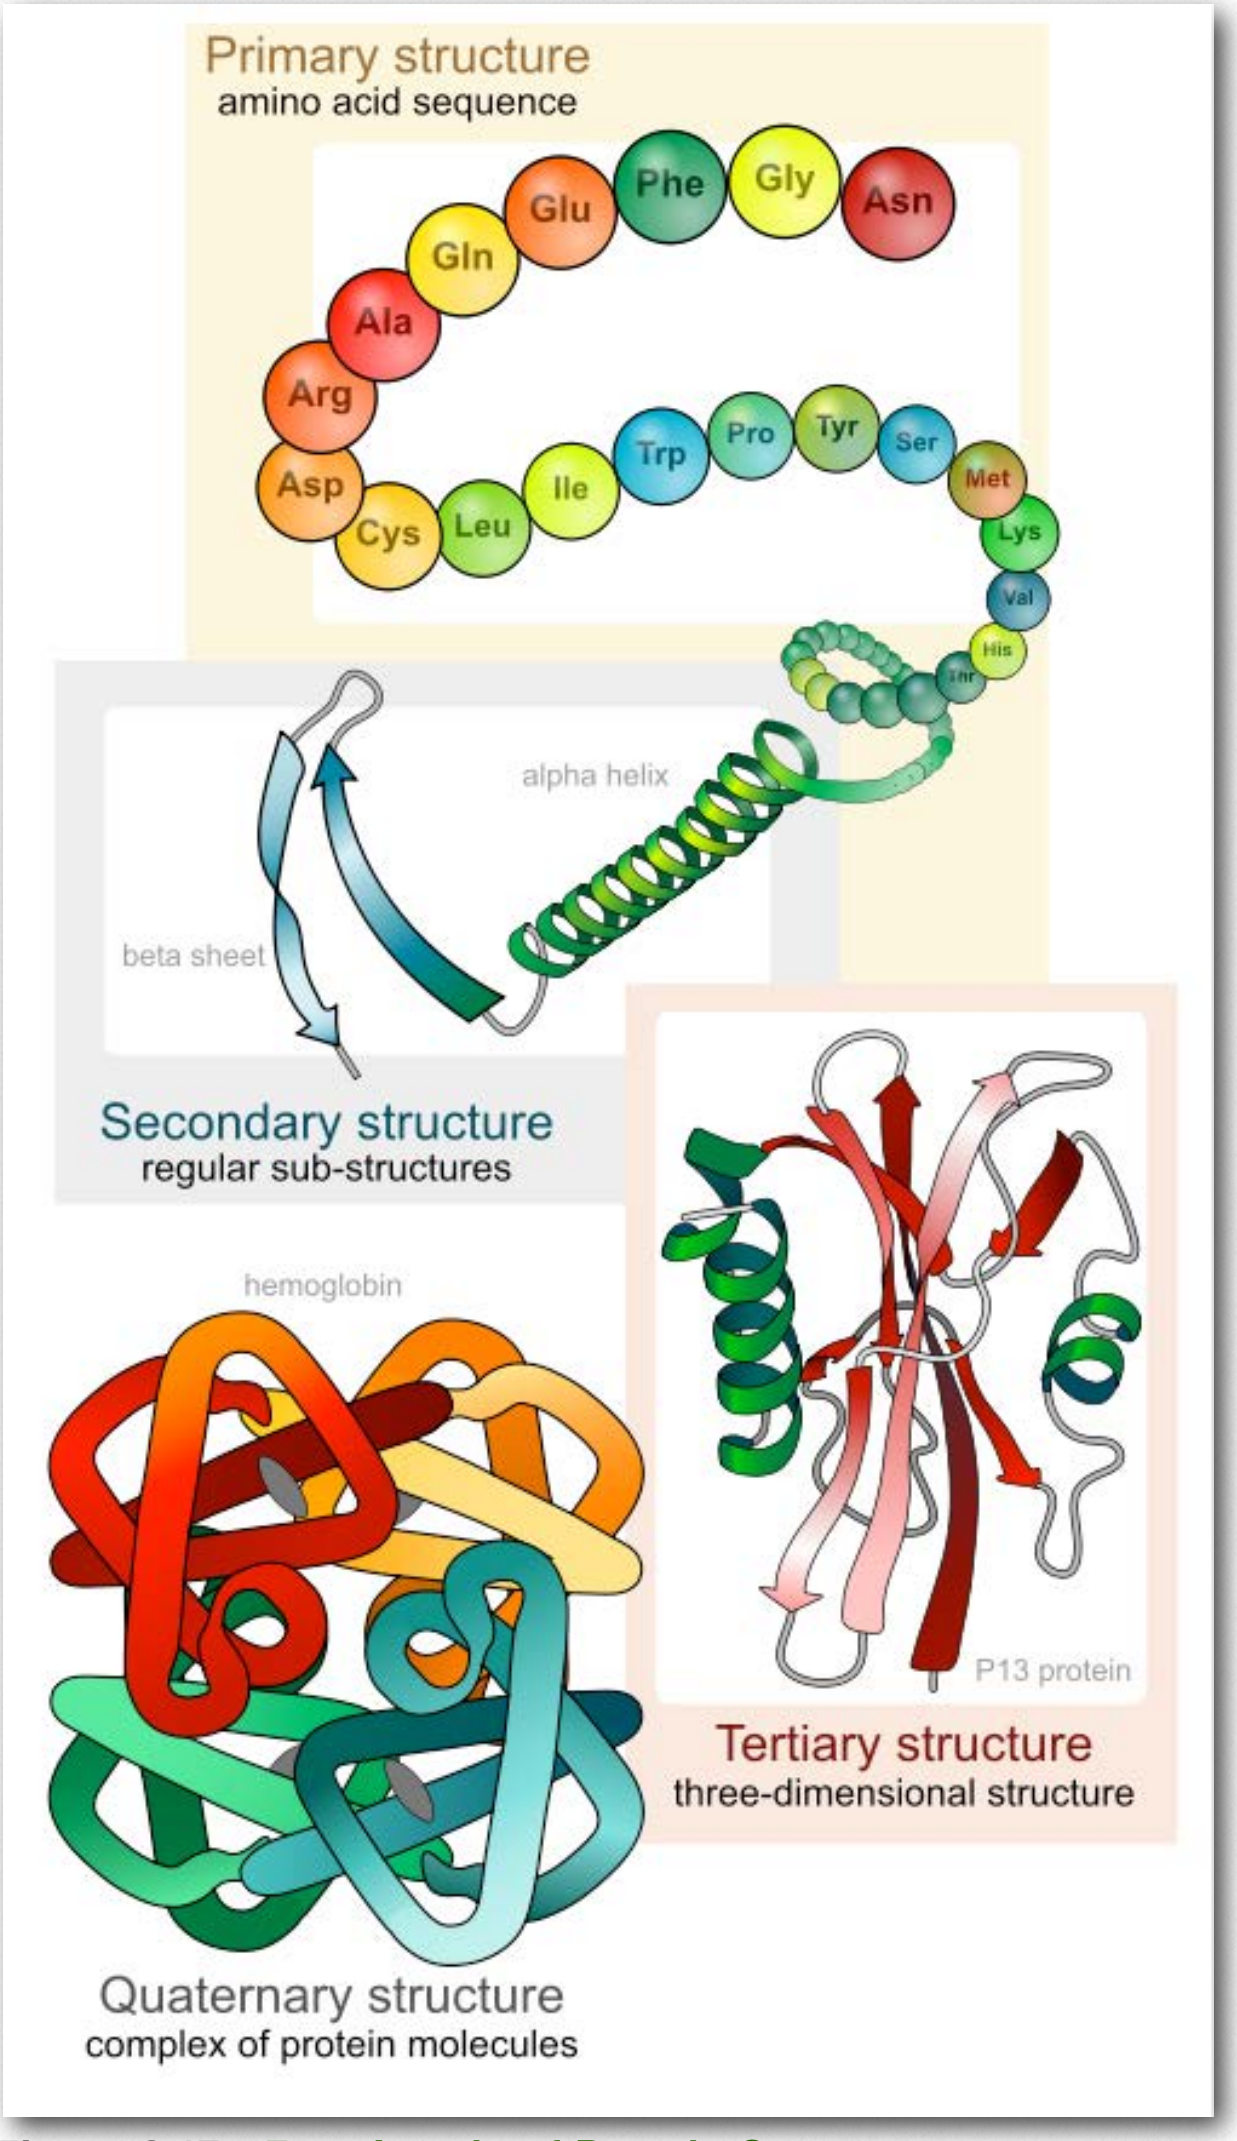

Figure 2.17 - Four Levels of Protein Structure

short peptide of 10 amino acids, we arrive at an enormous 10240000000000 combinations. Most proteins are much larger than this, making the possible number of proteins with unique amino acid sequences unimaginably huge.

Levels of structure

The significance of the unique sequence, or order, of amino acids, known as the protein's primary structure, is that it dictates the 3-D conformation the folded protein will have. This conformation, in turn, will determine the function of the protein. We shall examine protein structure at four distinct levels (Figure 2.17) - 1) how sequence of the amino acids in a protein (primary structure) gives identity and characteristics to a protein (Figure 2.18); 2) how local interactions between one part of the polypeptide backbone and another affect protein

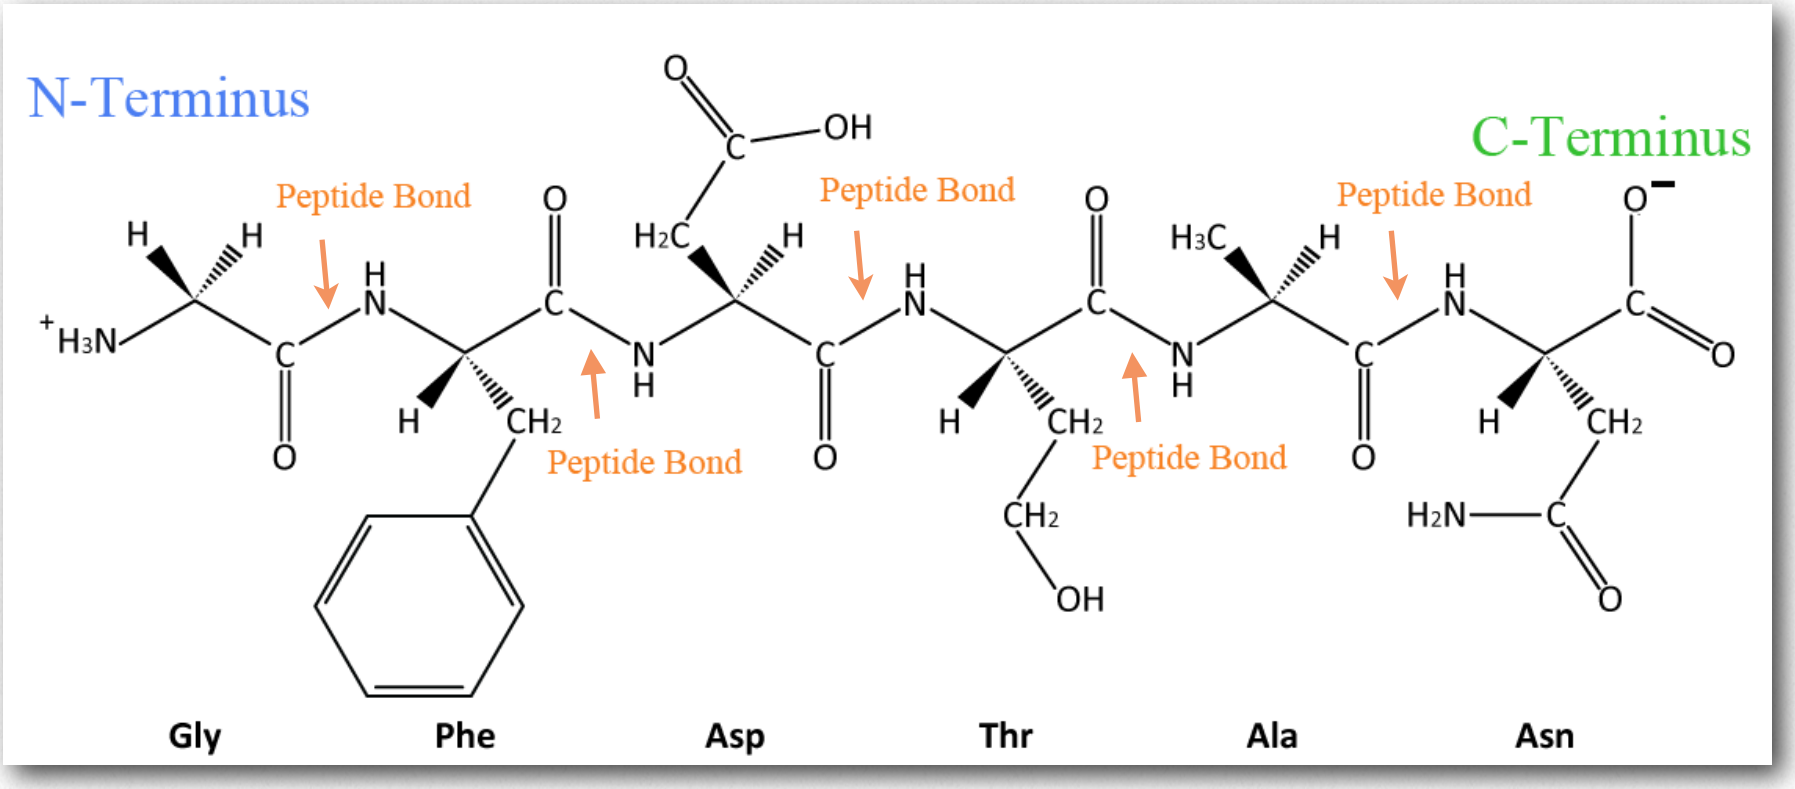

Figure 2.18 - Sequence of a simple polypeptide

Wikipedia

shape (secondary structure); 3) how the polypeptide chain of a protein can fold to allow amino acids to interact with each other that are not close in primary structure (tertiary structure); and 4) how different polypeptide chains interact with each other within a multi-subunit protein (quaternary structure). At this point, we should provide a couple of definitions. We use the term polypeptide to refer to a single polymer of amino acids. It may or may not have folded into its final, functional form. The term protein is sometimes used interchangeably with polypeptide, as in “protein synthesis”. It is generally used, however, to refer to a folded, functional molecule that may have one or more subunits (made up of individual polypeptides). Thus, when we use the term protein, we are usually referring to a functional, folded polypeptide or peptides. Structure is essential for function. If you alter the structure, you alter the function - usually, but not always, this means you lose all function. For many proteins, it is not difficult to alter the structure. Proteins are flexible, not rigidly fixed in structure. As we shall see, it is the flexibility of proteins that allows them to be amazing catalysts and allows them to adapt to, respond to, and pass on signals upon binding of other molecules or proteins. However, proteins are not infinitely flexible. There are constraints on the conformations that proteins can adopt and these constraints govern the conformations that proteins display.

Subtle changes

Even very tiny, subtle changes in protein structure can give rise to big changes in the behav-

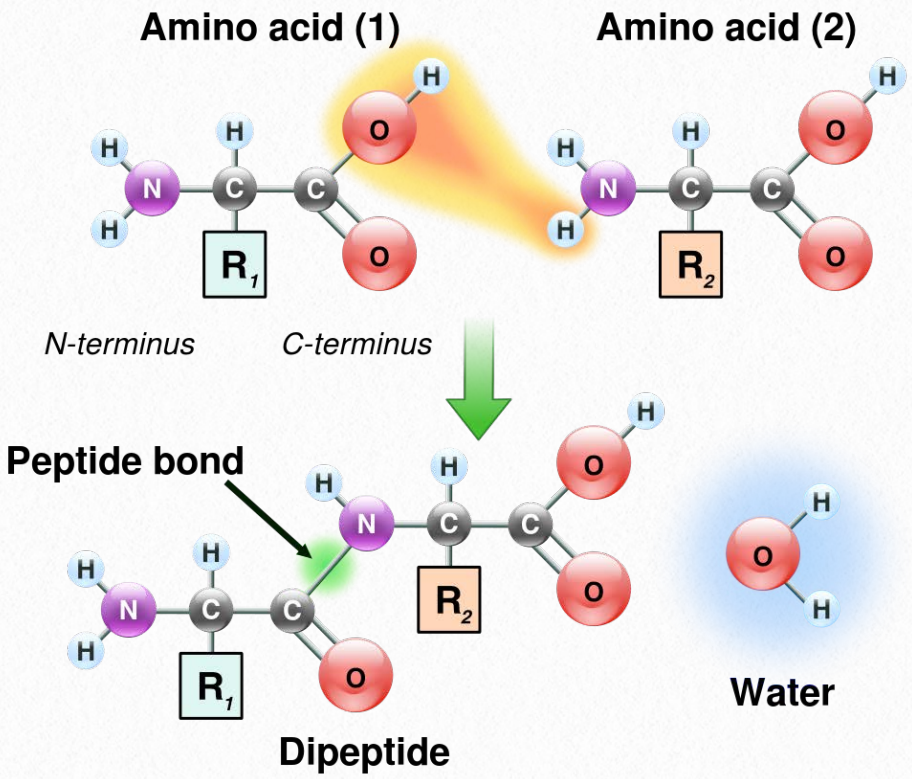

Figure 2.19 Linking of amino acids through peptide bond formation

ior of proteins. Hemoglobin, for example, undergoes an incredibly small structural change upon binding of one oxygen molecule, and that simple change causes the remainder of the protein to gain a considerably greater affinity for oxygen that the protein didn't have before the structural change.

Sequence, structure and function

As discussed earlier, the number of different amino acid sequences possible, even for short peptides, is very large . No two proteins with different amino acid sequences (primary structure) have identical overall structure.

The unique amino acid sequence of a protein is reflected in its unique folded structure. This structure, in turn, determines the protein's function. This is why mutations that alter amino acid sequence can affect the function of a protein.

Protein synthesis

Synthesis of proteins occurs in the ribosomes and proceeds by joining the carboxyl terminus of the first amino acid to the amino terminus of the next one (Figure 2.19). The end of the protein that has the free α-amino group is referred to as the amino terminus or N-terminus. The other end is called the carboxyl terminus or C-terminus , since it contains the only free α-carboxyl group. All of the other α-amino groups and α-carboxyl groups are tied up in forming peptide

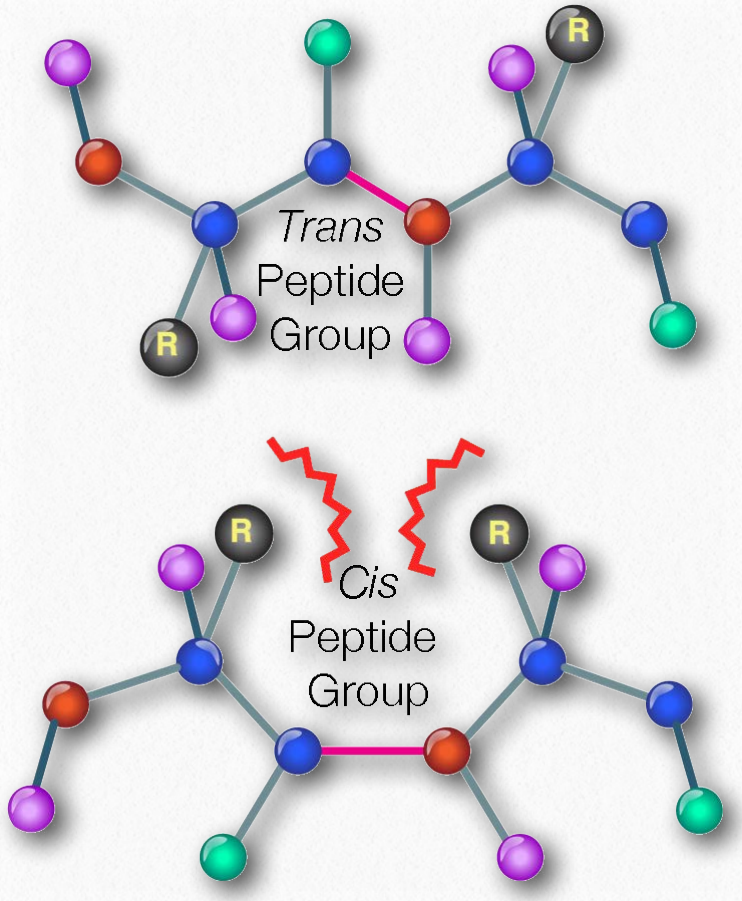

Figure 2.20 - *Cis* vs *trans* orientation of R-groups around peptide bond

Image by Aleia Kim

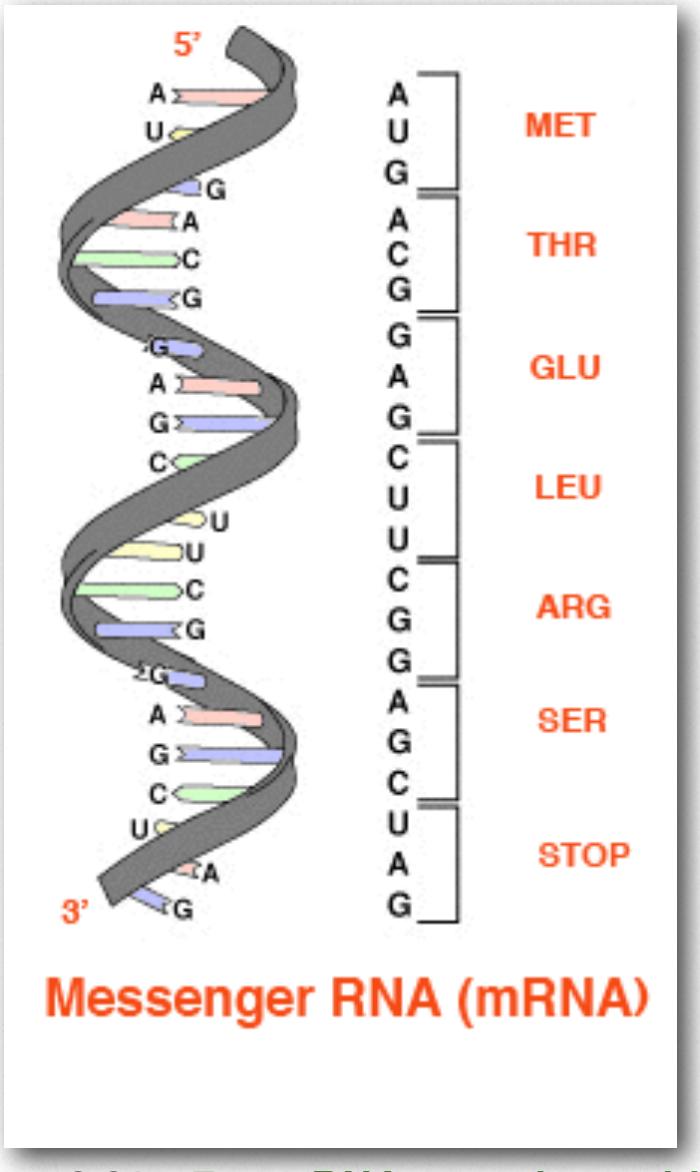

Figure 2.21 - From RNA to amino acids - the genetic code

Wikipedia

bonds that join adjacent amino acids together. Proteins are synthesized starting with the amino terminus and ending at the carboxyl terminus.

Schematically, in Figure 2.18, we can see how sequential R-groups of a protein are arranged in an alternating orientation on either side of the polypeptide chain. Organization of R-groups in this fashion is not random. Steric hindrance can occur when consecutive R-groups are oriented on the same side of a peptide backbone (Figure 2.20)

Primary structure

Primary structure is the ultimate determinant of the overall conformation of a protein. The primary structure of any protein arrived at its current state as a result of mutation and selection over evolutionary time. Primary structure of proteins is mandated by the sequence of DNA coding for it in the genome. Regions of DNA specifying proteins are known as coding regions (or genes).

The base sequences of these regions directly specify the sequence of amino acids in proteins, with a one-to-one correspondence between the codons (groups of three consecutive bases) in the DNA and the amino acids in the encoded protein. The sequence of codons in DNA, copied into messenger RNA, specifies a sequence of amino acids in a protein. (Figure 2.21). The order in which the amino acids are joined together in protein synthesis starts defining a set of interactions between amino acids even as the synthesis is occurring. That is, a polypeptide can fold even as it is being made.

The order of the R-group structures and resulting interactions are very important because early interactions affect later interactions. This is because interactions start establishing structures - secondary and tertiary. If a helical structure (secondary structure), for example, starts to form, the possibilities for interaction of a particular amino acid R-group may be different than if the helix had

not formed (Figure 2.22). R-group interactions can also cause bends in a polypeptide sequence (tertiary structure) and these bends can create (in some cases) opportunities for interactions that wouldn't have been possible without the bend or prevent (in other cases) similar interaction possibilities.

YouTube Lectures by Kevin HERE & HERE

Secondary structure

As protein synthesis progresses, interactions between amino acids close to each other begin to occur, giving rise to local patterns called secondary structure. These secondary structures include the well known **α**-helix and **β**-strands. Both were predicted by Linus Pauling, Robert Corey, and Herman Branson in 1951. Each structure has unique features.

α-helix

The **α**-helix has a coiled structure, with 3.6 amino acids per turn of the helix (5 helical turns = 18 amino acids). Helices are predominantly right handed - only in rare cases, such as in sequences with many glycines can left handed α- helices form. In the α-helix, hydrogen bonds form between C=O groups and N-H groups in the polypeptide backbone that are four amino acids distant. These hydrogen bonds are the primary forces stabilizing the α-helix.

We use the terms rise, repeat, and pitch to describe the parameters of any helix. The repeat is the number of residues in a helix before it begins to repeat itself. For an **α**-helix, the repeat

Hydrophobic amino acids are shown in yellow and ionizing amino acids are shown in blue. Hydrophobic amino acids tend to interact with each other and not with ionizing amino acids.

Wikipedia

is 3.6 amino acids per turn of the helix. The rise is the distance the helix elevates with addition of each residue. For an α-helix, this is 0.15 nm per amino acid. The pitch is the distance between complete turns of the helix. For an α-helix, this is 0.54 nm. The stability of an **α**-helix is enhanced by the presence of the amino acid aspartate.

β strand/sheet

A helix is, of course, a three-dimensional object. A flattened form of helix in two dimen-

sions is a common description for a **β**-strand. Rather than coils, β-strands have bends and these are sometimes referred to as pleats, like the pleats in a curtain. β-strands can be organized to form elaborately organized structures, such as sheets, barrels, and other arrangements. Higher order β-strand structures are sometimes called supersecondary structures), since they involve interactions between amino acids not close in primary sequence. These structures, too, are stabilized by hydrogen bonds between carbonyl oxygen atoms and hydrogens of amine groups in the polypeptide backbone (Figure 2.28). In a higher order structure, strands can be arranged parallel (amino to carboxyl orientations the same) or anti-parallel (amino to carboxyl orientations opposite of each other (in Figure 2.27, the direction of the strand is shown by the arrowhead in the ribbon diagrams).

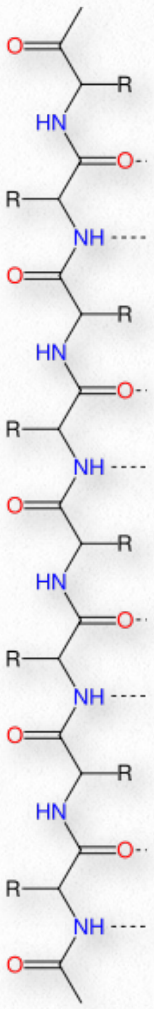

Figure 2.26 - β strand

Turns

Turns (sometimes called reverse turns) are a type of secondary structure that, as the name suggests, causes a turn in the structure of a polypeptide chain. Turns give rise to tertiary structure ultimately, causing interruptions in the secondary structures (**α**-helices and **β**-strands) and often serve as connecting regions between two regions of secondary structure in a protein. Proline and glycine play common roles in turns, providing less flexibility (starting the turn) and greater flexibility (facilitating the turn), respectively.

There are at least five types of turns, with numerous variations of each giving rise to many different turns. The five types of turns are

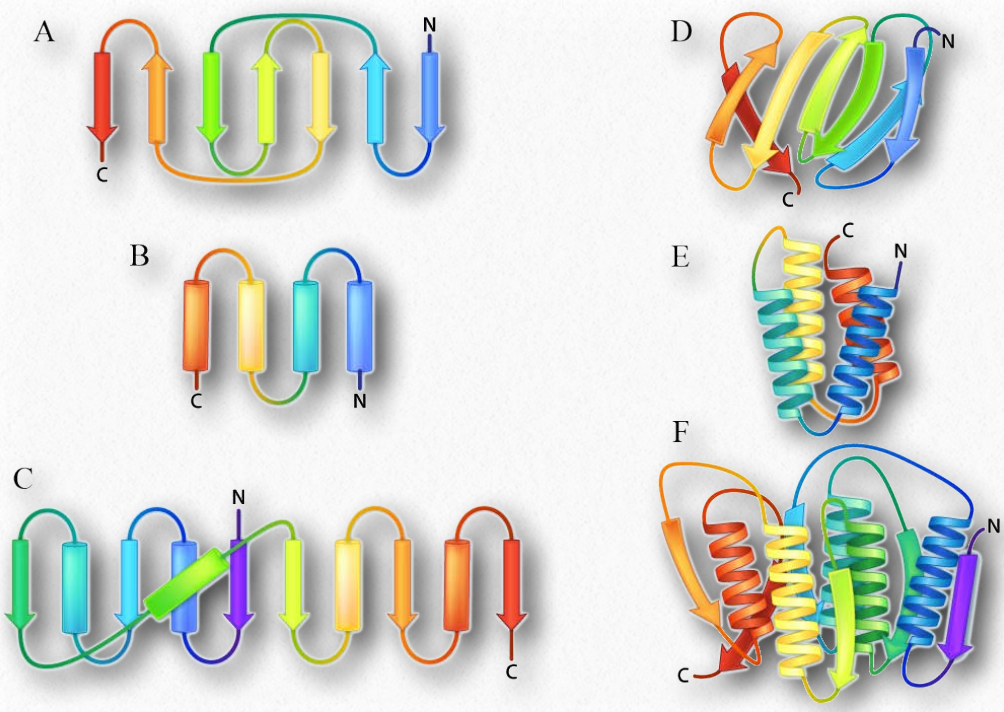

Figure 2.27 - Ribbon depictions of supersecondary β-sheets (A-D) and α-helix arrangements (E-F)

Image by Aleia Kim

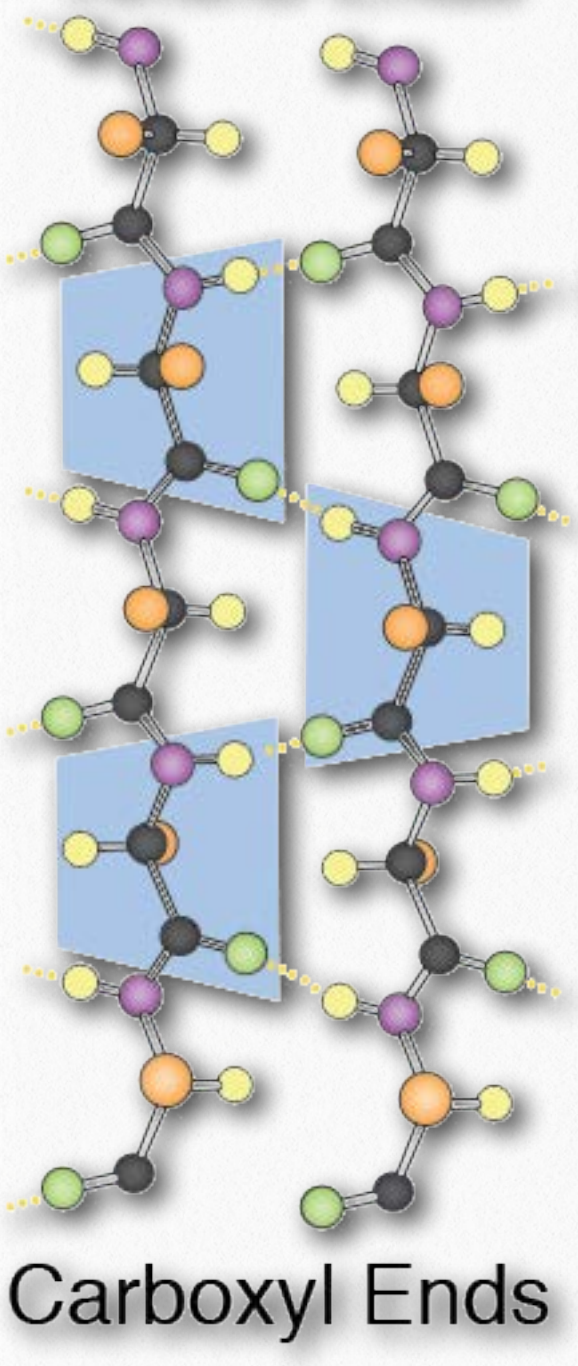

Figure 2.28 - Components of a β-sheet in a parallel arrangement. H-bonds in yellow.

Image by Aleia Kim

- **δ**-turns - end amino acids are separated by one peptide bond
- **γ**-turns - separation by two peptide bonds
- **β**-turns - separation by three peptide bonds
- **α**-turns - separation by four peptide bonds
- **π**-turns - separation by five bonds

Of these, the β-turns are the most common form and the δ-turns are theoretical, but unlikely, due to steric limitations. Figure 2.29 depicts a β-turn.

YouTube Lectures by Kevin HERE & HERE

3_{10} helices

In addition to the **α**-helix, **β**-strands, and various turns, other regular, repeating structures are seen in proteins, but occur much less commonly. The 3_{10} helix is the

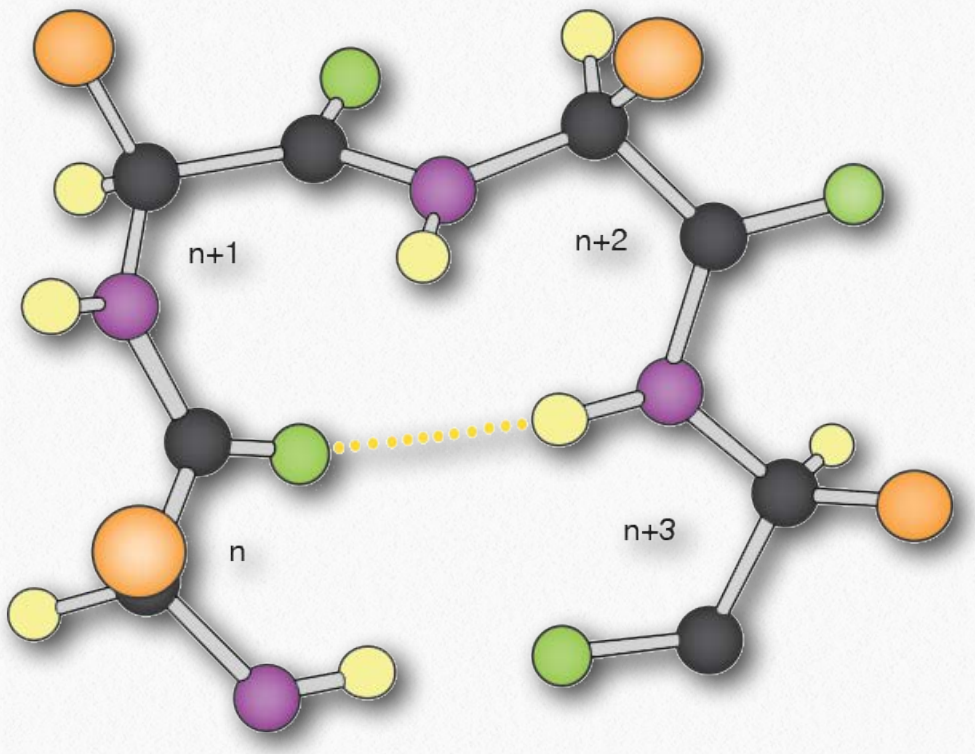

Figure 2.29 - β-turn. R-groups are shown in orange, hydrogens in yellow, carbons in charcoal, nitrogens in purple, and oxygens in green. A stabilizing hydrogen bond is indicated with the dotted line.

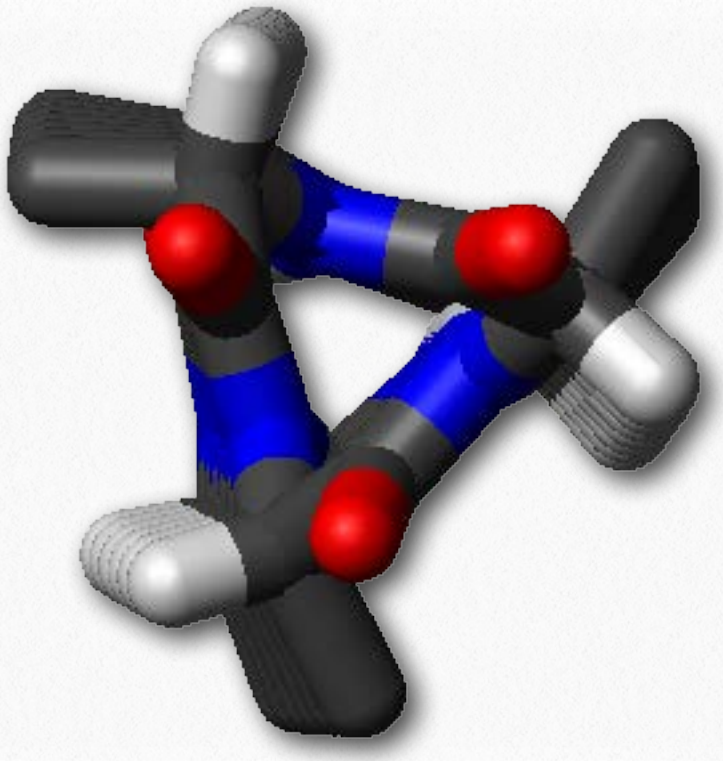

Figure 2.30 - Top view of a 3_{10} Helix. Carbonyl groups are in red and pointed upwards. Note the almost perfect 3-fold symmetry

Wikipedia

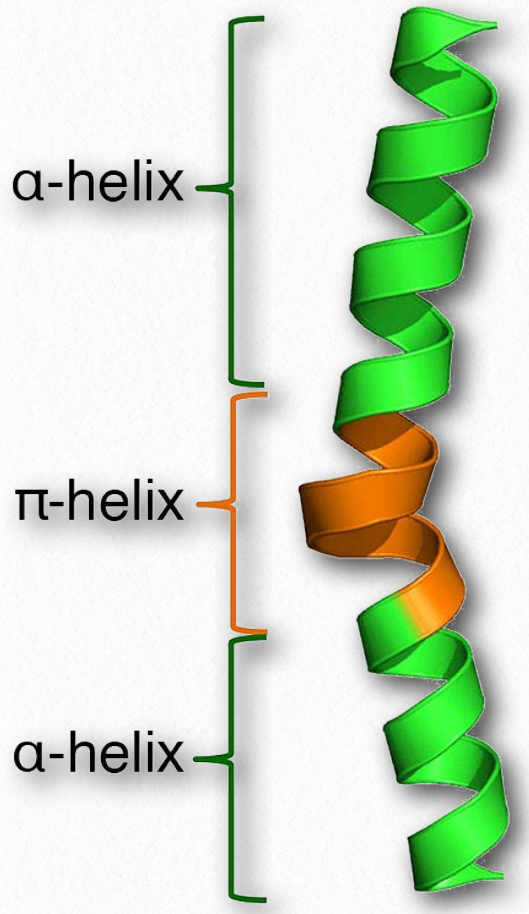

Figure 2.32 - π helix

Wikipedia

fourth most abundant secondary structure in proteins, constituting about 10-15% of all helices. The helix derives its name from the fact that it contains 10 amino acids in 3 turns. It is right-handed. Hydrogen bonds form between amino acids that are three residues apart. Most commonly, the 3_{10} helix appears at the amine or carboxyl end of an α-helix. Like the α-helix, the 3_{10} helix is stabilized by the presence of aspartate in its sequence.

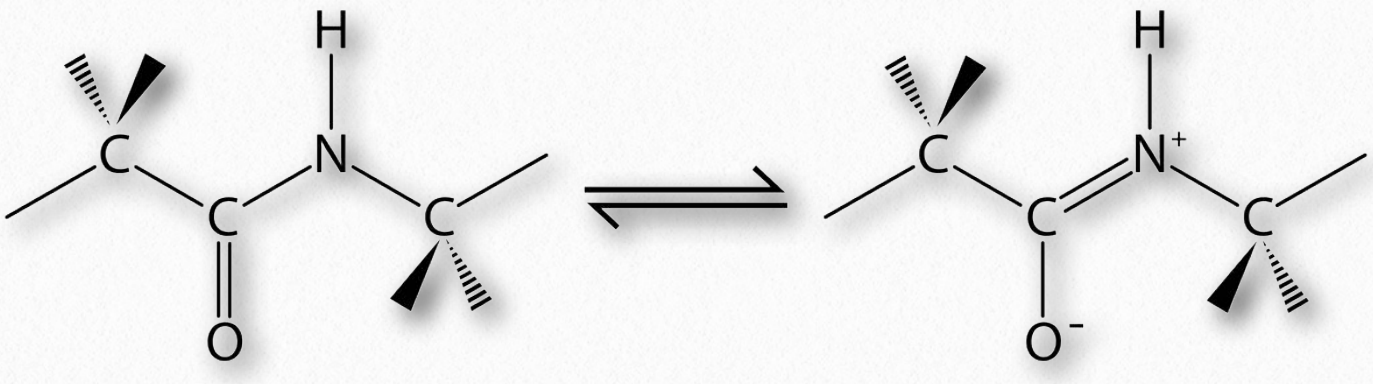

Figure 2.31 - Resonance of the peptide bond

Wikipedia

π-helices

A **π**-helix may be thought of as a special type of **α**-helix. Some sources describe it as an α-helix with an extra amino acid stuck in the middle of it (Figure 2.32). π-helices

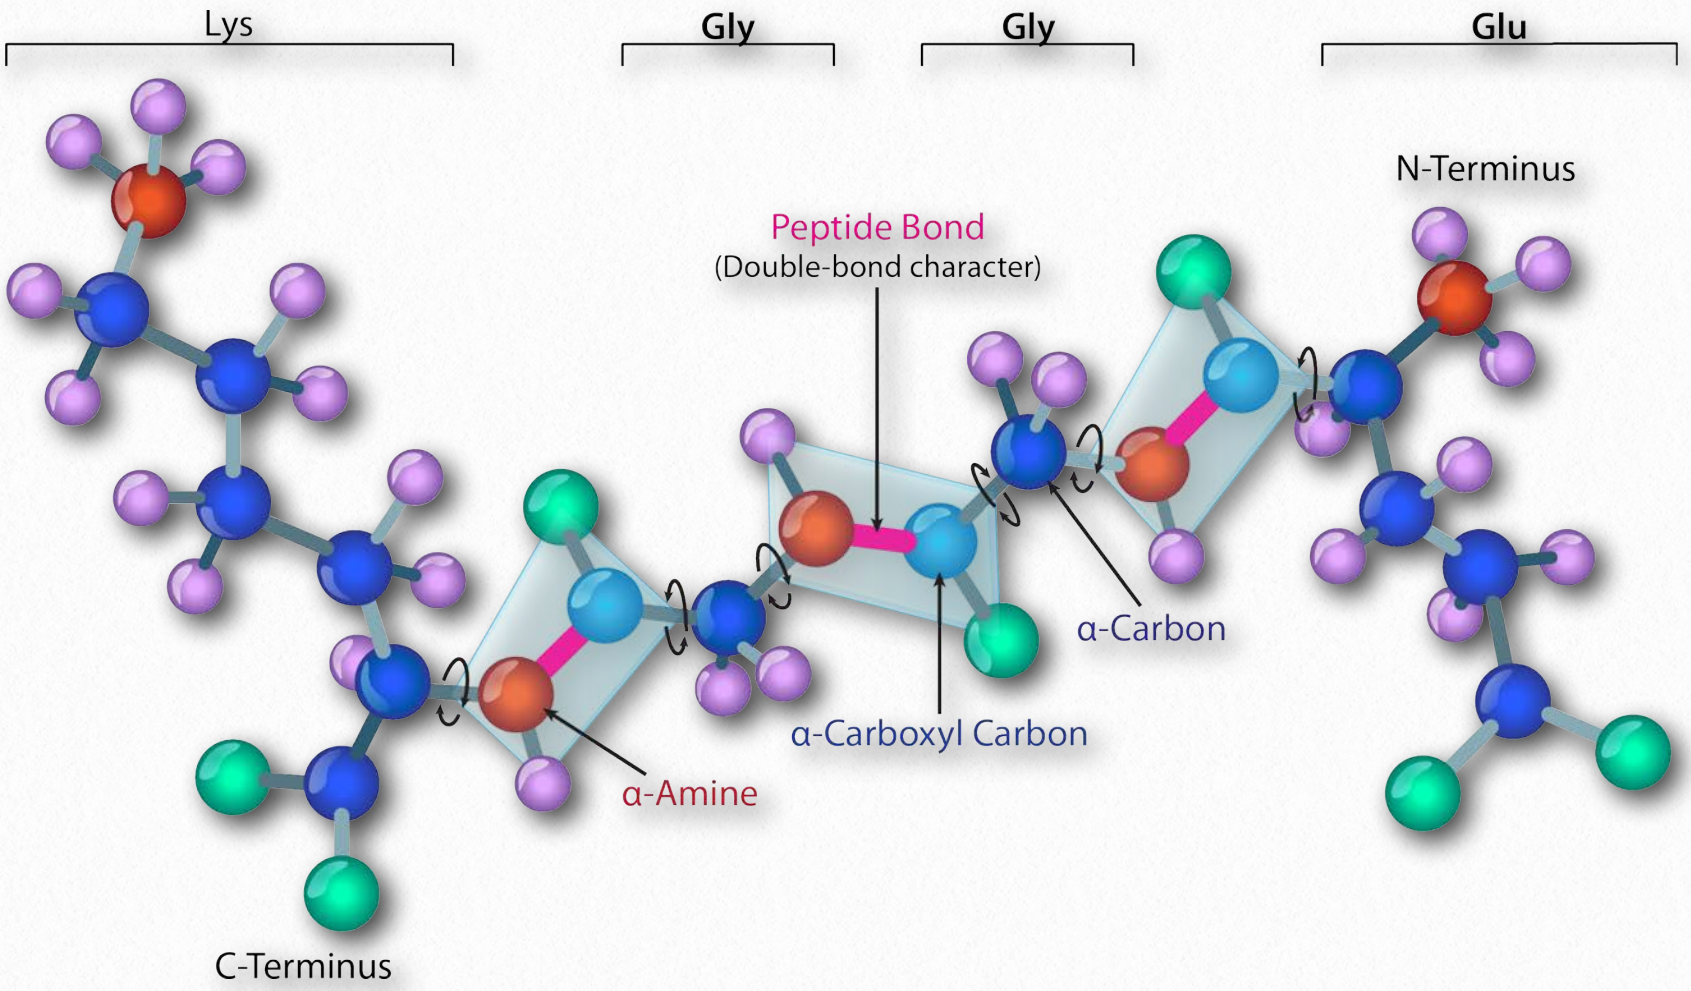

Figure 2.33 - Planes (light blue) defined by the double-bonded character of the peptide bond

Image by Aleia Kim

are not exactly rare, occurring at least once in as many as 15% of all proteins. Like the α-helix, the π-helix is right-handed, but where the α-helix has 18 amino acids in 5 turns, the π-helix has 22 amino acids in 5 turns. π-helices typically do not stretch for very long distances. Most are only about 7 amino acids long and the sequence almost always occurs in the middle of an α-helical region.

Ramachandran plots

In 1963, G.N. Ramachandran, C. Ramakrishnan, and V. Sasisekharan described a novel way to describe protein structure. If one considers the backbone of a polypeptide chain, it consists of a repeating set of three bonds. Sequentially (in the amino to carboxyl direction) they are 1) a rotatable bond (ψ) between α-carbon and α-carboxyl preceding the peptide bond (see HERE), 2) a non-rotatable peptide bond (ω) between the α-carboxyl and α-amine groups), and 3) a rotatable bond (φ) between the α-amine and α-carbon following the peptide bond (see HERE). Note in Figures 2.33 and 2.34 that the amino to carboxyl direction is right to left.

The presence of the carbonyl oxygen on the α-carboxyl group allows the peptide bond to exist as a resonant structure, meaning that it behaves some of the time as a double

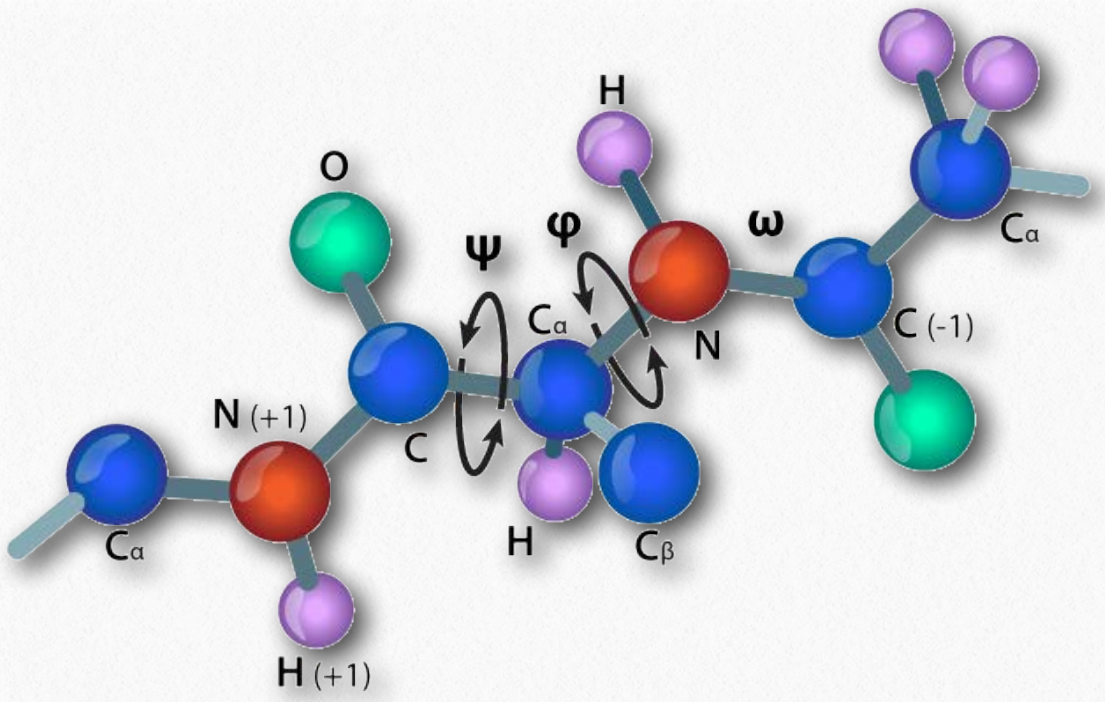

Figure 2.34 - ω, ψ, and ϕ rotational angles in a peptide
Image by Aleia Kim

bond. Double bonds cannot, of course, rotate, but the bonds on either side of it have some freedom of rotation. The φ and ψ angles are restricted to certain values, because some angles will result in steric hindrance. In addition, each type of secondary structure has a characteristic range of values for φ and ψ.

Ramachandran and colleagues made theoretical calculations of the energetic stability of all possible angles from 0° to 360° for each of the φ and ψ angles and plotted the results on a Ramachandran Plot (also called a φ-ψ plot), delineating regions of angles that were theoretically the most stable (Figure 2.35).

Three primary regions of stability were identified, corresponding to **φ-ψ** angles of β-strands (top left), right handed α-helices (bottom left), and left-handed α-helices (upper right). The plots of predicted stability are remarkably accurate when compared to φ-ψ angles of actual proteins.

Secondary structure prediction

By comparing primary structure (amino acid sequences) to known 3D protein structures, one can tally each time an amino acid is

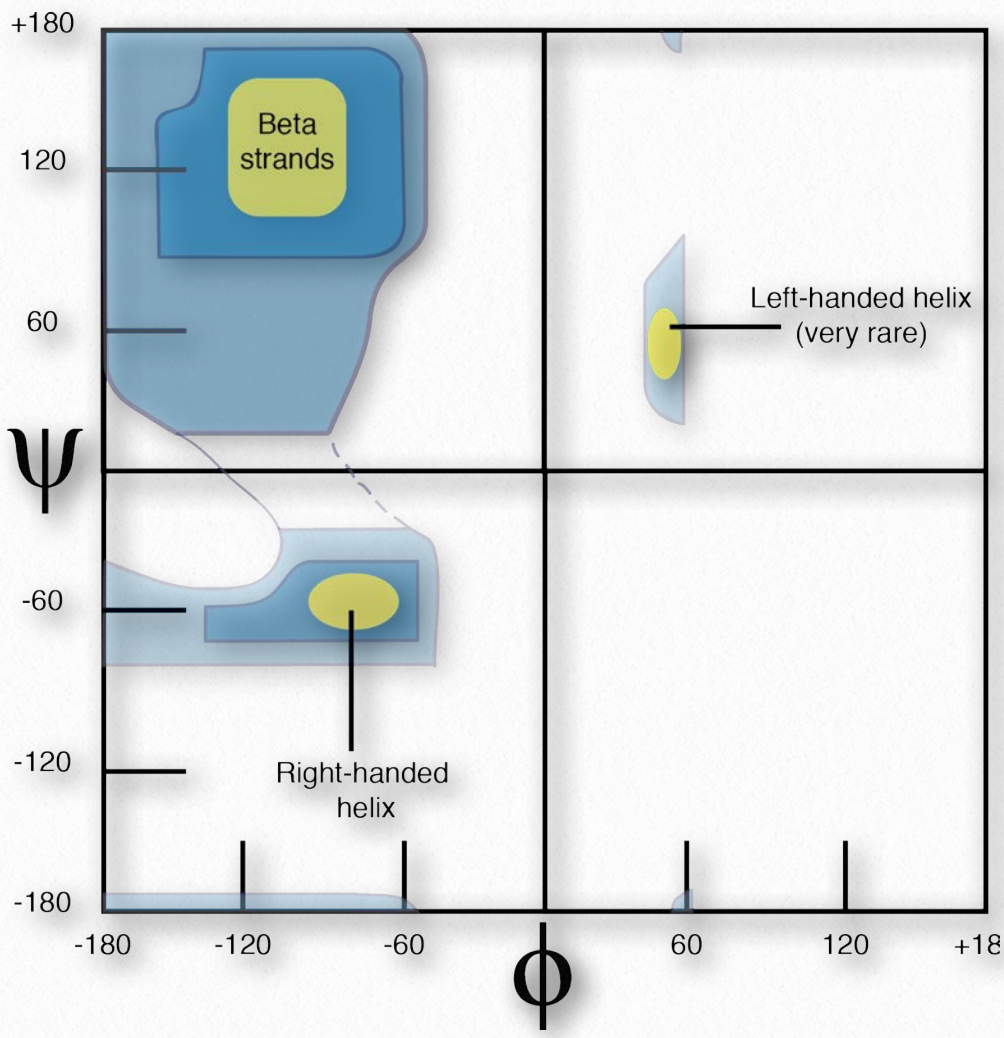

Figure 2.35 - Theoretical Ramachandran plot
Image by Penelope Irving

found in an α-helix, β-strand/sheet, or a turn. Computer analysis of thousands of these sequences allows one to assign a likelihood of any given amino acid appearing in each of these structures. Using these tendencies, one can, with up to 80% accuracy, predict regions of secondary structure in a protein based solely on amino acid sequence. This is seen in Table 2.3. Occurrence in primary sequence of three consecutive amino acids with relative tendencies higher than one is an indicator that that region of the polypeptide is in the corresponding secondary structure. An online resource for predicting secondary structures called PSIPRED is available HERE.

Hydrophobicity

The chemistry of amino acid R-groups affects the structures they are most commonly found in. Subsets of their chemical properties can give clues to structure and, sometimes, cellular location. A prime example is the hydrophobicity (water-avoiding tendencies) of some R-groups. Given the aqueous environment of the cell, such R-groups are not likely to be on the outside surface of a folded protein. However, this rule does not hold for regions of protein that may be embedded within the lipid bilayers of cellular/organelle membranes. This is because the region of such proteins that form the transmembrane domains are are buried in the hydrophobic environment in the middle of the lipid bilayer.

Amino Acid Hydropathy Scores

Amino Acid	One Letter Code	Hydropathy Score

Lysine	K	-3.9
Arginine	R	-4.5

Table 2.4 - Hydropathy Scores

Wikipedia

Not surprisingly, scanning primary sequences for specifically sized/spaced stretches of hydrophobic amino acids can help to identify proteins found in membranes. Table 2.4 shows hydrophobicity values for R-groups of the amino acids. In this set, the scale runs from positive values (hydrophobic) to negative values (hydrophilic). A Kyte-Doolittle Hydropathy plot for the RET protooncogene membrane protein is shown in Figure 2.36. Two regions of the protein are very hydrophobic as can be seen from the peaks near amino acids 5-10 and 630-640. Such regions might be reasonably expected to be situated either within the interior of the folded protein or to be part of transmembrane domains.

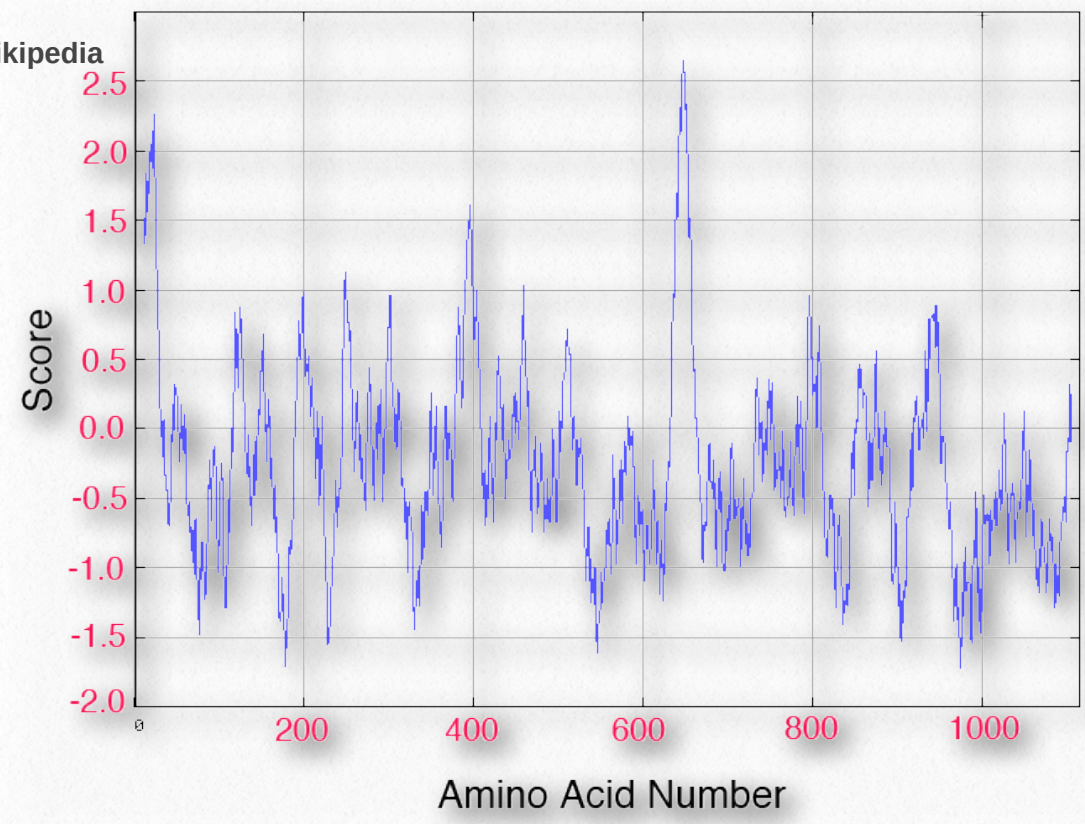

Figure 2.36 Kyte-Doolittle hydropathy plot for the RET protooncogene

Wikipedia

Random coils

Some sections of a protein assume no regular, discernible structure and are sometimes said to lack secondary structure, though they may have hydrogen bonds. Such segments are described as being in random coils and may have fluidity to their structure that results in them having multiple stable forms. Random coils are identifiable with spectroscopic methods, such as circular dichroism

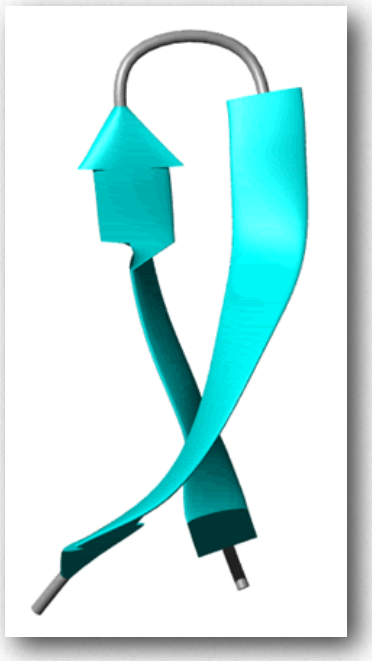

Figure 2.37 - Ribbon depiction of a β-hairpin. Shown are two β strands in turquoise interacting with each other.

and nuclear magnetic resonance (NMR) in which distinctive signals are observed. See also metamorphic proteins (HERE) and intrinsically disordered proteins (HERE).

Supersecondary structure

Another element of protein structure is harder to categorize because it incorporates elements of secondary and tertiary structure. Dubbed supersecondary structure (or structural motifs), these structures contain multiple nearby secondary structure components arranged in a specific way and that appear in multiple proteins. Since there are many ways of making secondary structures from different primary structures, so too can similar motifs arise from different primary sequences. An example of a structural motif is shown in Figure 2.37.

Tertiary structure

Proteins are distinguished from each other by the sequence of amino acids comprising them. The sequence of amino acids of a protein determines protein shape, since the chemical properties of each amino acid are forces that give rise to intermolecular interactions to begin to create secondary structures, such as α-helices and β-strands. The sequence also defines turns and random coils that play important roles in the process of protein folding.

Since shape is essential for protein function, the sequence of amino acids gives rise to all of the properties a protein has. As protein synthesis proceeds, individual components of secondary structure start to interact with each other, giving rise to folds that bring amino acids close together that are not near each other in primary structure (Figure 2.38). At the tertiary level of structure, inter-

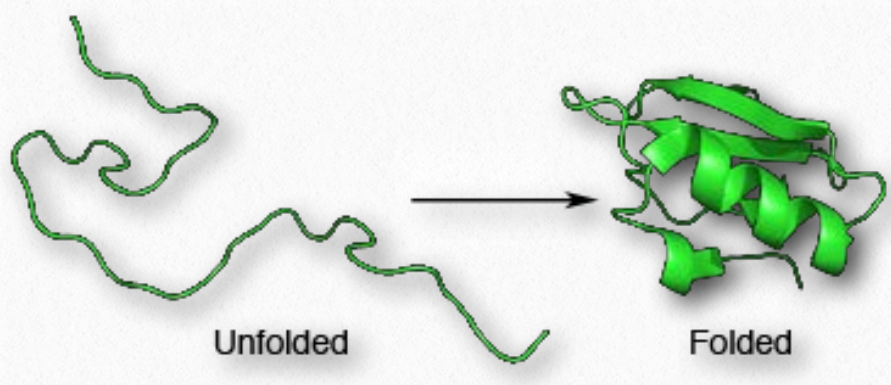

Figure 2.38 - Folding of a polypeptide chain

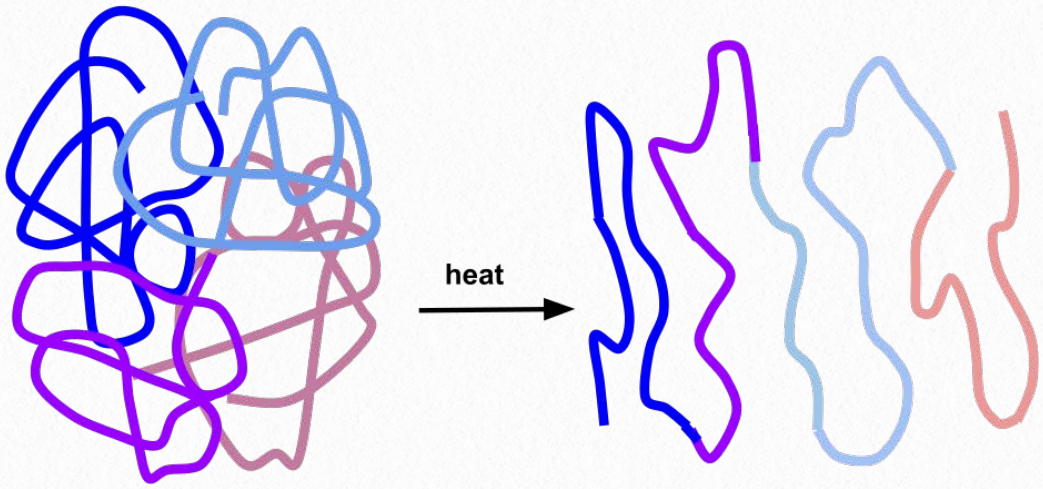

Figure 2.39 - **Unfolding (denaturation) of a protein**

Wikipedia

actions among the R-groups of the amino acids in the protein, as well as between the polypeptide backbone and amino acid side groups play a role in folding.

Globular proteins

Folding gives rise to distinct 3-D shapes in proteins that are non-fibrous. These proteins are called globular. A globular protein is stabilized by the same forces that drive its formation. These include ionic interactions, hydrogen bonding, hydrophobic forces, ionic bonds, disulfide bonds and metallic bonds. Treatments such as heat, pH changes, detergents, urea and mercaptoethanol overpower the stabilizing forces and cause a protein to unfold, losing its structure and (usually) its function (Figure 2.39). The ability of heat and detergents to denature proteins is why we cook our food and wash our hands before eating - such treatments denature the proteins in the microorganisms on our hands. Organisms that live in environments of high temperature (over 50°C) have proteins with changes in stabilizing forces - additional hydrogen bonds, additional salt bridges (ionic interactions), and compactness may all play roles in keeping these proteins from unfolding.

Protein stabilizing forces

Before considering the folding process, let us consider some of the forces that help to stabilize proteins.

Hydrogen bonds

Hydrogen bonds arise as a result of partially charged hydrogens found in covalent bonds. This occurs when the atom the hydrogen is bonded to has a greater electronegativity than hydrogen itself does, resulting in hydrogen having a partial positive charge be-

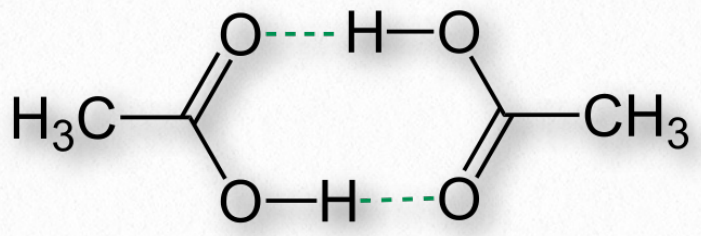

Figure 2.40 - **Hydrogen bonds (dotted lines) between two molecules of acetic acid**

cause it is not able to hold electrons close to itself (Figure 2.40).

Hydrogen partially charged in this way is attracted to atoms, such as oxygen and nitrogen that have partial negative charges, due to having greater electronegativities and thus holding electrons closer to themselves. The partially positively charged hydrogens are called donors, whereas the partially negative atoms they are attracted to are called acceptors. (See Figure 1.30).

YouTube Lectures by Kevin HERE & HERE

Individual hydrogen bonds are much weaker than a covalent bond, but collectively, they can exert strong forces. Consider liquid water, which contains enormous numbers of hydrogen bonds (Figure 2.41). These forces help water to remain liquid at room temperature. Other molecules lacking hydrogen bonds of equal or greater molecular weight than water, such as methane or carbon dioxide, are gases at the same temperature. Thus, the intermolecular interactions between water molecules help to "hold" water together and remain a liquid. Notably, only by raising the temperature of water to boiling are the forces of hydrogen bonding overcome, allowing water to become fully gaseous.

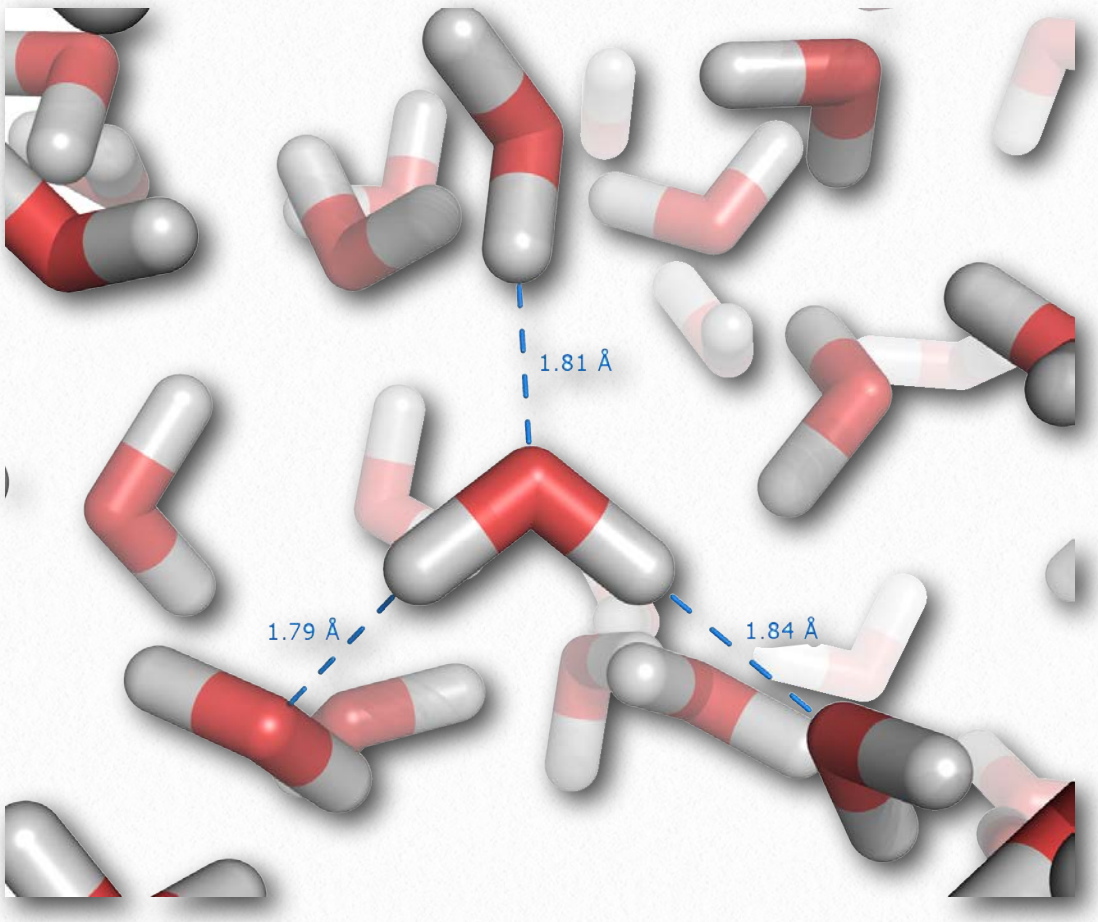

Figure 2.41 - Hydrogen bonding in liquid water
Wikipedia

Hydrogen bonds are important forces in biopolymers that include DNA, proteins, and cellulose. All of these polymers lose their native structures upon boiling. Hydrogen bonds between amino acids that are close to each other in primary structure can give rise to regular repeating structures, such as helices or pleats, in proteins (secondary structure).

Ionic interactions

Ionic interactions are important forces stabilizing protein structure that arise from ionization of R-groups in the amino acids comprising a protein. These include the carboxyl amino acids (HERE), the amine amino acids

An Ode to Protein Structure

by Kevin Ahern

The twenty wee amino A's
Define a protein many ways

Their order in a peptide chain
Determines forms that proteins gain

And when they coil, it leaves me merry
Cuz that makes structures secondary

It's tertiary, I am told
That happens when a protein folds

But folded chains are downright scary
When put together quaternary

They're nature's wonders, that's for sure
Creating problems, making cures

A fool can fashion peptide poems
But proteins come from ribosoems

(HERE), as well as the sulfhydryl of cysteine and sometimes the hydroxyl of tyrosine.

Hydrophobic forces

Hydrophobic forces stabilize protein structure as a result of interactions that favor the exclusion of water. Non-polar amino acids (commonly found in the interior of proteins) favor associating with each other and this has the effect of excluding water. The excluded water has a higher entropy than water interacting with the hydrophobic side chains. This is because water aligns itself very regularly and in a distinct pattern when interacting with hydrophobic molecules.

When water is prevented from having these kinds of interactions, it is much more disordered that it would be if it could associate with the hydrophobic regions. It is partly for this reason that hydrophobic amino acids are found in protein interiors - so they can exclude water and increase entropy.

Disulfide bonds

Disulfide bonds, which are made when two sulfhydryl side-chains of cysteine are brought into close proximity, covalently join together different protein regions and can give great strength to the overall structure (Figures 2.42 & 2.43).

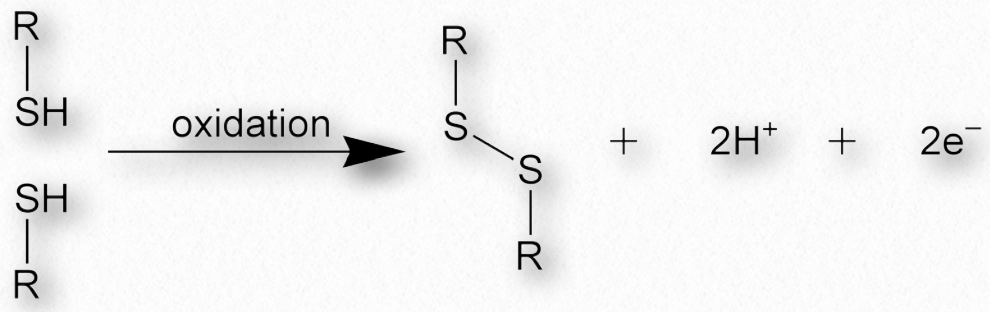

Figure 2.42 - Formation of a disulfide bond

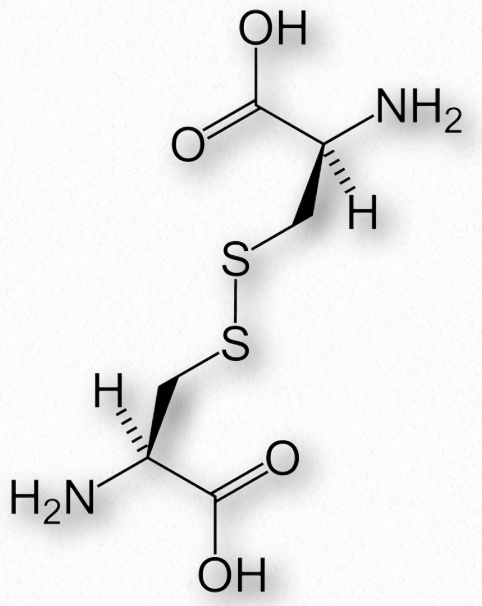

Figure 2.43 - Cystine - Two cysteines joined by a disulfide bond

These joined residues of cysteine are sometimes referred to as cystine. Disulfide bonds are the strongest of the forces stabilizing protein structure.

van der Waals forces

van der Waals forces is a term used to describe various weak interactions, including those caused by attraction between a polar molecule and a transient dipole, or between two temporary dipoles. van der Waals forces are dynamic because of the fluctuating nature of the attraction, and are generally weak in comparison to covalent bonds, but can, over very short distances, be significant.

Post-translational modifications

Post-translational modifications can result in formation of covalent bonds stabilizing proteins as well. Hydroxylation of lysine and proline in strands of collagen can result in cross-linking of these groups and the resulting covalent bonds help to strengthen and stabilize the collagen.

Folding models

Two popular models of protein folding are currently under investigation. In the first (diffusion collision model), a nucleation event begins the process, followed by secondary structure formation. Collisions between the secondary structures (as in the β-hairpin in Figure 2.37) allow for folding to begin. By contrast, in the nucleation-condensation model, the secondary and tertiary structures form together.

Folding in proteins occurs fairly rapidly (0.1 to 1000 seconds) and can occur during synthesis - the amino terminus of a protein can start to fold before the carboxyl terminus is even made, though that is not always the case.

Folding process

Protein folding is hypothesized to occur in a "folding funnel" energy landscape in which a folded protein's native state corresponds to the minimal free energy possible in conditions of the medium (usually aqueous solvent) in which the protein is dissolved. As seen in the diagram (Figure 2.44), the energy funnel has numerous local minima (dips) in which a folding protein can become trapped as it

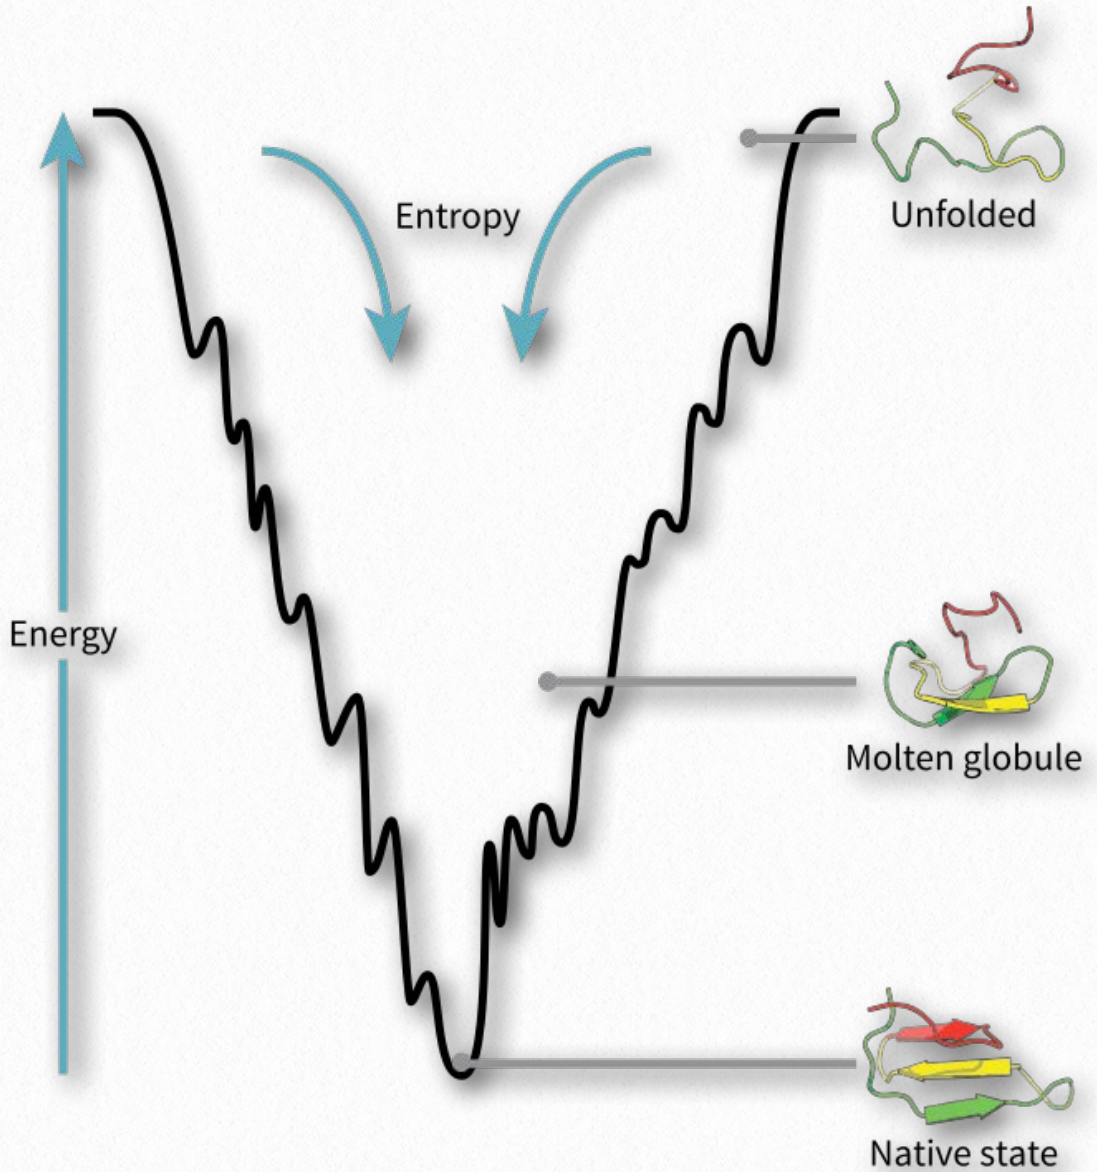

Figure 2.44 Folding funnel energy model of folding Wikipedia

Getting stuck

As the folding process proceeds towards an energy minimum (bottom of the funnel in Figure 2.44), a protein can get "stuck" in any of the local minima and not reach the final folded state. Though the folded state is, in general, more organized and therefore has reduced entropy than the unfolded state, there are two forces that overcome the entropy decrease and drive the process forward.

The first is the magnitude of the decrease in energy as shown in the graph. Since

$$\Delta G = \Delta H - T\Delta S,$$

moves down the energy plot. Other factors, such as temperature, electric/magnetic fields, and spacial considerations likely play roles.

If external forces affect local energy minima during folding, the process and end-product can be influenced. As the speed of a car going down a road will affect the safety of the journey, so too do energy considerations influence and guide the folding process, resulting in fully functional, properly folded proteins in some cases and misfolded "mistakes" in others.

a decrease in ΔH can overcome a negative ΔS to make ΔG negative and push the folding process forward. Favorable (decreased) energy conditions arise with formation of ionic bonds, hydrogen bonds, disulfide bonds, and metallic bonds during the folding process. In addition, the hydrophobic effect increases entropy by allowing hydrophobic amino acids in the interior of a folded protein to exclude water, thus countering the impact of the ordering of the protein structure by making the ΔS less negative.

Structure prediction

Computer programs are very good at predicting secondary structure solely based on amino acid sequence, but struggle with determining tertiary structure using the same information. This is partly due to the fact that secondary structures have repeating points of stabilization based on geometry and any regular secondary structure (e.g., α-helix) varies very little from one to another. Folded structures, though, have an enormous number of possible structures as shown by Levinthal's Paradox.

YouTube Lectures by Kevin HERE & HERE

Spectroscopy

Because of our inability to accurately predict tertiary structure based on amino acid sequence, proteins structures are actually determined using techniques of spectroscopy. In these approaches, proteins are subjected to varied forms of electromagnetic radiation and the ways they interact with the radiation allows researchers to determine atomic coordinates at Angstrom resolution from electron densities (see X-ray crystallography) and how nuclei spins interact (see NMR).

Levinthal's paradox

In the late 1960s, Cyrus Levinthal outlined the magnitude of the complexity of the protein folding problem. He pointed out that for a protein with 100 amino acids, it would have 99 peptide bonds and 198 considerations for φ and ψ angles. If each of these had only three conformations, that would result in 3^{198} different possible foldings or 2.95×10^{94}.

Even allowing a reasonable amount of time (one nanosecond) for each possible fold to occur, it would take longer than the age of the universe to sample all of them, meaning clearly that the process of folding is not occurring by a sequential random sampling and that attempts to determine protein structure by random sampling were doomed to fail. Levinthal, therefore, proposed that folding occurs by a sequential process that begins with a nucleation event that guides the process rapidly and is not unlike the funnel process depicted in Figure 2.44.

Diseases of protein misfolding

The proper folding of proteins is essential to their function. It follows then that

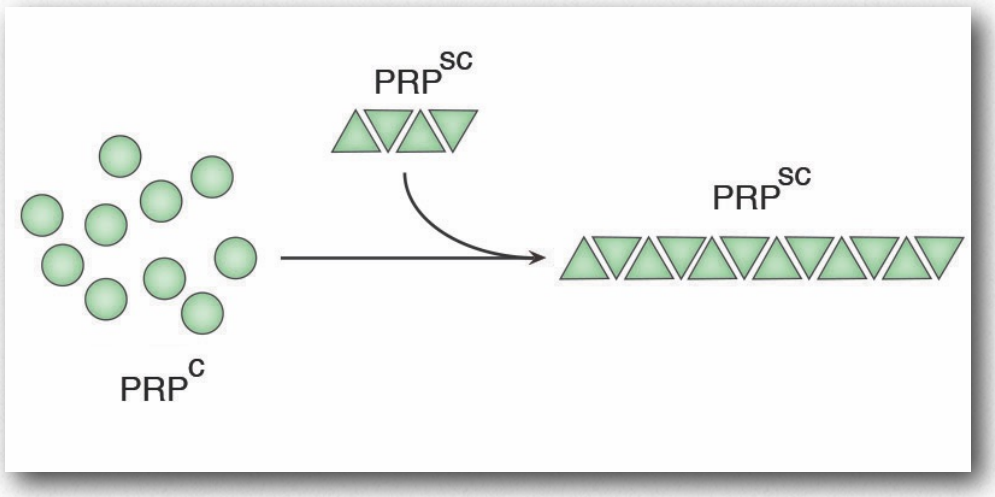

Figure 2.45 - Misfolding of the normal PRP^c protein induced by PRP^{sc}

Image by Penelope Irving

Figure 2.46 - Cows with Mad Cow Disease lose their ability to stand

misfolding of proteins (also called proteopathy) might have consequences. In some cases, this might simply result in an inactive protein. Protein misfolding also plays a role in numerous diseases, such as Mad Cow Disease, Alzheimers, Parkinson's Disease, and Creutzfeld-Jakob disease. Many, but not all, misfolding diseases affect brain tissue.

Insoluble deposits

Misfolded proteins will commonly form aggregates called amyloids that are harmful to tissues containing them because they change from being soluble to insoluble in water and form deposits. The process by which misfolding (Figure 2.45) occurs is not completely clear, but in many cases, it has been demonstrated that a "seed" protein which is misfolded can induce the same misfolding in other copies of the same protein. These seed proteins are known as prions and they act as infectious agents, resulting in the spread of disease. The list of human diseases linked to protein misfolding is long and continues to grow. A Wikipedia link is HERE.

Prions

Prions are infectious protein particles that cause transmissible spongiform encephalopathies (TSEs), the best known of which is Mad Cow disease. Other manifesta-

Figure 2.47 - Diffuse amyloidosis in a blood vessel (red dots)

Wikipedia

tions include the disease, scrapie, in sheep, and human diseases, such as Creutzfeldt-Jakob disease (CJD), Fatal Familial Insomnia, and kuru. The protein involved in these diseases is a membrane protein called PrP. PrP is encoded in the genome of many organisms and is found in most cells of the body. PrP^{c} is the name given to the structure of PrP that is normal and not associated with disease. PrP^{Sc} is the name given to a misfolded form of the same protein, that is associated with the development of disease symptoms (Figure 2.45).

I think that if I chanced to be on
A protein making up a prion
I'd twist it and for goodness sakes
Stop it from making fold mistakes

Misfolded

The misfolded PrP^{Sc} is associated with the TSE diseases and acts as an infectious particle. A third form of PrP, called PrP^{res} can be found in TSEs, but is not infectious. The 'res' of PrP^{res} indicates it is protease resistant. It is worth noting that all three forms of PrP have the same amino acid sequence and differ from each other only in the ways in which the polypeptide chains are folded. The most dangerously misfolded form of PrP is PrP^{Sc}, because of its ability to act like an infectious agent - a seed protein that can induce misfolding of PrP^{c}, thus converting it into PrP^{Sc}.

Function

The function of PrP^{c} is unknown. Mice lacking the PrP gene do not have major abnormalities. They do appear to exhibit problems with long term memory, suggesting a function for PrP^{c}. Stanley Prusiner, who discovered prions and coined the term, received the Nobel Prize in Medicine in 1997 for his work.

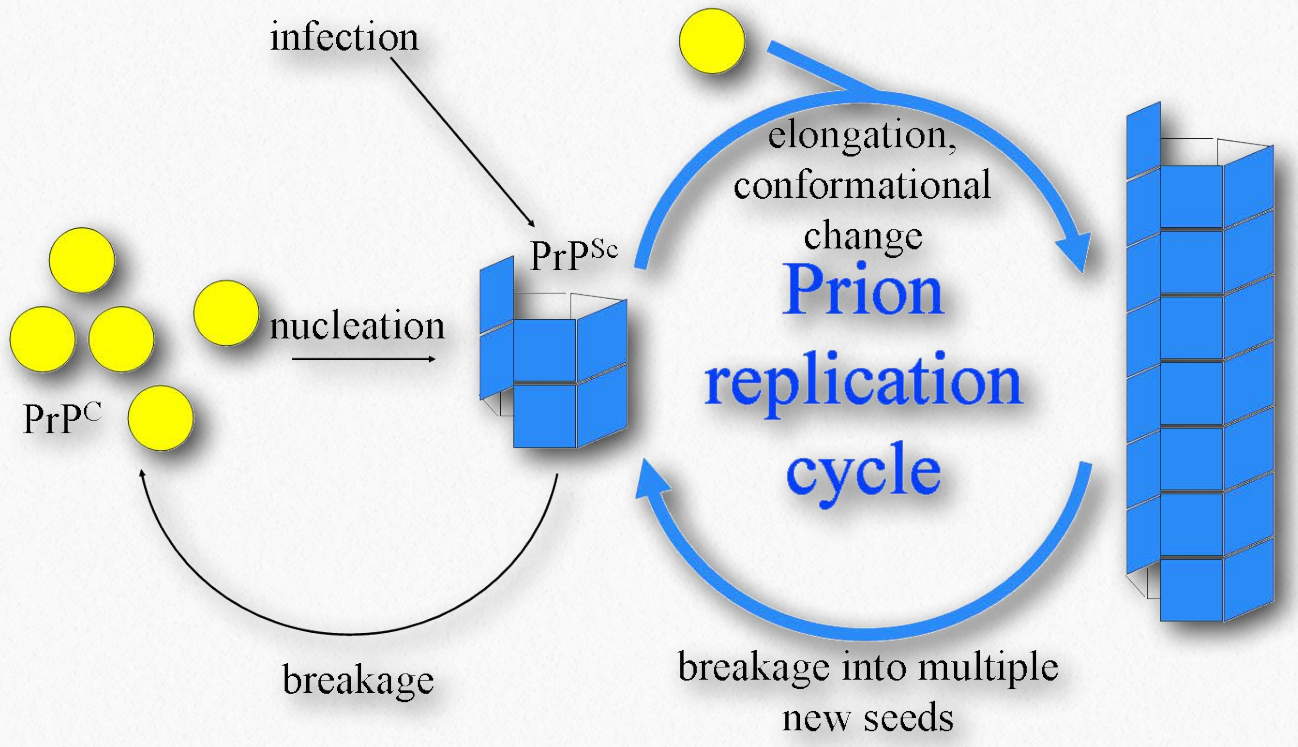

Figure 2.48 - One model of prion propagation

Wikipedia

Amyloids

Amyloids are a collection of improperly folded protein aggregates that are found in the human body. As a consequence of their misfolding, they are insoluble and contribute to some twenty human diseases including important neurological ones involving prions. Diseases include (affected protein in parentheses) - Alzheimer's disease (Amyloid β), Parkinson's disease (α-synuclein), Huntington's disease (huntingtin), rheumatoid arthritis (serum amyloid A), fatal familial insomnia (PrP^{Sc}), and others.

Amino acid sequence plays a role in amyloidogenesis. Glutamine-rich polypeptides are common in yeast and human prions. Trinucleotide repeats are important in Huntington's disease. Where sequence is not a factor, hydrophobic association between β-sheets can play a role.

Amyloid β

Amyloid β refers to collections of small proteins (36-43 amino acids) that appear to play a role in Alzheimer's disease. (Tau protein is the other factor.) They are, in fact, the main components of amyloid plaques found in the brains of patients suffering from the disease and arise from proteolytic cleavage of a larger amyloid precursor glycoprotein called Amyloid Precursor Protein, an integral membrane protein of nerve cells whose function is not known. Two proteases, β-secretase and γ-secretase perform this function. Amyloid β proteins are improperly folded and appear to induce other proteins to misfold and thus precipitate and form the amyloid characteristic of the disease. The plaques are toxic to nerve cells and give rise to the dementia characteristic of the disease.

It is thought that aggregation of amyloid β proteins during misfolding leads to generation of reactive oxygen species and that this is the means by which neurons are damaged. It is not known what the actual function of amyloid β is. Autosomal dominant mutations in the protein lead to early onset of the disease, but this occurs in no more than 10% of the cases. Strategies for treating the disease in-

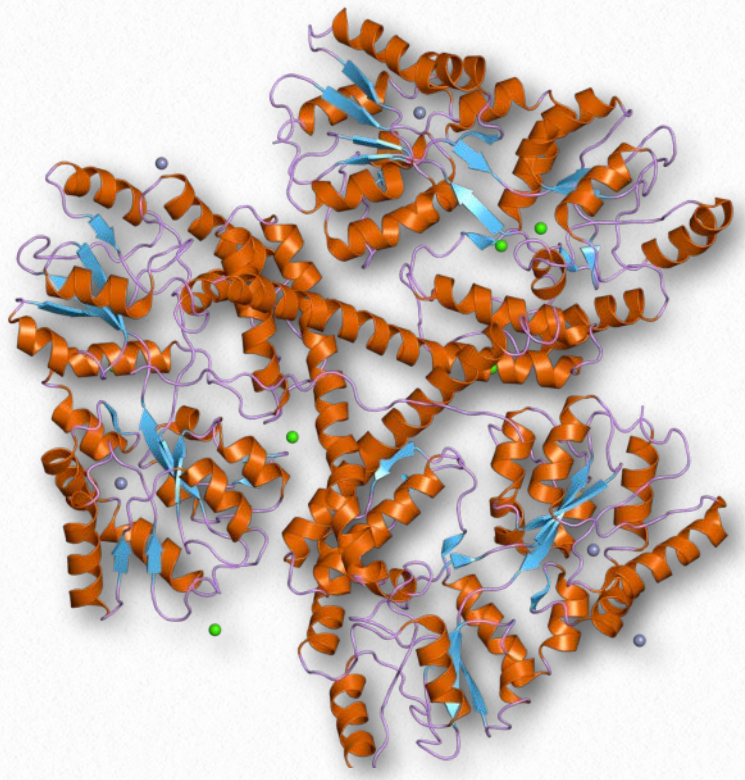

Figure 2.49 - Huntingtin

clude inhibition of the secretases that generate the peptide fragments from the amyloid precursor protein.

Huntingtin

Huntingtin is the central gene in Huntington's disease. The protein made from it is glutamine rich, with 6-35 such residues in its wild-type form. In Huntington's disease, this gene is mutated, increasing the number of glutamines in the mutant protein to between 36 and 250. The size of the protein varies with the number of glutamines in the mutant protein, but the wild-type protein has over 3100 amino acids and a molecular weight of about 350,000 Da. Its precise function is not known, but huntingtin is found in nerve cells, with the highest level in the brain. It is thought to possibly play roles in transport, signaling, and protection against apoptosis. Huntingtin is also required for early embryonic development. Within the cell, huntingtin is found localized primarily with microtubules and vesicles.

Trinucleotide repeat

The huntingtin gene contains many copies of the sequence CAG (called trinucleotide repeats), which code for the many glutamines in the protein. Huntington's disease arises when extra copies of the CAG sequence are generated when the DNA of the gene is being copied. Expansion of repeated sequences can occur due to slipping of the polymerase relative to the DNA template during replication. As a result, multiple additional copies of the trinucleotide repeat may be made, resulting in proteins with variable numbers of glutamine residues. Up to 35 repeats can be tolerated without problem. The number of repeats can expand over the course of a person's lifetime, however, by the same mechanism. Individuals with 36-40 repeats begin to show signs of the disease and if there are over 40, the disease will be present.

YouTube Lectures by Kevin HERE & HERE

Molecular chaperones

The importance of the proper folding of proteins is highlighted by the diseases associated with misfolded proteins, so it is no surprise, then, that cells expend energy to facilitate the proper folding of proteins. Cells use two classes of proteins known as molecular chaperones, to facilitate such folding in cells. Molecular chaperones are of two kinds, the chaperones, and the chaperonins. An example of the first category is the Hsp70 class of proteins. Hsp stands for "heat shock protein", based on the fact that these proteins were first observed in large amounts in cells that had been briefly subjected to high temperatures. Hsps function to assist cells in stresses arising from heat shock and exposure to oxidizing conditions or toxic heavy metals, such as cadmium and mercury. However, they also play an important role in

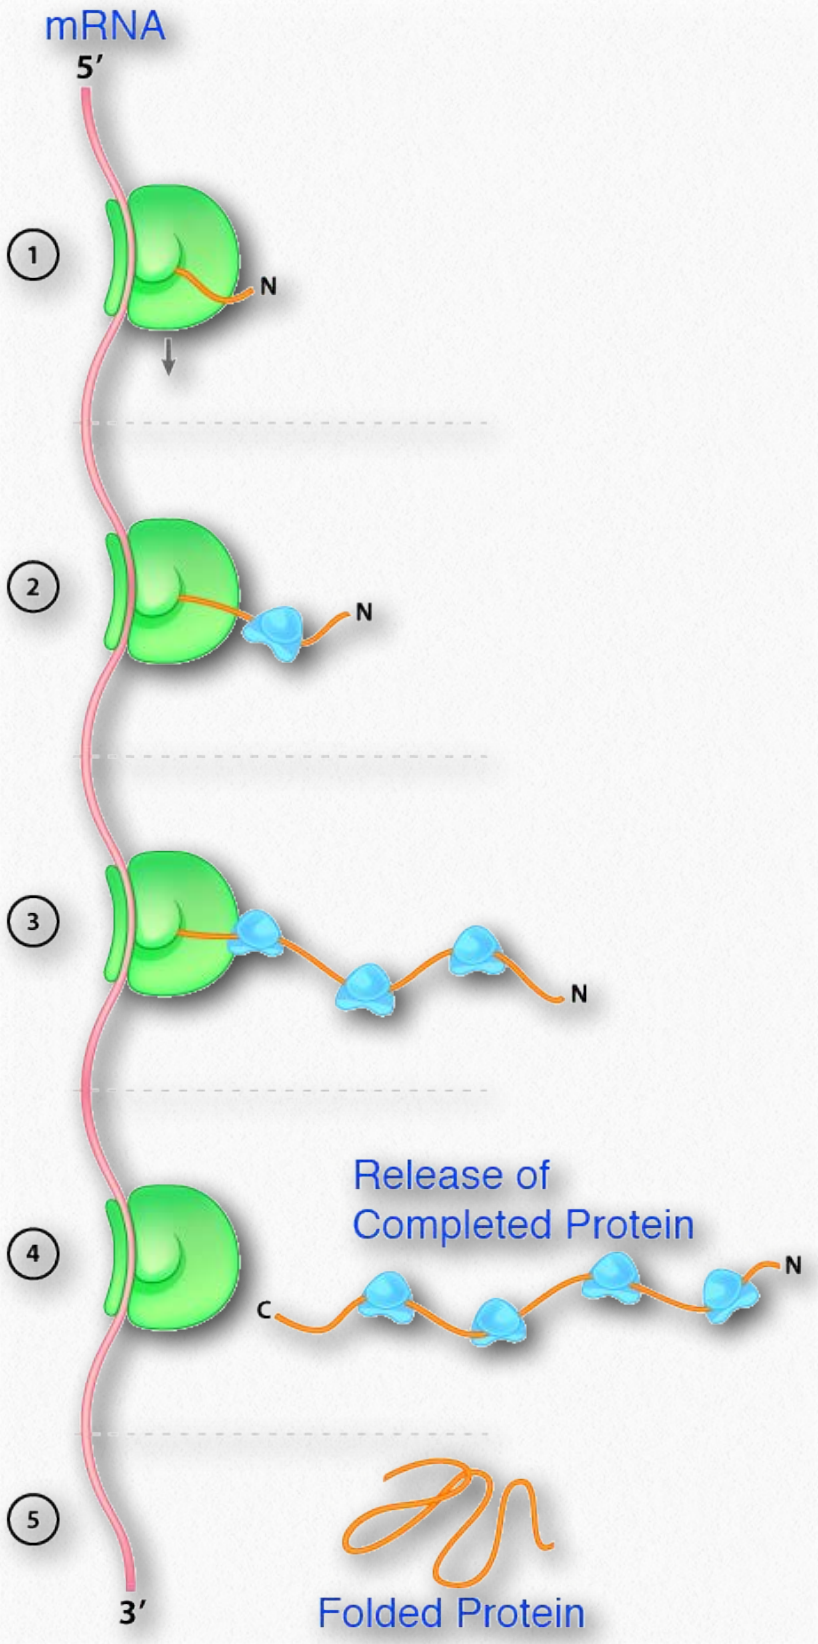

Figure 2.50 - Action of Hsp70 (blue) to facilitate proper folding of a protein (orange)

Image by Aleia Kim

normal conditions, where they assist in the proper folding of polypeptides by preventing aberrant interactions that could lead to misfolding or aggregation.

The Hsp70 proteins are found in almost all cells and use ATP hydrolysis to stimulate structural changes in the shape of the chaperone to accommodate binding of substrate proteins. The binding domain of Hsp70s contains a β-barrel structure which wraps around the polypeptide chain of the substrate and has affinity for hydrophobic side chains of amino acids. As shown in Figure 2.50, Hsp70 binds to polypeptides as they emerge from ribosomes during protein synthesis. Binding of substrate stimulates ATP hydrolysis and this is facilitated by another heat shock protein known as Hsp40. The hydrolysis of ATP causes the Hsp70 to taken on a closed conformation that helps shield exposed hydrophobic residues and prevent aggregation or local misfolding.

After protein synthesis is complete, ADP is released and replaced by ATP and this results in release of the substrate protein, which then allows the full length polypeptide to fold correctly.

In heat shock

In times of heat shock or oxidative stress, Hsp70 proteins bind to unfolded hydrophobic regions of proteins to similarly prevent them from aggregating and allowing them to properly refold. When proteins are damaged, Hsp70 recruits enzymes that ubiquitinate the damaged protein to target them for destruction in proteasomes. Thus, the Hsp70 proteins play an important role in ensuring

not only that proteins are properly folded, but that damaged or nonfunctional proteins are removed by degradation in the proteasome.

Chaperonins

A second class of proteins involved in assisting other proteins to fold properly are known as chaperonins. There are two primary categories of chaperonins - Class I (found in bacteria, chloroplasts, and mitochondria) and Class II (found in the cytosol of eukaryotes and archaebacteria). The best studied chaperonins are the GroEL/GroES complex proteins found in bacteria (Figure 2.51).

GroEL/GroES may not be able to undo aggregated proteins, but by facilitating proper folding, it provides competition for misfolding as a process and can reduce or eliminate problems arising from improper folding. GroEL is a double-ring 14mer with a hydrophobic region that can facilitate folding of substrates 15-60 kDa in size. GroES is a single-ring heptamer that binds to GroEL in the presence of ATP and functions as a cover over GroEL. Hydrolysis of ATP by chaperonins induce large conformational changes that affect binding of substrate proteins and their folding. It is not known exactly how chaperonins fold proteins. Passive models postulate the chaperonin complex functioning inertly by preventing unfavorable intermolecular interactions or placing restrictions on spaces available for folding to occur. Active models propose that structural changes in the chaperonin complex induce structural changes in the substrate protein.

Protein breakdown

Another protein complex that has an important function in the lifetime dynamics of proteins is the proteasome (Figure 2.52). Proteasomes, which are found in all eukaryotes and archaeans, as well as some bacteria, function to break down unneeded or damaged proteins by proteolytic degradation. Proteasomes help to regulate the concentration of some proteins and degrade ones that are misfolded.

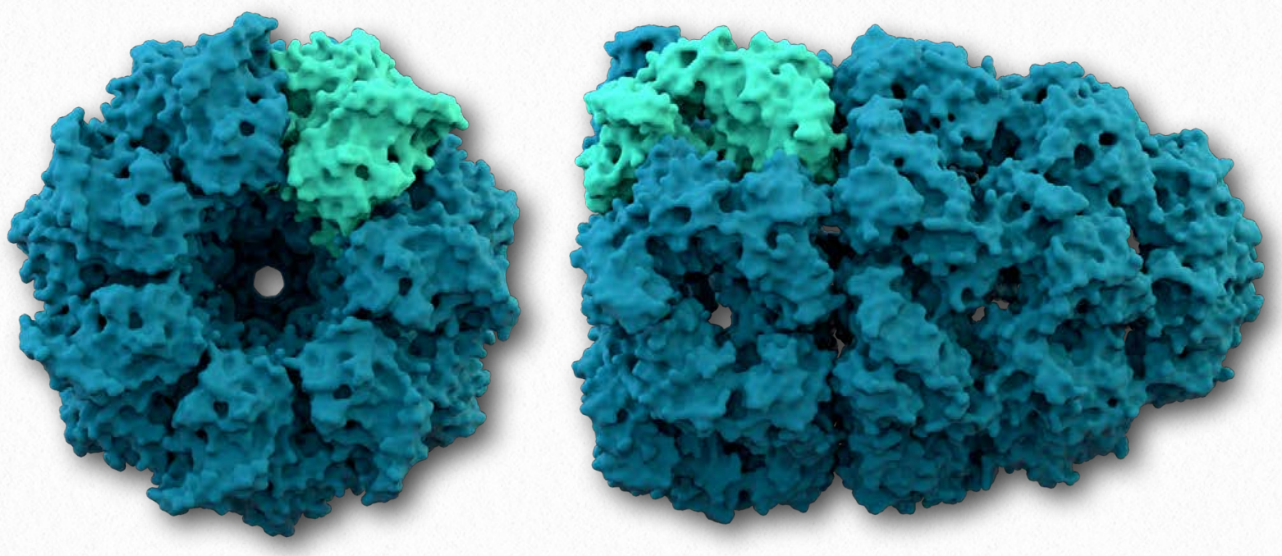

Figure 2.51 - View from bottom of GroEL (left) and GroEL/GroES complex (right)

Wikipedia

The proteasomal degradation pathway plays

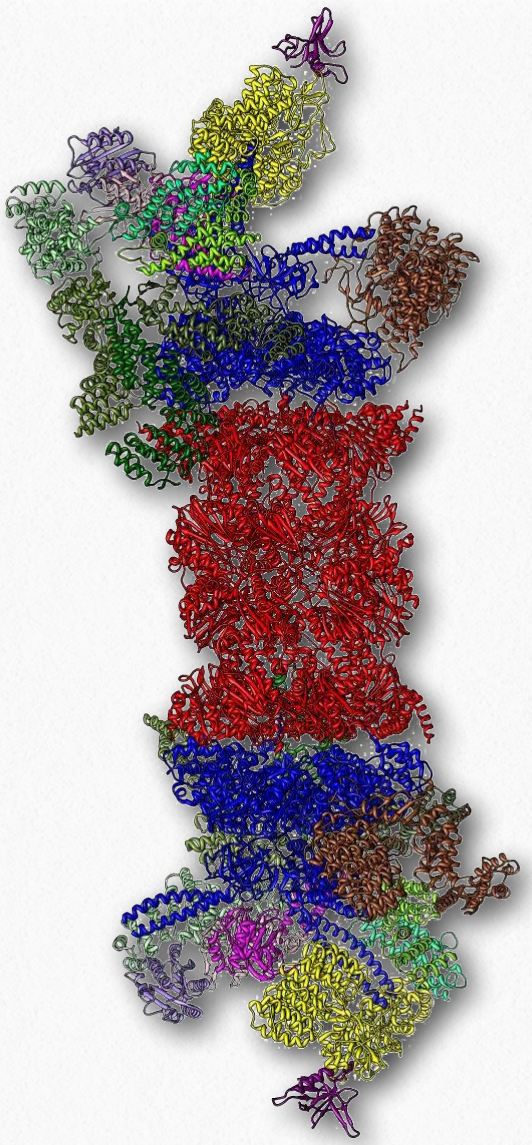

Figure 2.52 - 26S proteasome. Active site shown in red

Wikipedia

an important role in cellular processes that include progression through the cell cycle, modulation of gene expression, and response to oxidative stresses.

Degradation in the proteasome yields short peptides seven to eight amino acids in length. Threonine proteases play important roles. Breakdown of these peptides yields individual amino acids, thus facilitating their recycling in cells. Proteins are targeted for degradation in eukaryotic proteasomes by attachment to multiple copies of a small protein called ubiquitin (8.5 kDa - 76 amino acids). The enzyme catalyzing the reaction is known as ubiquitin ligase. The resulting polyubiquitin chain is bound by the proteasome and degradation begins. Ubiquitin was named due to it ubiquitously being found in eukaryotic cells.

Ubiquitin

Ubiquitin (Figure 2.53) is a small (8.5 kDa) multi-functional protein found in eukaryotic cells. It is commonly added to target proteins by action of ubiquitin ligase enzymes (E3 in Figure 2.54). One (ubiquitination)

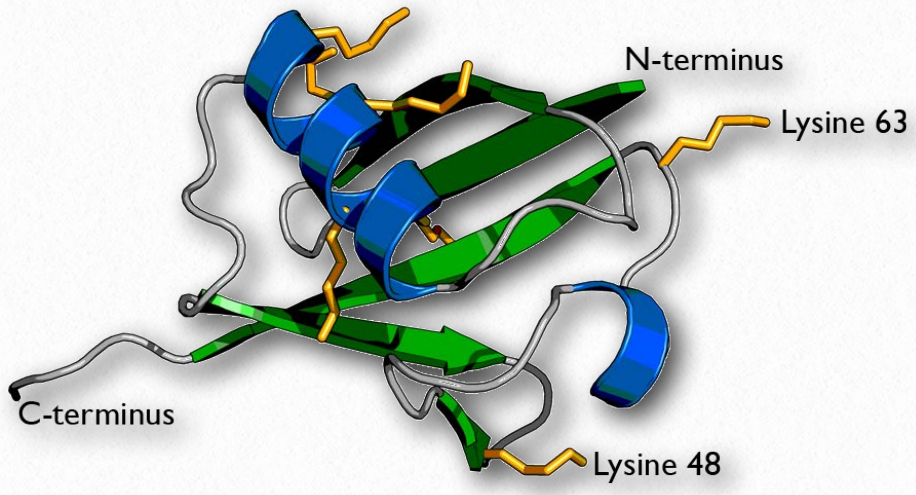

Figure 2.53 - Ubiquitin (lysine side chains shown in yellow)

Wikipedia

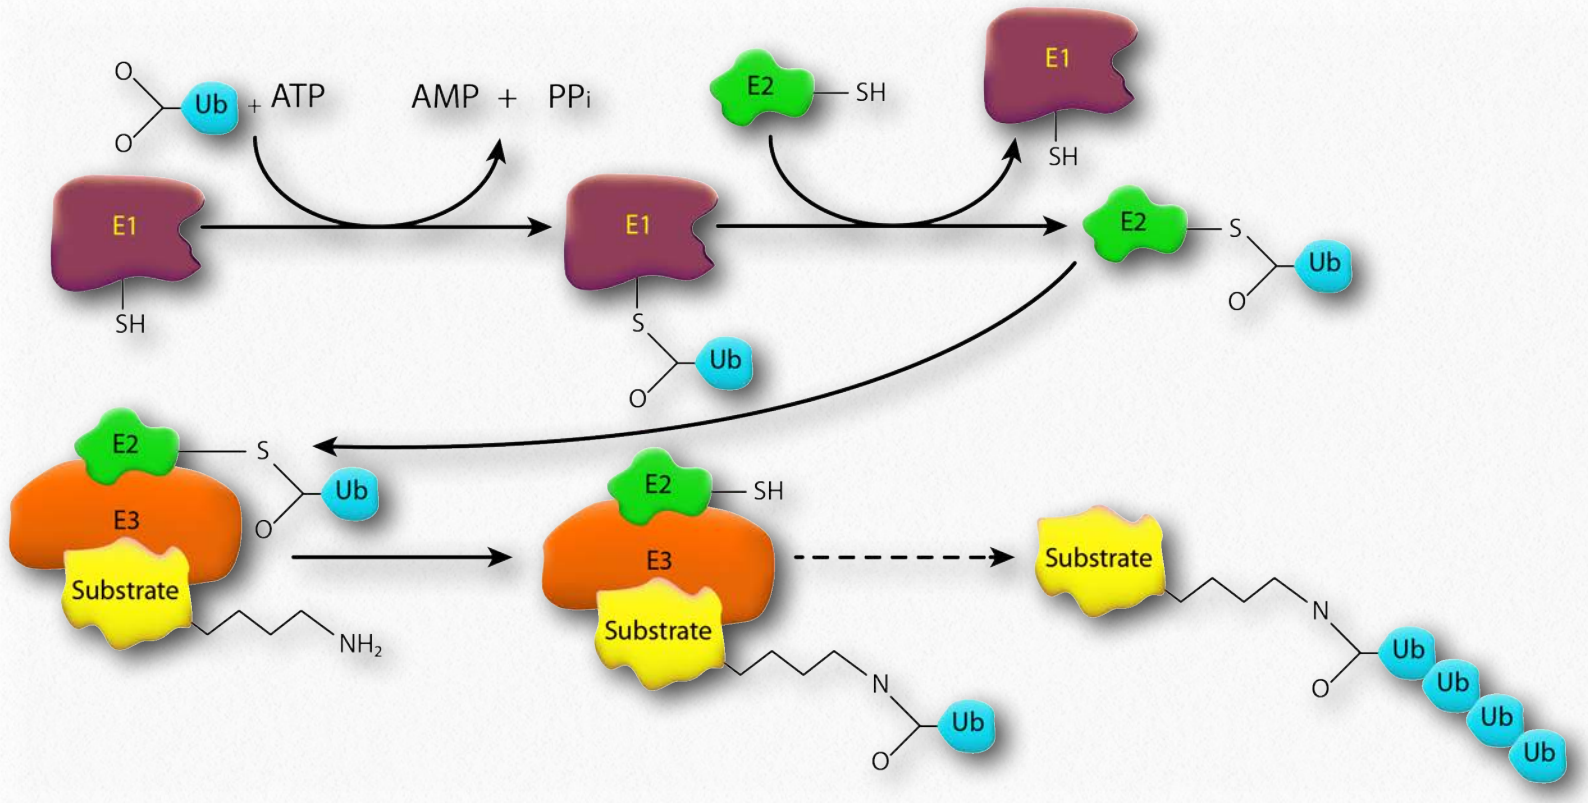

Figure 2.54 - Pathway for ubiquitination of a target substrate protein

Image by Pehr Jacobson

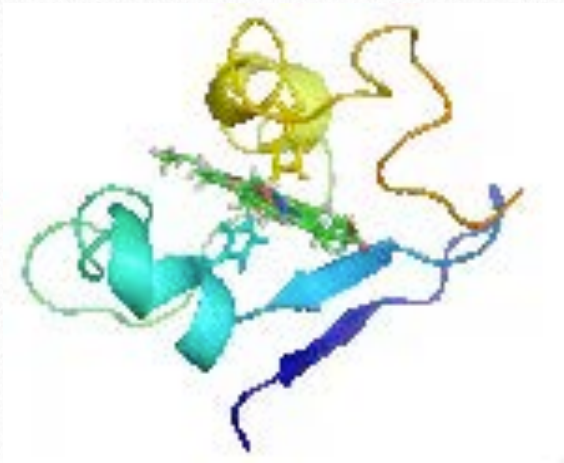
or many (polyubiquitination) ubiquitin molecules may be added. Attachment of the ubiquitin is through the side chain of one of seven different lysine residues in ubiquitin. The addition of ubiquitin to proteins has many effects, the best known of which is targeting the protein for degradation in the proteasome. Proteasomal targeting is seen when polyubiquitination occurs at lysines #29 and 48. Polyubiquitination or monoubiquitination at other lysines can result in altered cellular location and changed protein-protein interactions. The latter may alter affect inflammation, endocytic trafficking, translation and DNA repair.

Ubiquitin ligase malfunction

Parkin is a Parkinson's disease-related protein that, when mutated, is linked to an inherited form of the disease called autosomal recessive juvenile Parkinson's disease. The function of the protein is not known, but it is a component of the E3 ubiquitin ligase system responsible for transferring ubiquitin from the E2 protein to a lysine side chain on the target protein. It is thought that mutations in parkin lead to proteasomal dysfunction and a consequent inability to break down proteins harmful to dopaminergic neurons. This results in the death or malfunction of these neurons, resulting in Parkinson's disease.

Intrinsically disordered proteins

As is evident from the many examples described elsewhere in the book, the 3-D structure of proteins is important for their function. But, increasingly, it is becoming evident that not all proteins fold into a stable structure. Studies on the so-called intrinsically disordered proteins (IDPs) in the past cou-



Movie 2.1 - Dynamic movement of cytochrome C in solution

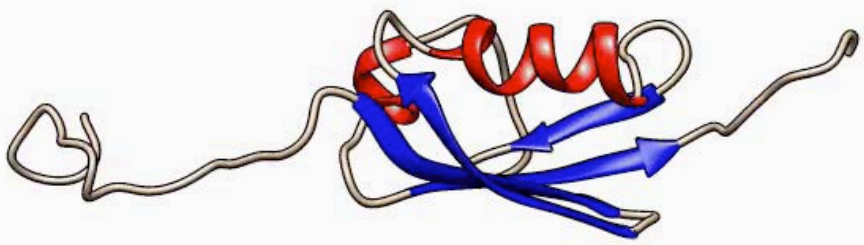
Wikipedia

ple of decades has shown that many proteins are biologically active, even though they fail to fold into stable structures. Yet other proteins exhibit regions that remain unfolded (IDP regions) even as the rest of the polypeptide folds into a structured form.

YouTube Lectures by Kevin HERE & HERE

Intrinsically disordered proteins and disordered regions within proteins have, in fact, been known for many years, but were regarded as an anomaly. It is only recently, with the realization that IDPs and IDP regions are widespread among eukaryotic proteins, that it has been recognized that the observed disorder is a "feature, not a bug".

Comparison of IDPs shows that they share sequence characteristics that appear to favor their disordered state. That is, just as some amino acid sequences may favor the folding of a polypeptide into a particular structure, the amino acid sequences of IDPs favor their remaining unfolded. IDP regions are seen to be low in hydrophobic residues and unusually rich in polar residues and proline. The presence of a large number of charged amino acids in the IDPs can inhibit folding through charge repulsion, while the lack of hydrophobic residues makes it difficult to form a stable hydrophobic core, and proline discourages the formation of helical structures. The observed differences between amino acid sequences in IDPs and structured proteins have been used to design algorithms to



Movie 2.2 SUMO-1, a protein with intrinsically disordered sections

Wikipedia

predict whether a given amino acid sequence will be disordered.

What is the significance of intrinsically disordered proteins or regions? The fact that this property is encoded in their amino acid sequences suggests that their disorder may be linked to their function. The flexible, mobile nature of some IDP regions may play a crucial role in their function, permitting a transition to a folded structure upon binding a protein partner or undergoing post-translational modification. Studies on several well-known proteins with IDP regions suggest some answers. IDP regions may enhance the ability of proteins like the lac repressor to translocate along the DNA to search for specific binding sites. The flexibility of IDPs can also be an asset in protein-protein interactions, especially for proteins that are known to interact with many different protein partners. For example, p53 has IDP regions that may allow the protein to interact with a variety of functional partners. Comparison of the known functions of proteins with predictions of disorder in these

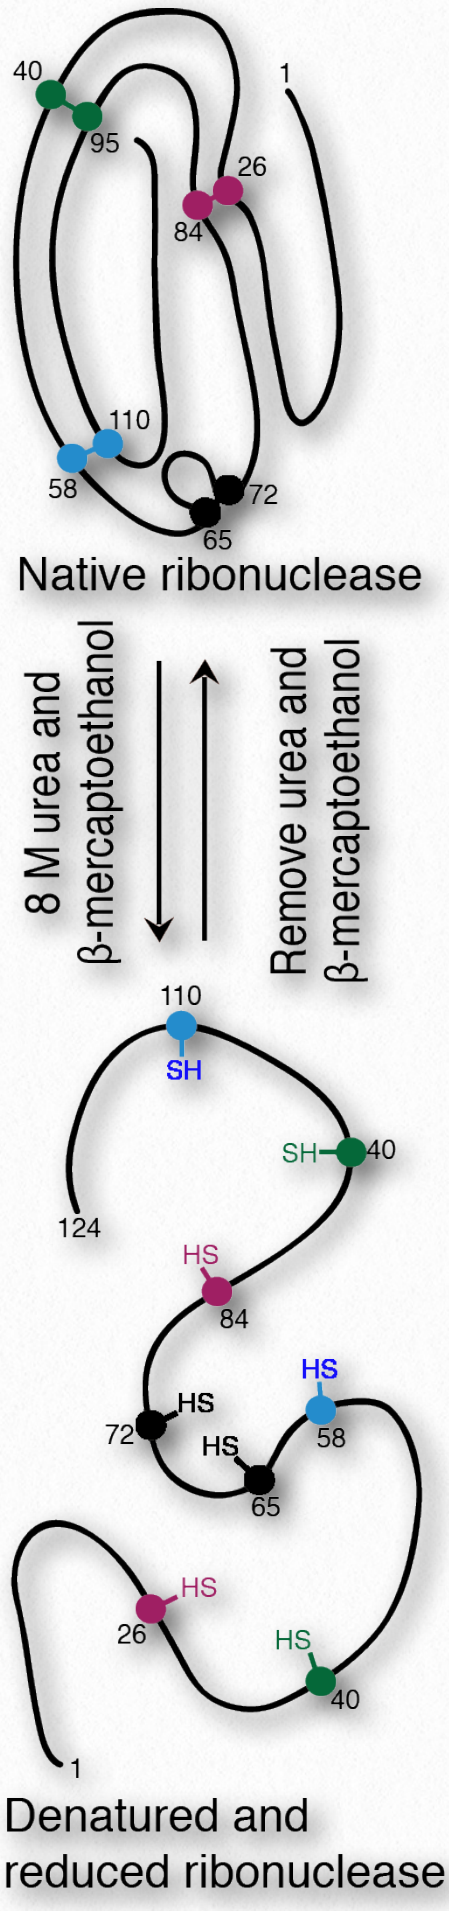


Figure 2.55 - Denaturation and renaturation of ribonuclease

Wikipedia

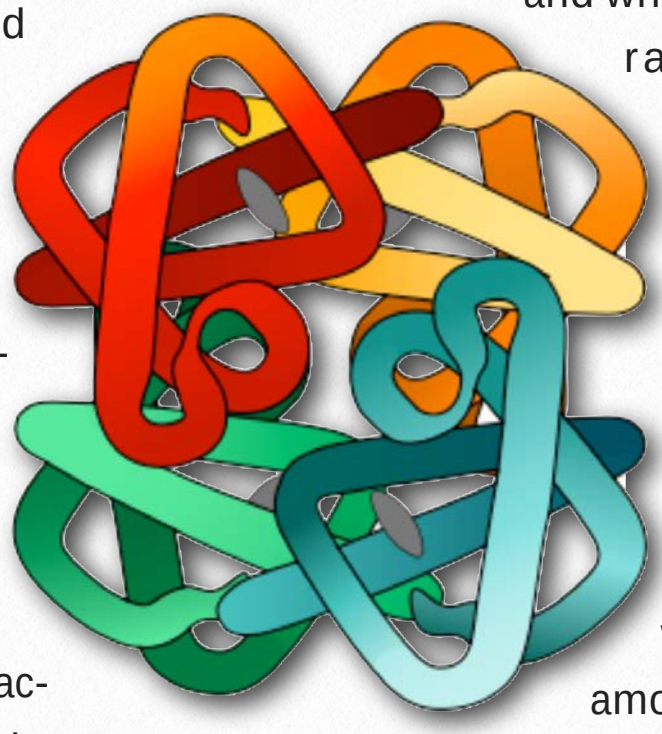
proteins suggests that IDPs and IDP regions may disproportionately function in signaling and regulation, while more structured proteins skew towards roles in catalysis and transport. Interestingly, many of the proteins found in both ribosomes and spliceosomes are predicted to have IDP regions that may play a part in correct assembly of these complexes. Even though IDPs have not been studied intensively for very long, what little is known of them suggests that they play an important and underestimated role in cells.

Metamorphic proteins.

Another group of proteins that have recently changed our thinking about protein structure and function are the so-called metamorphic proteins. These proteins are capable of forming more than one stable, folded state starting with a single amino acid sequence. Although it is true that multiple folded conformations are not ruled out

There are not very many ways
Inactivating RNase
It's stable when it's hot or cold
Because disulfides tightly hold
If you desire to make it stall
Use hot mercaptoethanol

by the laws of physics and chemistry, metamorphic proteins are a relatively new discovery. It was known, of course, that prion proteins were capable of folding into alternative structures, but metamorphic proteins appear to be able to toggle back and forth between two stable structures. While in some cases, the metamorphic protein undergoes this switch in response to binding another molecule, some proteins that can accomplish this transition on their own. An interesting example is the signaling molecule, lymphotactin. Lymphotactin has two biological functions that are carried out by its two conformers- a monomeric form that binds the lymphotactin receptor and a dimeric form that binds heparin. It is possible that this sort of switching is more widespread than has been thought.



Refolding denatured proteins

All information for protein folding is contained in the amino acid sequence of the protein. It may seem curious then that most proteins do not fold into their proper, fully active form after they have been denatured and the denaturant is removed. A few do, in fact. One good example is bovine ribonuclease (Figure 2.55). Its catalytic activity is very resistant to heat and urea and attempts to denature it don't work very well. However, if one treats the enzyme with β-mercaptoethanol (which breaks disulfide bonds) prior to urea treatment and/or heating, activity is lost, indicating that the covalent disulfide bonds help stabilize the overall enzyme structure and when they are broken, denaturation can readily occur. When the mixture cools back down to room temperature, over time some enzyme activity reappears, indicating that ribonuclease re-folded under the new conditions.

Interestingly, renaturation will occur maximally if a tiny amount of β-mercaptoethanol is left in the solution during the process. The reason for this is because β-mercaptoethanol permits reduction (and breaking) of accidental, incorrect disulfide bonds during the folding process. Without it, these disulfide bonds will prevent proper folds from forming.

Irreversible denaturation

Most enzymes, however, do not behave like bovine ribonuclease. Once denatured, their activity cannot be recovered to any significant

extent. This may seem to contradict the idea of folding information being inherent to the sequence of amino acids in the protein. It does not.

Most enzymes don't refold properly after denaturation for two reasons. First, normal folding may occur as proteins are being made. Interactions among amino acids early in the synthesis are not "confused" by interactions with amino acids later in the synthesis because those amino acids aren't present as the process starts.

Chaperonins' role

In other cases, the folding process of some proteins in the cell relied upon action of chaperonin proteins (see HERE). In the absence of chaperonins, interactions that might result in misfolding occur, thus preventing proper folding. Thus, early folding and the assistance of chaperonins eliminate some potential "wrong-folding" interactions that can occur if the entire sequence was present when folding started.

Quaternary structure

A fourth level of protein structure is that of quaternary structure. It refers to structures that arise as a result of interactions between multiple polypeptides. The units can be identical multiple copies or can be different polypeptide chains. Adult hemoglobin is a good example of a protein with quaternary structure, being composed of two identical chains called α and two identical chains called β.

Though the α-chains are very similar to the β-chains, they are not identical. Both of the α- and the β-chains are also related to the single polypeptide chain in the related protein called myoglobin. Both myoglobin and hemoglobin have similarity in binding oxygen, but their behavior towards the molecule differ significantly. Notably, hemoglobin's multiple subunits (with quaternary structure) compared to myoglobin's single subunit (with no quaternary structure) give rise to these differences. (See HERE).

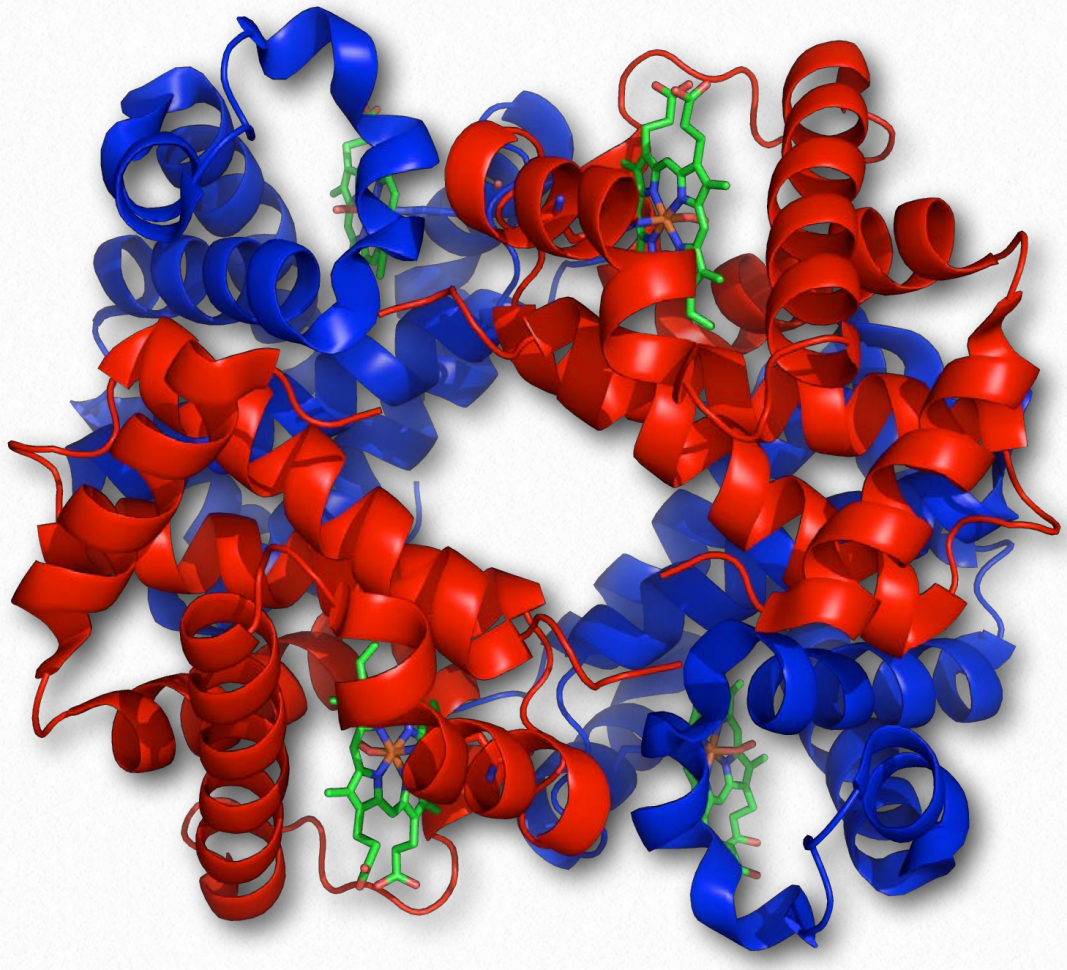
Structure and Function: Proteins II



Hemoglobin

Wikipedia

Structure and function

In this section, we hope to bring to life the connection between structure and function of proteins. So far, we have described notable features of the four elements (primary, secondary, tertiary, and quaternary) of protein structure and discussed example proteins/motifs exhibiting them. In this section, we will examine from a functional perspective a few proteins/domains whose function relies on secondary, tertiary, or quaternary structure.

YouTube Lectures by Kevin
HERE & HERE

It is, of course a bit of a narrow focus to ascribe protein function to any one component of structure, but our hope is by presenting these examples, we can bring to life the way in which a protein's secondary, tertiary, and quarternary structure lead to the functions it has.

Fibrous proteins - secondary structure

Proteins whose cellular or extracellular roles have a strong structural component are com-

posed primarily of primary and second structure, with little folding of the chains. Thus, they have very little tertiary structure and are fibrous in nature. Proteins exhibiting these traits are commonly insoluble in water and are referred to as fibrous proteins (also called scleroproteins). The examples described in this category are found exclusively in animals where they serve roles in flesh, connective tissues and hardened external structures, such as hair. They also contain the three common fibrous protein structures **α**-helices (keratins), **β**-strands/sheets (fibroin & elastin) and triple helices (collagen). The fibrous proteins have some commonality of amino acid sequence. Each possesses an abundance of repeating sequences of amino acids with small, non-reactive side groups. Many contain short repeats of sequences, often with glycine.

Keratins

The keratins are a family of related animal proteins that take numerous forms. α-keratins are structural components of the outer layer of human skin and are integral to hair, nails, claws, feathers, beaks, scales, and hooves. Keratins provide strength to tissues, such as

We wouldn't be too popular
If keratins were globular
Our nails and hair would be as knots
Their structures folded up like clots
No strength they'd have and oh by gosh
They'd rearrange with every wash

Figure 2.56 - The horns of an impala are composed of keratin

Wikipedia

the tongue, and over 50 different keratins are encoded in the human genome. At a cellular level, keratins comprise the intermediate filaments of the cytoskeleton. α-keratins primarily contain **α**-helices, but can also have **β**-strand/sheet structures. Individual α-helices are often intertwined to form coils of coiled structures and these strands can also be further joined together by disul-

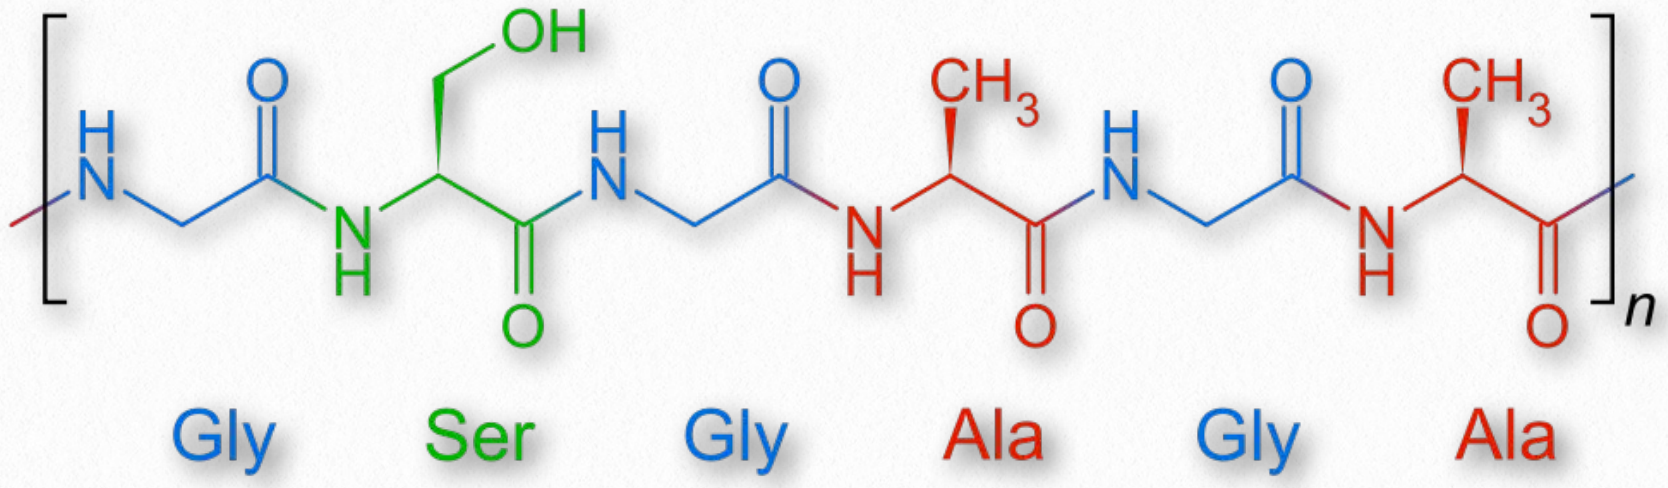


Figure 2.57 - The repeating amino acid sequence of fibroin

fide bonds, increasing structural strength considerably. This is particularly relevant for α-keratin in hair, which contains about 14% cysteine. The odor of burned hair and that of the chemicals used to curl/uncurl hair (breaking/re-making disulfide bonds) arise from their sulfurous components. β-keratins are comprised of β-sheets, as their name implies. Wikipedia link HERE.

Fibroin

An insoluble fibrous protein that is a component of the silk of spiders and the larvae of moths and other insects, fibroin is comprised of anti-parallel **β**-strands tightly packed together to form β-sheets. The primary structure of fibroin is a short repeating sequence with glycine at every other residue (Figure 2.57). The small R-groups of the glycine and alanine in the repeating sequence allows for the tight packing characteristic of the fibers of silk. Wikipedia link HERE

Wikipedia

Elastin

As suggested by its name, elastin is a protein with elastic characteristics that functions in many tissues of the body to allow them to resume their shapes after expanding or contracting. The protein is rich in glycine and proline and can comprise over 50% of the weight of dry, defatted arteries. Elastin is made by linking tropoelastin proteins together through lysine residues to make a durable complex cross-linked by desmos-

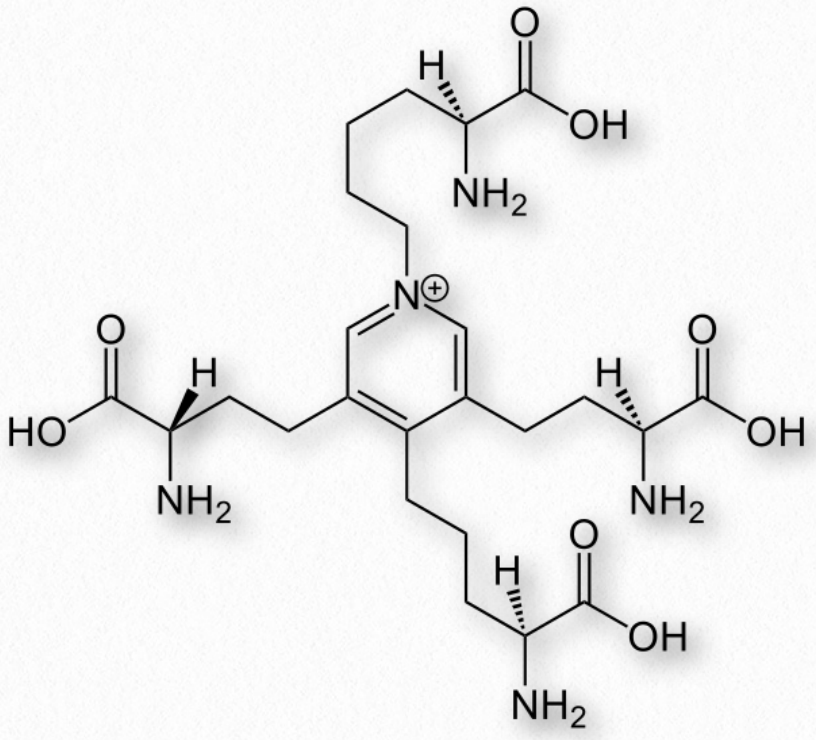

Figure 2.59 - Desmosine

Wikipedia

ine. In arteries, elastin helps with pressure wave propagation for facilitating blood flow. Wikipedia link HERE.

Collagen

Collagen is the most abundant protein in mammals, occupying up to a third of the total mass. There are at least 16 types of collagen. Its fibers are a major component of tendons and they are also found abundantly in skin. Collagen is also prominent in cornea, cartilage, bone, blood vessels and the gut.

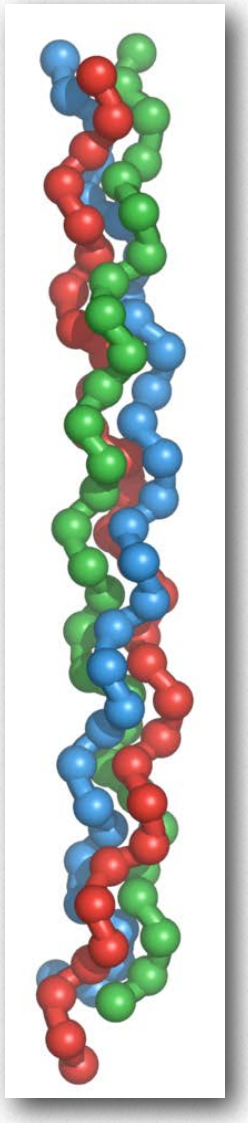

Figure 2.60 - Collagen's triple helix

Wikipedia

Collagen's structure is an example of a helix of helices, being composed of three left-handed helical chains that each are coiled together in a right-handed fashion to make the collagen fiber (Figure 2.60). Each helix

Gly-Pro-Met-Gly-Pro-Ser-Gly-Pro-Arg

Gly-Pro-Met-Gly-Pro-Arg-Gly-Pro-Hpr

Gly-Pro-Hpr-Gly-Lys-Asn-Gly-Asp-Asp

Hpr = Hydroxyproline

Figure 2.61 - Repeating sequences in collagen

is stretched out more than an α-helix, giving it an extended appearance. On the inside of the triple helical structure, only residues of glycine are found, since the side chains of other amino acids are too bulky. Collagen chains have the repeating structure glycine-m-n where m is often proline and n is often hydroxyproline (Figure 2.61).

Collagen is synthesized in a pre-procollagen form. Processing of the pre-procollagen in the endoplasmic reticulum results in glycosylation, removal of the 'pre'

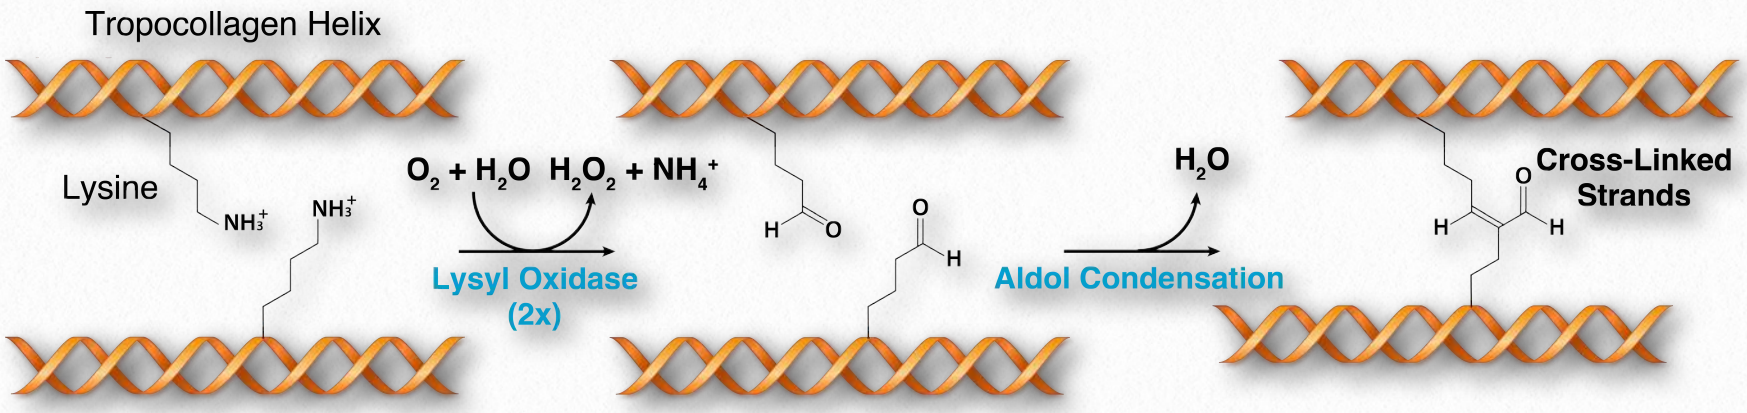

Figure 2.62 - Oxidation and cross-linking of lysine residues in tropocollagen. Only two strands of the triple helix are shown for simplicity

Image by Aleia Kim

sequence, and hydroxylation of lysine and proline residues (see below). The hydroxides can form covalent cross-links with each other, strengthening the collagen fibers. As pro-collagen is exported out of the cell, proteases trim it, resulting in a final form of collagen called tropocollagen.

Hydroxylation reactions

Hydroxylation of proline and lysine side chains occurs post-translationally in a reaction catalyzed by prolyl-4-hydroxylase and lysyl-hydroxylase (lysyl oxidase), respectively. The reaction requires vitamin C.

Since hydroxylation of these residues is essential for formation of stable triple helices at body temperature, vitamin C deficiency results in weak, unstable collagen and, consequently, weakened connective tissues. It is the cause of the disease known as scurvy. Hydrolyzed collagen is used to make gelatin, which is important in the food industry. collagens. Wikipedia link HERE

YouTube Lectures by Kevin HERE & HERE

Lamins

Lamins are fibrous proteins that provide structure in the cell nucleus and play a role in transcription regulation. They are similar to proteins making up the intermediate filaments, but have extra amino acids in one coil of the protein. Lamins help to form the nuclear lamin in the interior of the nuclear envelope and play important roles in assembling and disassembling the latter in the process of mitosis. They also help to position nuclear pores. In the process of mitosis, disassembly of the nuclear envelope is promoted by phosphorylation of lamins by a protein called mitosis promoting factor and assembly is favored by reversing the reaction (dephosphorylation).

Structural domains - tertiary structure

Every globular protein relies on its tertiary structure to perform its function, so rather than trying to find representative pro-

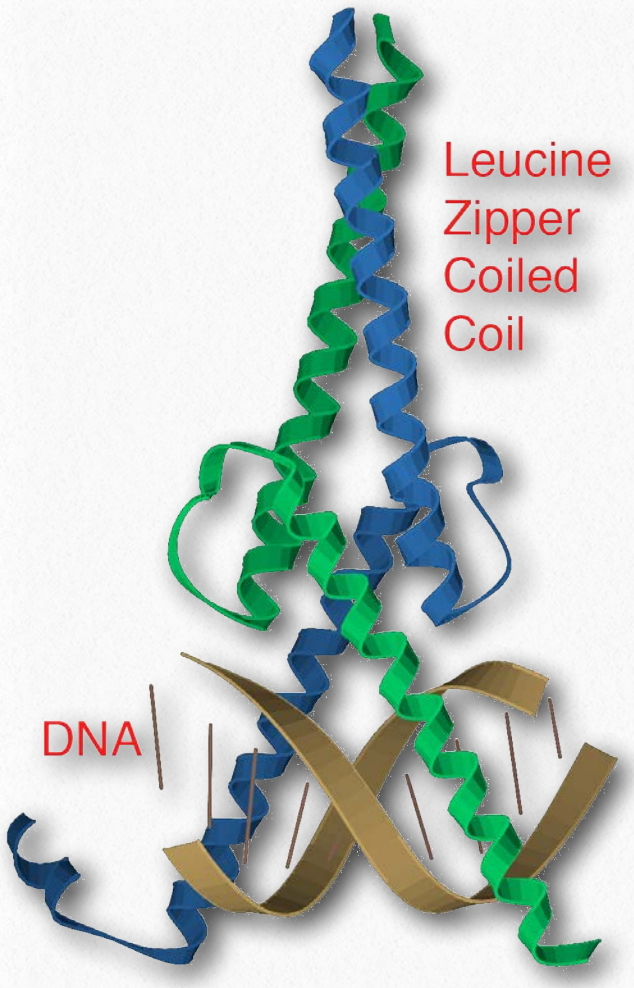

Figure 2.63 - Leucine zipper bound to DNA

Wikipedia

teins for tertiary structure (an almost impossible task!), we focus here on a few elements of tertiary structure that are common to many proteins. These are the structural domains and they differ from the structural motifs of supersecondary structure by being larger (25-500 amino acids), having a conserved amino acid sequence, and a history of evolving and functioning independently of the protein chains they are found in. Structural domains are fundamental units of tertiary structure and are found in more than one protein. A structural domain is self-stabilizing and often folds independently of the rest of the protein chain.

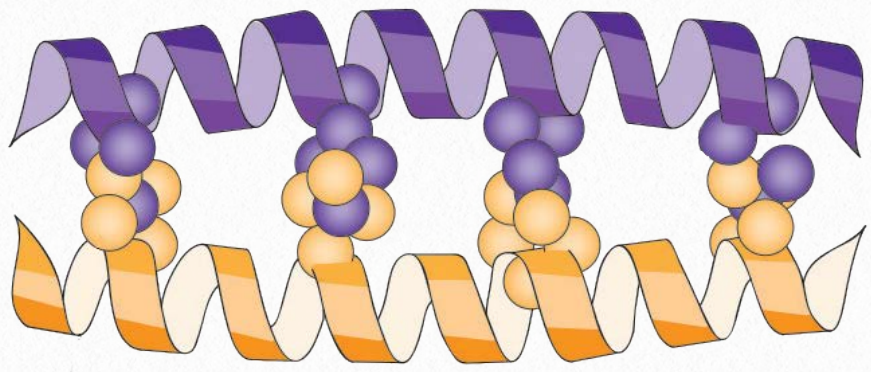

Figure 2.64 - Leucine zipper structure. Leucines are indicated by orange and purple balls.

Image by Penelope Irving

Leucine zipper

A common feature of many eukaryotic DNA binding proteins, leucine zippers are characterized by a repeating set of leucine residues in a protein that interact like a zipper to favor dimerization. Another part of the domain has amino acids (commonly arginine and lysine) that allow it to interact with the DNA double helix (Figure 2.63). Transcription factors that contain leucine zippers include Jun-B, CREB, and AP-1 fos/jun.

Zinc fingers

The shortest structural domains are the zinc fingers, which get their name from the fact that one or more coordinated zinc ions stabilize their finger-like structure. Despite their name, some zinc fingers do not bind zinc. There are many structural domains classified as zinc fingers and these are grouped into different families. Zinc fingers were first identified as components of DNA binding tran-

scription factors, but others are now known to bind RNA, protein, and even lipid structures. Cysteine and histidine side chains commonly play roles in coordinating the zinc.

Src SH_2 domain

The Src oncoprotein contains a conserved SH_2 structural domain that recognizes and binds phosphorylated tyrosine side chains in other proteins (Figure 2.65). Phosphorylation is a fundamental activity in signaling and phosphorylation of tyrosine and interaction between proteins carrying signals is critically needed for cellular communication. The SH_2 domain is found in over 100 human proteins.

Helix-turn-helix domain

Helix-turn-helix is a common domain found in DNA binding proteins, consisting

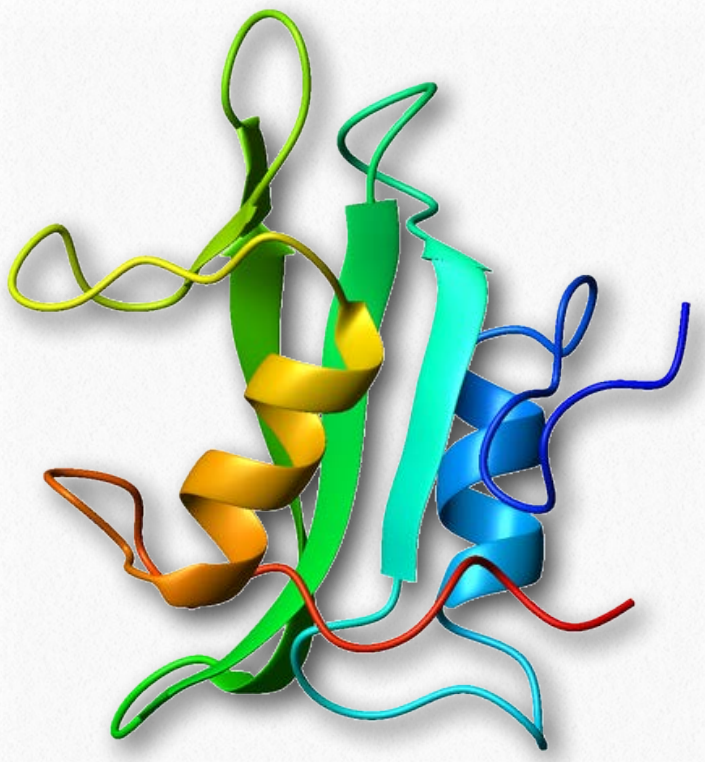

Figure 2.65 - SH_2 Domain

Wikipedia

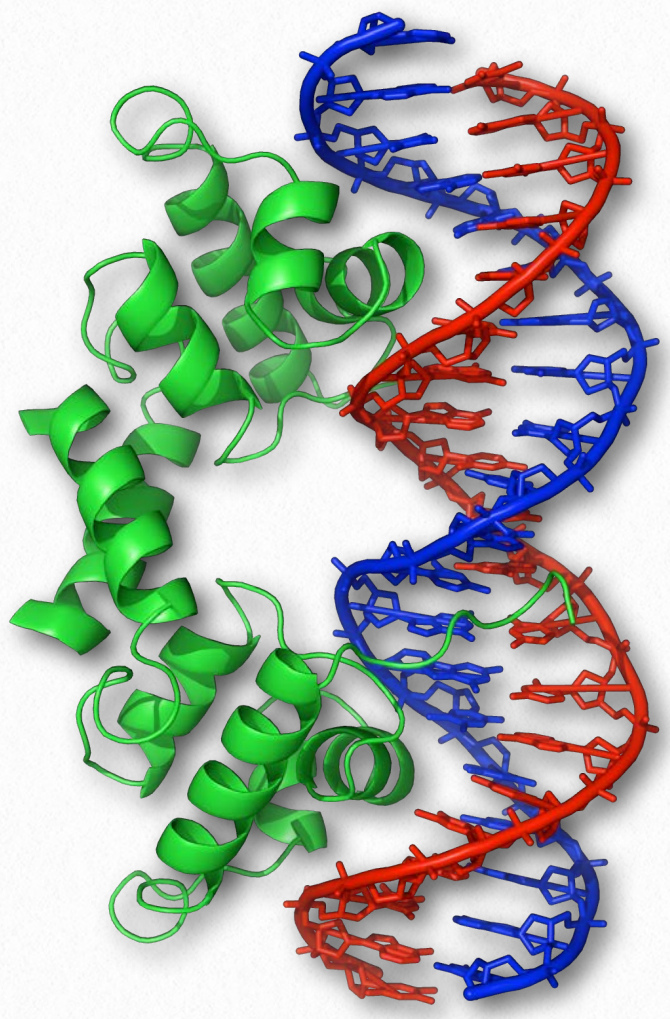

Figure 2.66 - Helix-Turn-Helix Domain of a Protein Bound to DNA

Wikipedia

of two α-helices separated by a small number of amino acids. As seen in Figure 2.66, the helix parts of the structural domain interact with the bases in the major groove of DNA. Individual α-helices in a protein are part of a helix-turn-helix structure, where the turn separates the individual helices.

Pleckstrin homology domain

Pleckstrin Homology (PH) domains are protein domains with important functions in the process of signaling. This arises partly from the affinity for binding phosphorylated inositides, such as PIP2 and PIP3, found in

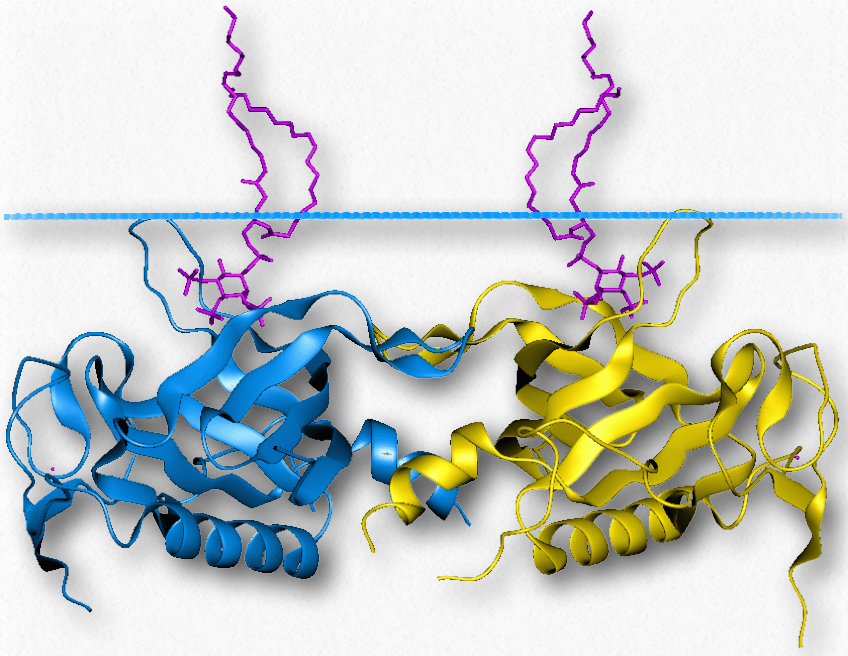

Figure 2.67 - Pleckstrin homology domain of Btk tyrosine protein kinase. The protein is embedded in a membrane (above blue line)

Wikipedia

biological membranes. PH domains can also bind to G-proteins and protein kinase C. The domain spans about 120 amino acids and is found in numerous signaling proteins. These include Akt/Rac Serine/Threonine Protein Kinases, Btk/Itk/Tec tyrosine protein kinases, insulin receptor substrate (IRS-1), Phosphatidylinositol-specific phospholipase C, and several yeast proteins involved in cell cycle regulation.

Structural globular proteins

Enzymes catalyze reactions and proteins such as hemoglobin perform important specialized functions. Evolutionary selection has reduced and eliminated waste so that we can be sure every protein in a cell has a function, even though in some cases we may not know what it is. Sometimes the structure of the pro-

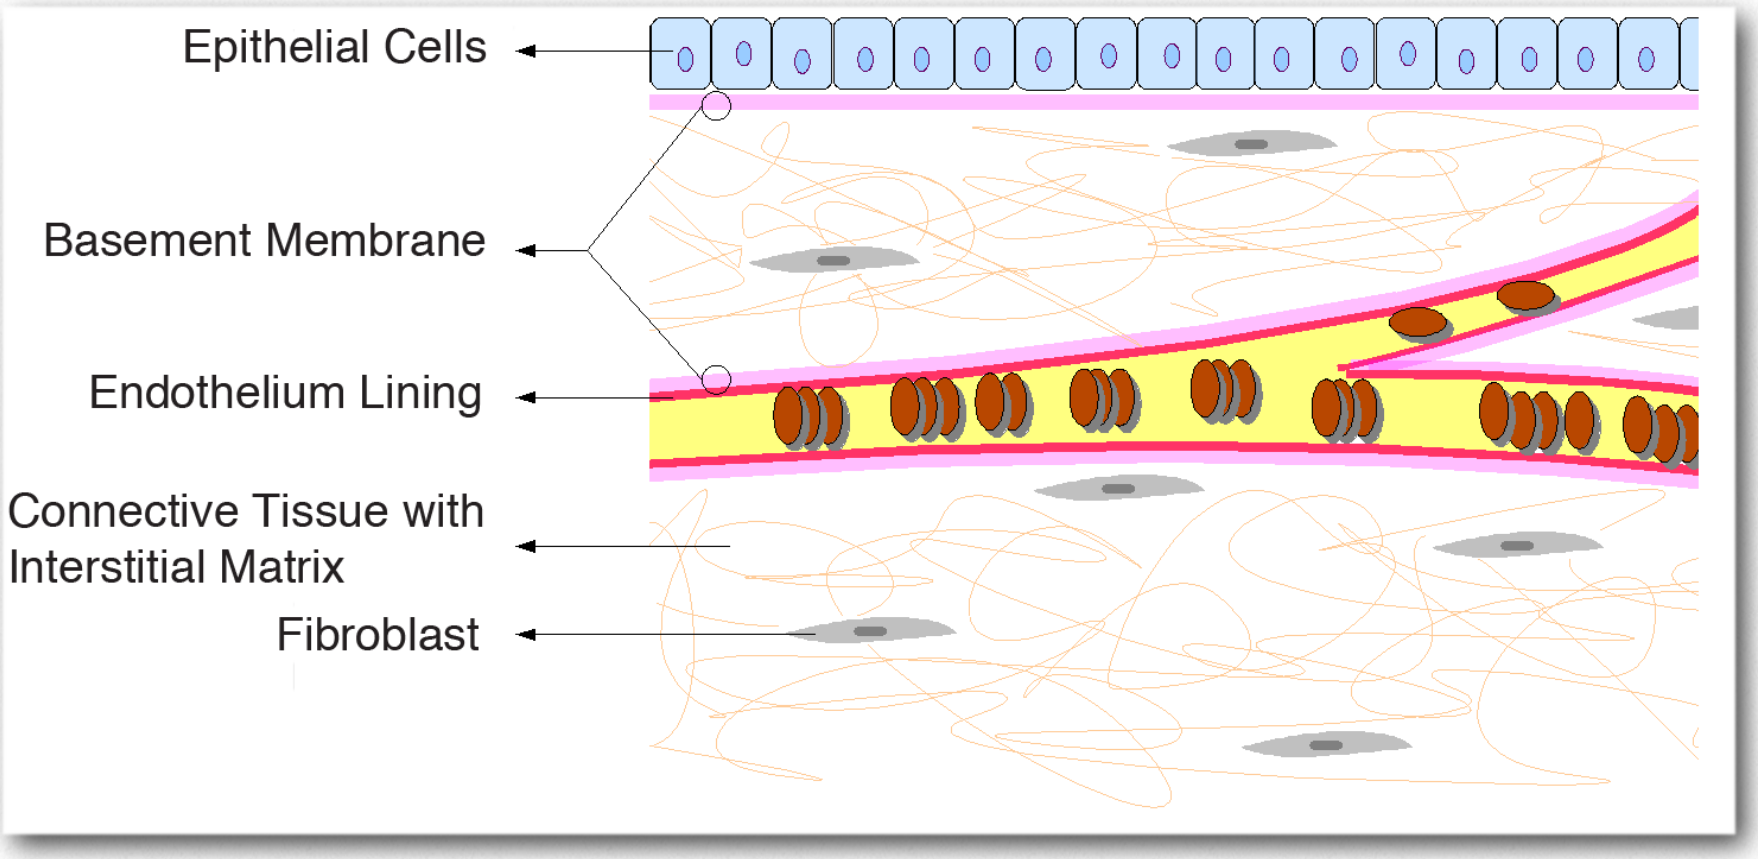

Figure 2.68 - Relationship of basement membrane to epithelium, endothelium, and connective tissue

tein *is* its primary function because the structure provides stability, organization, connections other important properties. It is with this in mind that we present the following proteins.

Basement membrane

The basement membrane is a layered extracellular matrix of tissue comprised of protein fibers (type IV collagen) and glycosaminoglycans that separates the epithelium from other tissues (Figure 2.68). More importantly, the basement membrane acts like a glue to hold tissues together. The skin, for example, is anchored to the rest of the body by the basement membrane. Basement membranes provide an interface of interaction between cells and the environment around them, thus facilitating signaling processes. They play roles in differentiation during embryogenesis and also in maintenance of function in adult organisms.

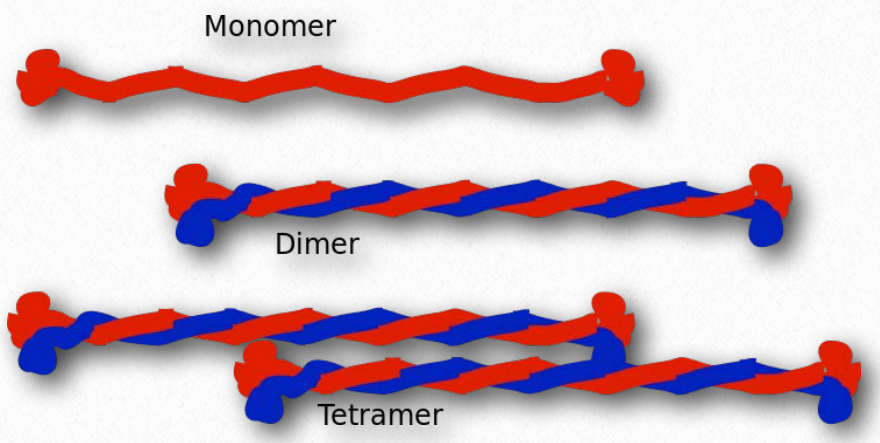

Figure 2.69 - Assembly of intermediate filaments

Actin

Actin is the most abundant globular protein found in most types of eukaryotic cells, comprising as much as 20% of the weight of muscle cells. Similar proteins have been identified in bacteria (MreB) and archaeons (Ta0583). Actin is a monomeric subunit able to polymerize readily into two different types of filaments. Microfilaments are major component of the cytoskeleton and are acted on by myosin in the contraction of muscle cells (See HERE). Actin will be discussed in more detail in the next section HERE.

Intermediate Filaments

Intermediate filaments are a part of the cytoskeleton in many animal cells and are comprised of over 70 different proteins. They are called intermediate because their size (average diameter = 10 nm) is between that of the microfilaments (7 nm) and the microtubules (25 nm).

The intermediate filament components include fibrous proteins, such as the keratins and the lamins, which are nuclear, as well as cytoplasmic forms. Intermediate filaments give flexibility to cells because of their own physical properties. They can, for example, be stretched to several times of their original length.

Six types

There are six different types of intermediate filaments. Type I and II are acidic or basic

and attract each other to make larger filaments. They include epithelial keratins and trichocytic keratins (hair components). Type III proteins include four structural proteins - desmin, GFAP (glial fibrillary acidic protein), peripherin, and vimentin. Type IV also is a grouping of three proteins and one multiprotein structure (neurofilaments). The three proteins are α-internexin, synemin, and syncoilin. Type V intermediate filaments encompass the lamins, which give structure to the nucleus. Phosphorylation of lamins leads to their disassembly and this is important in the process of mitosis. The Type VI category includes only a single protein known as nestin.

YouTube Lectures by Kevin HERE & HERE

Vimentin

Vimentin (Figure 2.70) is the most widely distributed protein of the intermediate filaments. It is expressed in fibroblasts, leukocytes, and blood vessel endothelial cells. The protein has a significant role maintaining the position of organelles in the cytoplasm, with attachments to the nucleus, mitochondria, and endoplasmic reticulum (Figure 2.70).

Vimentin provides elasticity to cells and resilience that does not arise from the microtubules or microfilaments. Wounded mice that lack the vimentin gene survive, but take longer to heal

Tubulin

A third type of filament found in cells is that of the microbutules. Comprised of a polymer of two units of a globular protein called tubulin, microtubules provide "rails" for motor proteins to move organelles and other "cargo" from one part of a cell to another. Microtubules and tubulin are discussed in more detail HERE.

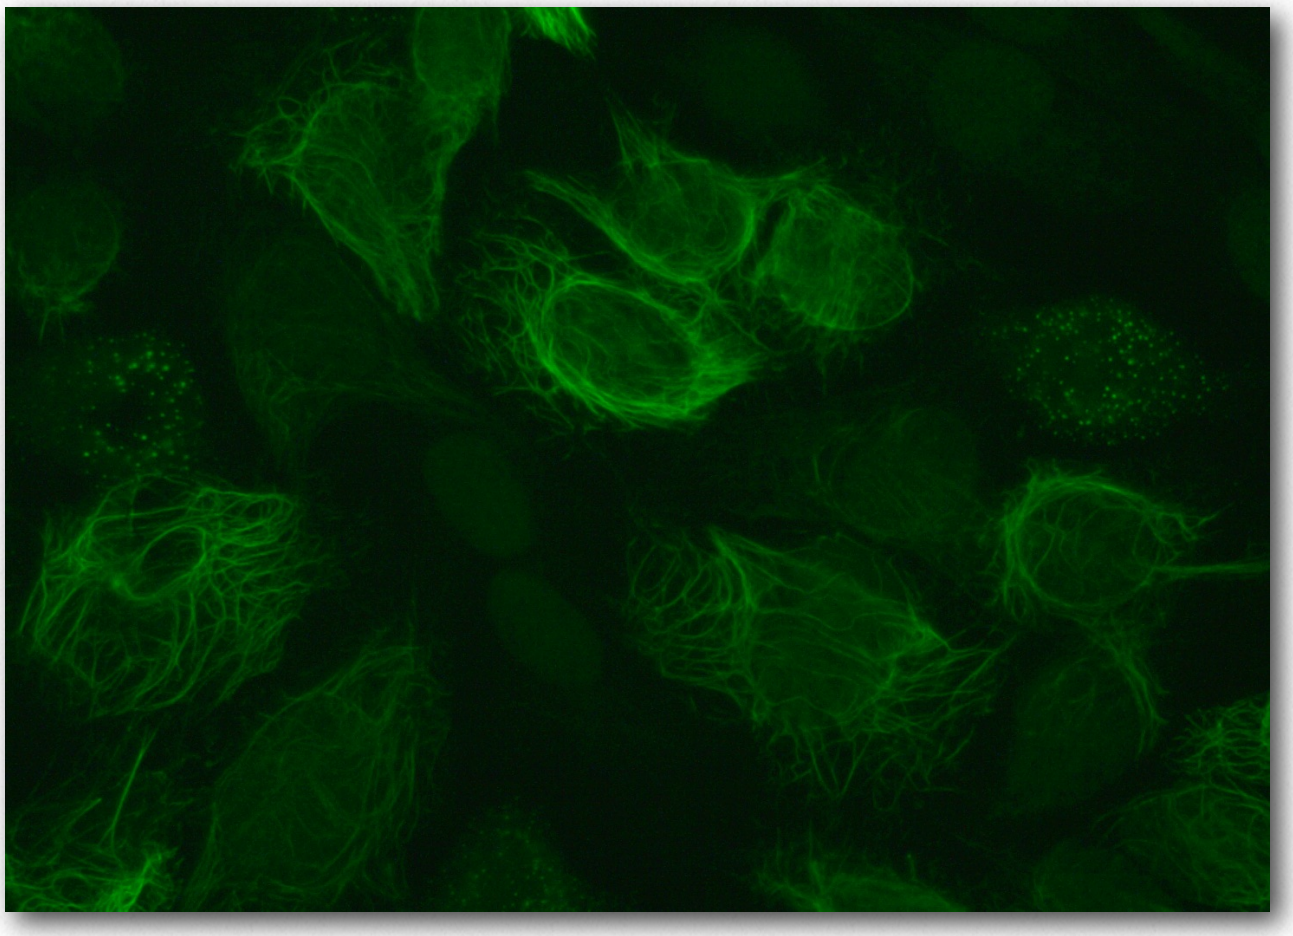

Figure 2.70 - Vimentin in cells

Wikipedia

wounds than wild type mice. Vimentin also controls the movement of cholesterol from lysosomes to the site of esterification. The result is a reduction in the amount of cholesterol stored inside of cells and has implications for adrenal cells, which must have esters of cholesterol.

Mucin

Mucins are a group of proteins found in animal epithelial tissue that have many glycosyl residues on them and typically are of high molecular weight (1 to 10 million Da). They are gel-like in their character and are often used for lubrication. Mucus is comprised of mucins.

In addition to lubrication, mucins also help to control mineralization, such as bone formation in vertebrate organisms and calcification in echinoderms. They also play roles in the immune system by helping to bind pathogens. Mucins are commonly secreted onto mucosal surfaces (nostrils, eyes, mouth, ears, stomach, genitals, anus) or into fluids, such as saliva. Because of their extensive mucosylation, mucins hold a considerable amount of water (giving them the "slimy" feel) and are resistant to proteolysis.

Vinculin

Vinculin (Figure 2.72) is a membrane cytoskeletal protein found in the focal adhesion structures of mammalian cells. It is found at cell-cell and cell-matrix junctions and interacts with integrins, talin, paxillins and F-actin. Vinculin is thought to assist (along with other proteins) in anchoring actin microfilaments to the membrane (Figure 2.71). Binding of vinculin to actin and to talin is regulating by polyphosphoinositides and can be inhibited by acidic phospholipids.

Syndecans

Syndecans are transmembrane proteins that make a single pass with a long amino acid chain (24-25 residues) through plasma membranes and facilitate G protein-coupled receptors' interaction with

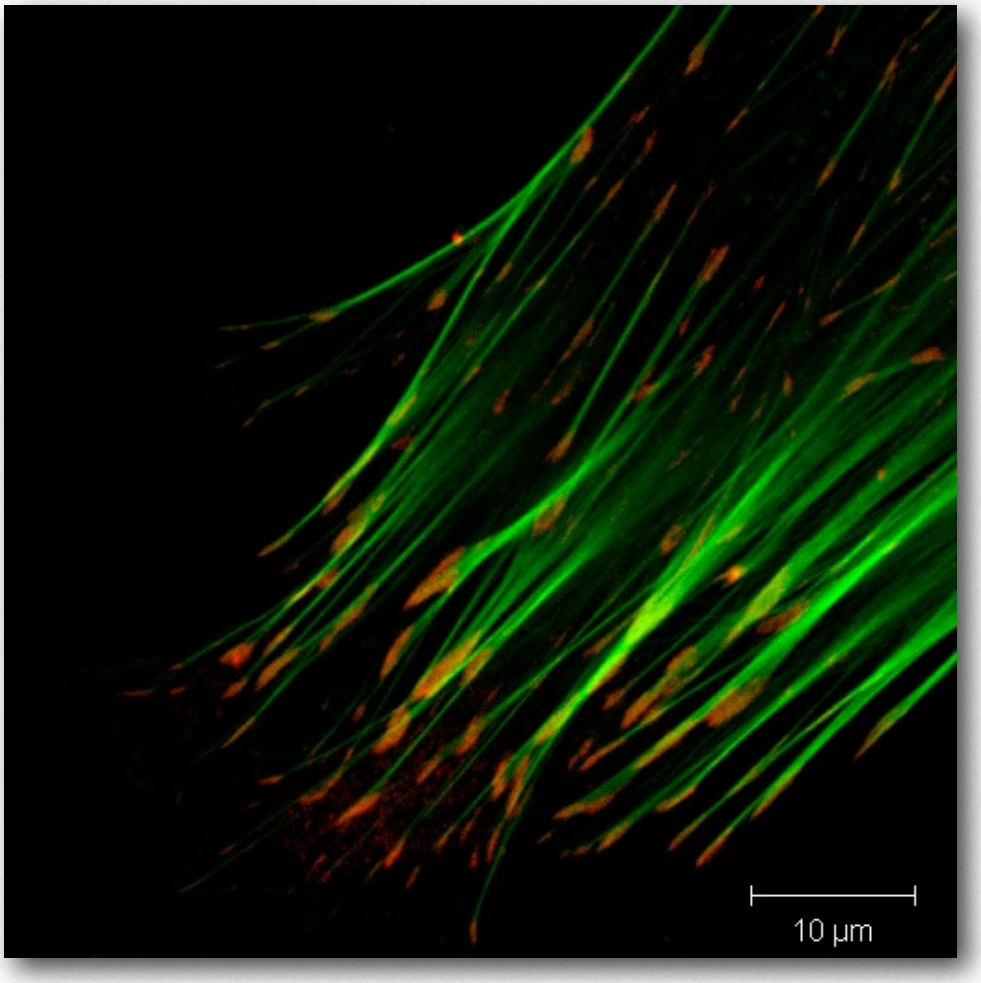

Figure 2.71 - Actin filaments (green) attached to vinculin in focal adhesion (red)

Wikipedia

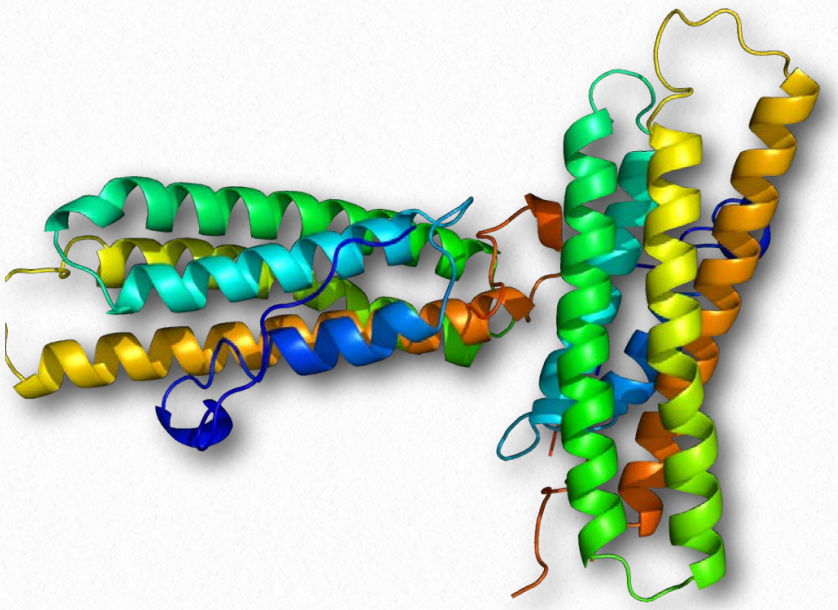

Figure 2.72 - Vinculin

ligands, such as growth factors, fibronectin, collagens (I, III, and IV) and antithrombin-1. Syndecans typically have 3-5 heparan sulfate and chondroitin sulfate chains attached to them.

Heparan sulfate can be cleaved at the site of a wound and stimulate action of fibroblast growth factor in the healing process. The role of syndecans in cell-cell adhesion is shown in mutant cells lacking syndecan I that do not adhere well to each other. Syndecan 4 is also known to adhere to integrin. Syndecans can also inhibit the spread of tumors by the ability of the syndecan 1 ectodomain to suppress growth of tumor cells without affecting normal epithelial cells.

Defensin

Defensins (Figure 2.73) are a group of small cationic proteins (rich in cysteine residues) that serve as host defense peptides in vertebrate and invertebrate organisms. They protect against infection by various bacteria, fungi, and viruses. Defensins contain between 18 and 45 amino acids with (typically) about 6-8 cysteine residues. In the immune system, defensins help to kill bacteria engulfed by phagocytosis by epithelial cells and neutrophils. They kill

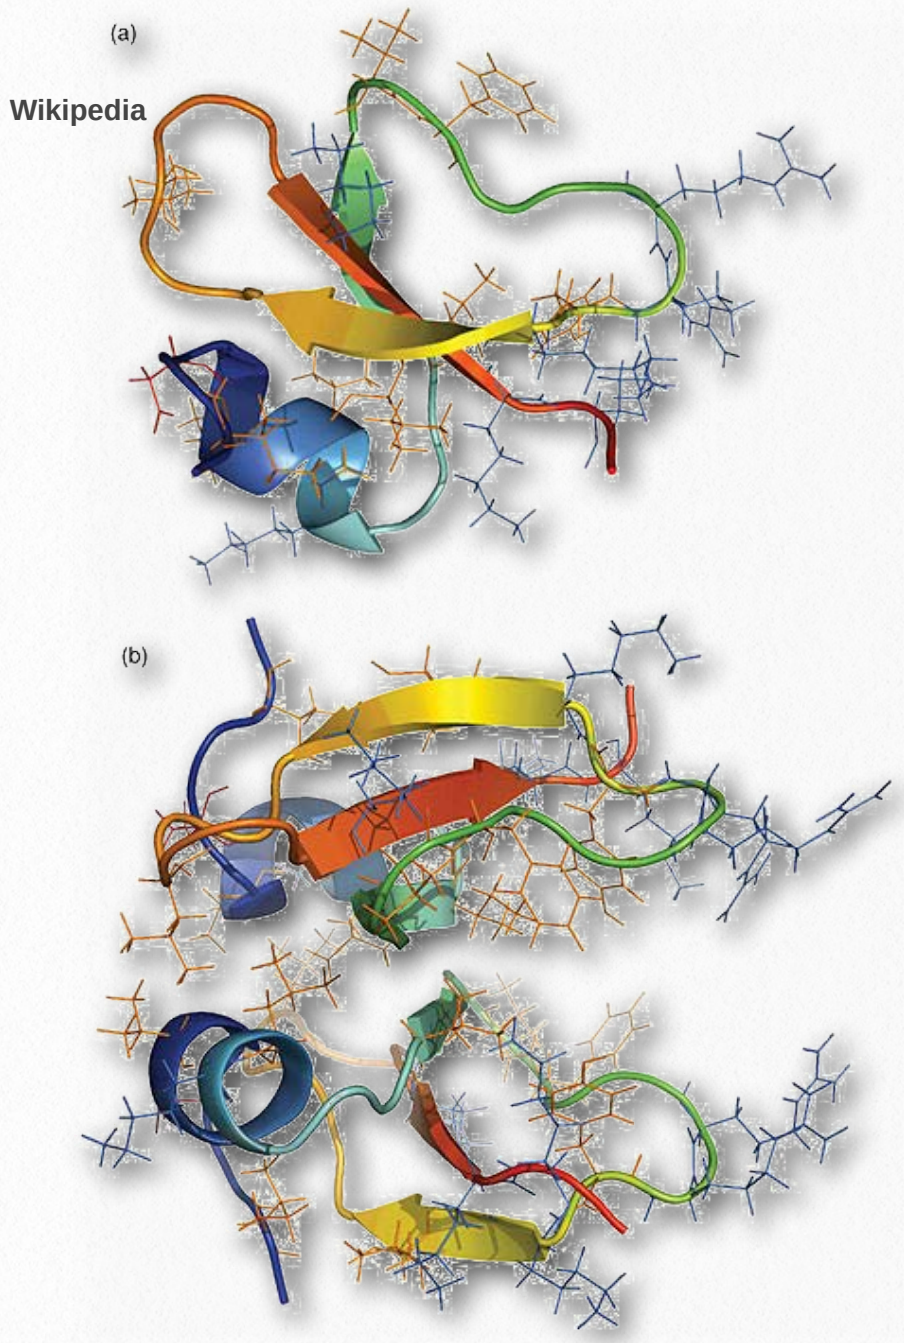

Figure 2.73 - Defensin monomer (top) and dimer (bottom) - Cationic residues in blue, hydrophobic residues in orange, and anionic residues in red

Wikipedia

bacteria by acting like ionophores - binding the membrane and opening pore-like structures to release ions and nutrients from the cells.

Focal adhesions

In the cell, focal adhesions are structures containing multiple proteins that mechanically link cytoskeletal structures (actin bundles) with the extracellular matrix. They are dynamic, with proteins bringing and leaving with signals regarding the cell cycle, cell motility, and more almost constantly. Focal adhesions serve as anchors and as a signaling hub at cellular locations where integrins bind molecules and where membrane clustering events occur. Over 100 different proteins are found in focal adhesions.

YouTube Lectures by Kevin HERE & HERE

Focal adhesions communicate important messages to cells, acting as sensors to update information about the status of the extracellular matrix, which, in turn, adjusts/affects their actions. In sedentary cells, they are stabler than in cells in motion because when cells move, focal adhesion contacts are established at the "front" and removed at the rear as motion progresses. This can be very important in white blood cells' ability to find tissue damage.

Ankyrin

Ankyrins (Figure 2.74) are a family of membrane adaptor proteins serving as "anchors" to interconnect integral membrane proteins to the spectrin-actin membrane cytoskeleton. Ankyrins are anchored to the plasma membrane by covalently linked palmitoyl-CoA. They bind to the β subunit of spectrin and at least a dozen groups of integral membrane proteins. The ankyrin proteins contain four functional domains: an N-terminal region with 24 tandem ankyrin repeats, a central spectrin-binding do-

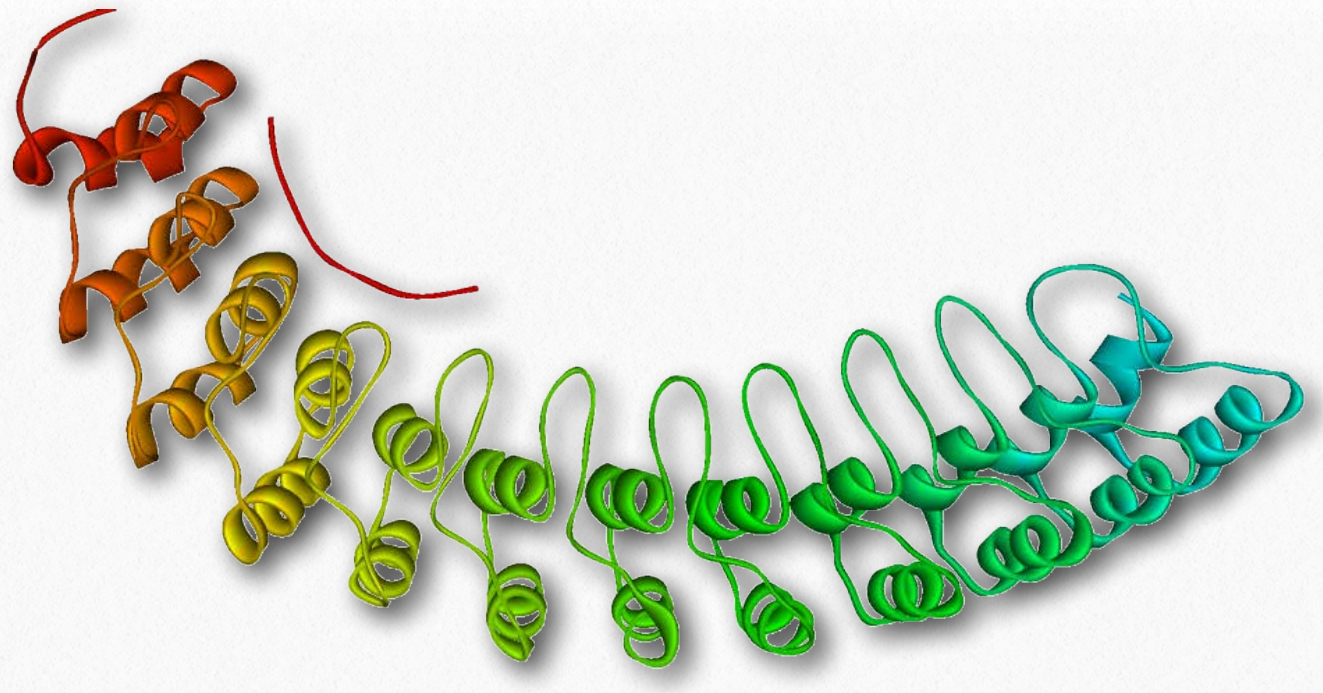

Figure 2.74 - Ankyrin's membrane-binding domain

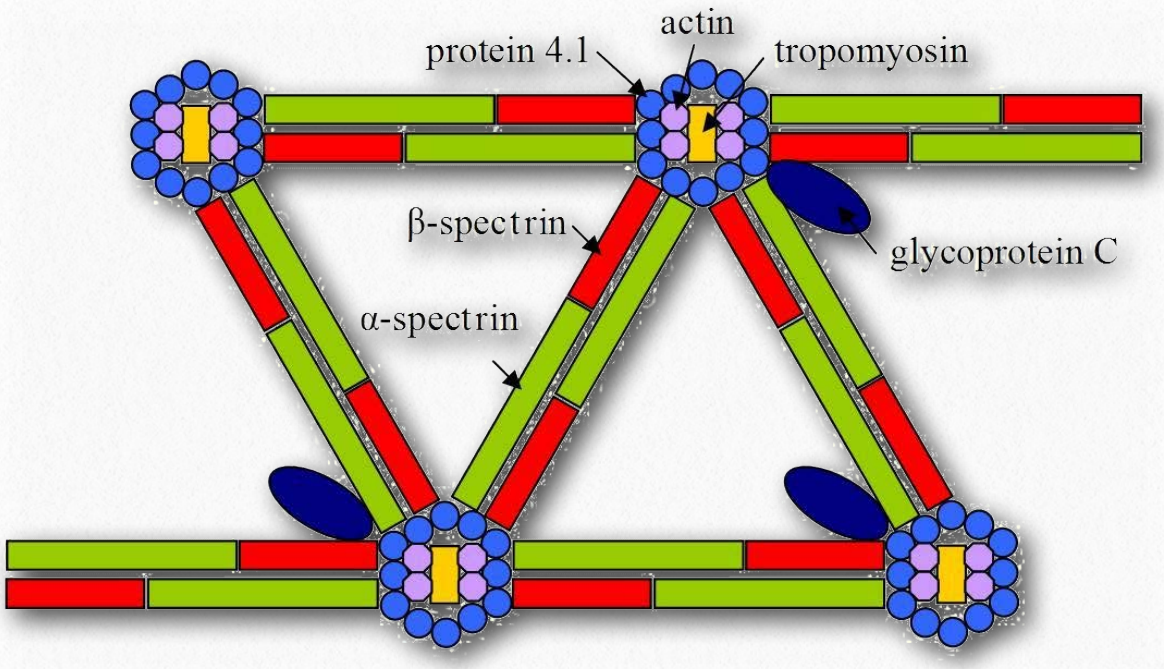

Figure 2.75 - Spectrin and other proteins in the cytoskeleton

Wikipedia

main, a “death domain” interacting with apoptotic proteins, and a C-terminal regulatory domain that is highly varied significantly among different ankyrins.

Spectrin

Spectrin (Figures 2.75 & 2.76) is a protein of the cellular cytoskeleton that plays an important role in maintaining its structure and the integrity of the plasma membrane. In animals, spectrin gives red blood cells their shape. Spectrin is located inside the inner layer of the eukaryotic plasma membrane where it forms a network of pentagonal or hexagonal arrangements.

Spectrin fibers collect together at junctional complexes of actin and is also attached to ankyrin for stability, as well as numerous integral membrane proteins, such as glycophorin.

Integrins

In multicellular organisms, cells need connections, both to each other and to the extracellular matrix. Facilitating these attachments at the cellular

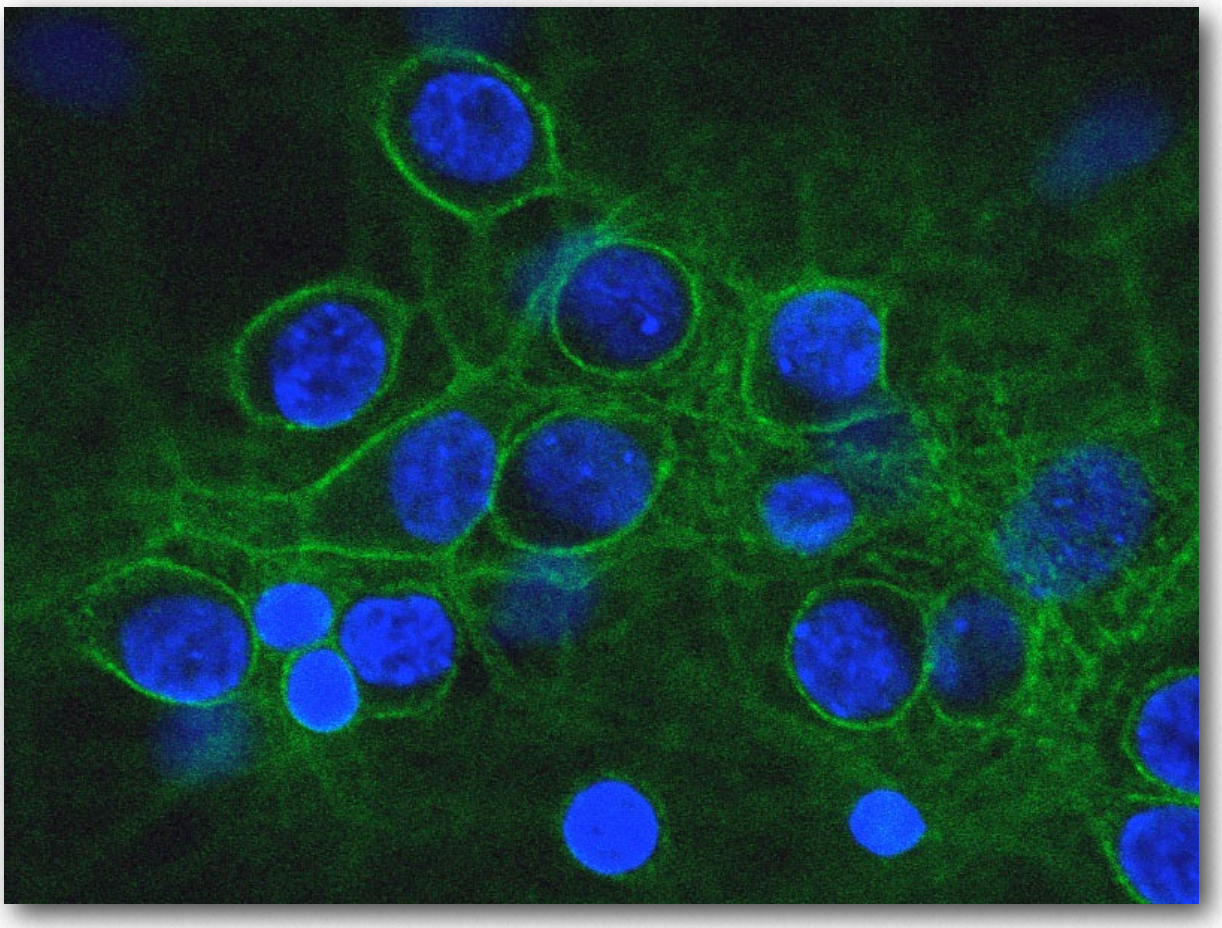

Figure 2.76 - Spectrin (green) and nuclei (Blue)

Wikipedia

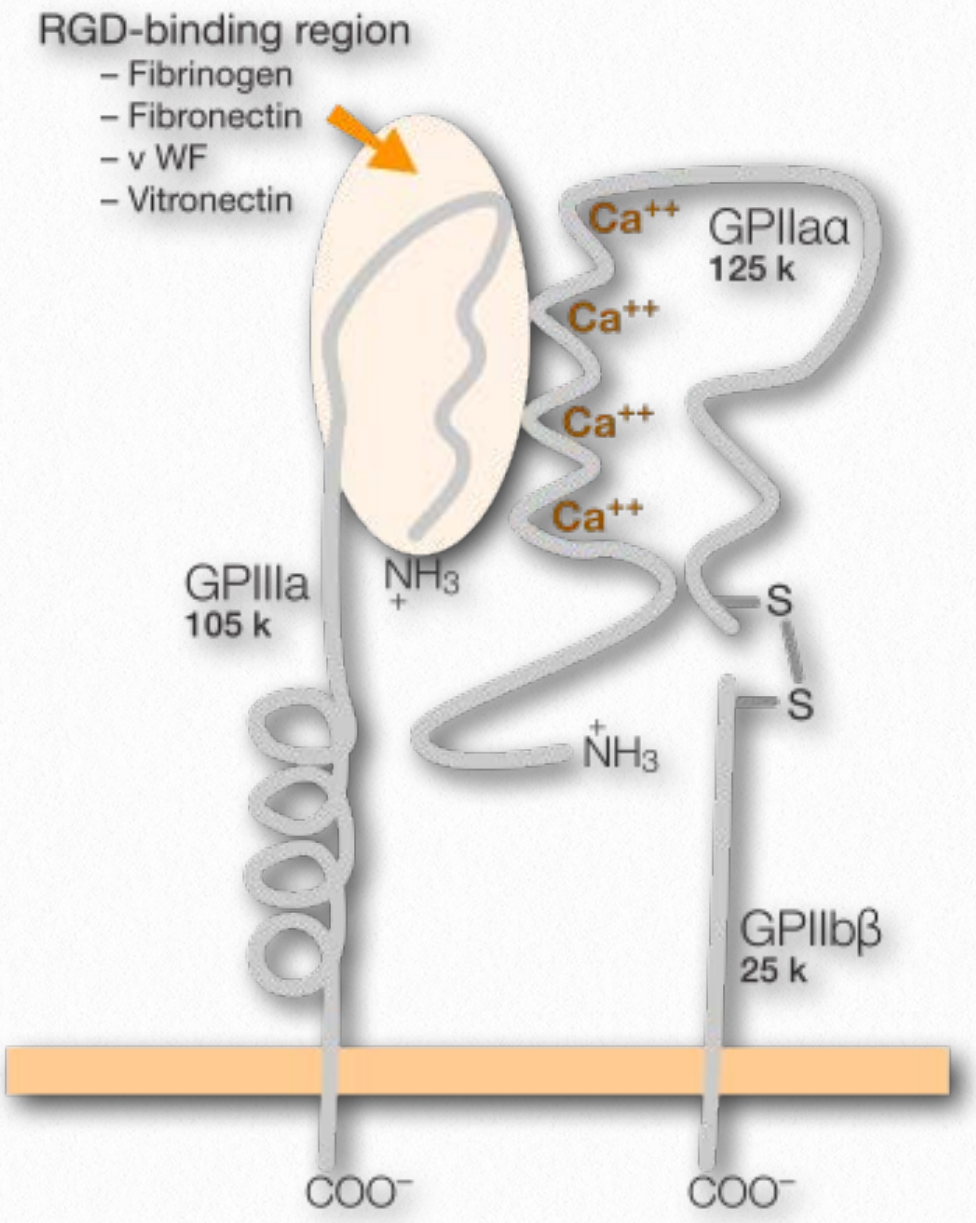

Figure 2.77 - Integrin and its binding site (on top left)

Wikipedia

end are transmembrane proteins known as integrins (Figure 2.77). Integrins are found in all metazoan cells. Ligands for the integrins include collagen, fibronectin, laminin, and vitronectin. Integrins function not only in attachment, but also in communication, cell migration, virus linkages (adenovirus, for example), and blood clotting. Integrins are able to sense chemical and mechanical signals about the extracellular matrix and move that information to intracellular domains as part of the process of signal transduction. Inside the cells, responses to the signals affect cell shape, regulation of the cell cycle, movement, or changes in other cell receptors in the membrane. The process is dynamic and allows for rapid responses as may be necessary, for example in the process of blood clotting, where the integrin known as GPIbIIIa (on the surface of blood platelets) attaches to fibrin in a clot as it develops.

Integrins work along with other receptors, including immunoglobulins, other cell adhesion molecules, cadherins, selectins, and syndecans. In mammals the proteins have a large number of subunits - 18 α- and 8 β-chains. They are a bridge between its links outside the cell to the extracellular matrix (ECM) and its links inside the cell to the cytoskeleton. Integrins play central role in formation and stability of focal adhesions. These are large molecular complexes arising from clustering of integrin-ECM connections. In the process of cellular movement, integrins at the “front” of the cell (in the direction of the movement), make new attachments to substrate and release connections to

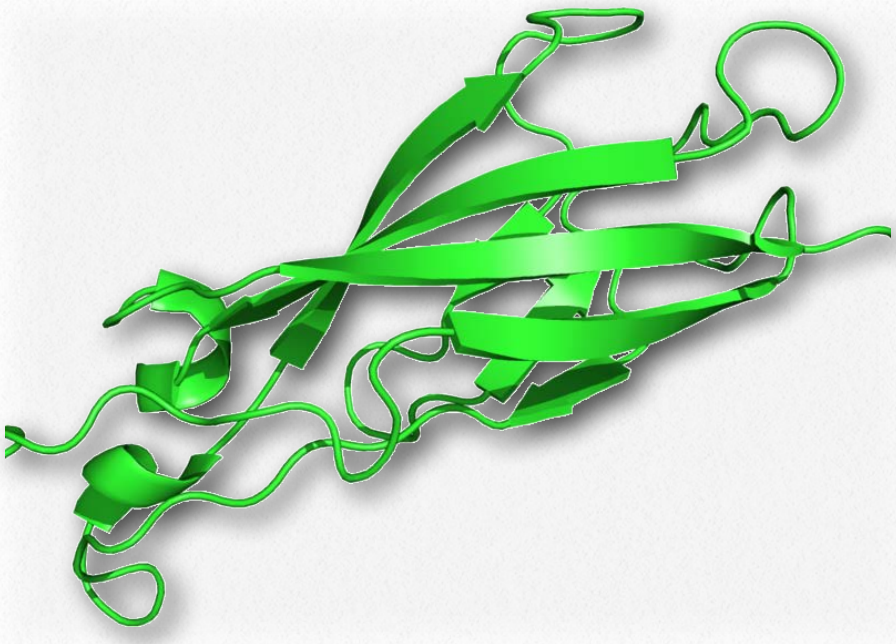

Figure 2.78 - Extracellular ectodomain of a cadherin

substrate in the back of the cell. These latter integrins are then endocytosed and reused.

Integrins also help to modulate signal transduction through tyrosine kinase receptors in the cell membrane by regulating movement of adapters to the plasma membrane. β1c integrin, for example, recruits the Shp2 phosphatase to the insulin growth factor receptor to cause it to become dephosphorylated, thus turning off the signal it communicates. Integrins can also help to recruit signaling molecules inside of the cell to activated tyrosine kinases to help them to communicate their signals.

Cadherins

Cadherins (Figure 2.78) constitute a type-1 class of transmembrane proteins playing important roles in cell adhesion. They require calcium ions to function, forming adherens junctions that hold tissues together (See Figure 2.69). Cells of a specific cadherin type will preferentially cluster with each other in preference to associating with cells containing a different cadherin type. Caderins are both receptors and places for ligands to attach. They assist in the proper positioning of cells in development, separation of different tissue layers, and cell migration.

Selectins

Selectins (Figure 2.79) are cell adhesion glycoproteins that bind to sugar molecules. As such, they are a type of lectin - proteins that bind sugar polymers (see HERE also). All selectins have an N-terminal calcium-dependent lectin domain, a single transmembrane domain, and an intracellular cytoplasmic tail.

There are three different types of selectins, 1) E-selectin (endothelial); 2) L (lymphocytic; and 3) P (platelets and endothelial cells. Selectins function in lymphocyte homing (adhesion of blood lymphocytes to cells in lymphoid organs), in inflammation processes, and in cancer metastasis. Near the site of inflammation, P-selectin on the surface of blood capillary cells interacts with glycoproteins on leukocyte cell surfaces. This has the effect of slowing the movement of the leukocyte. At the target site of inflammation, E- selectin on the endothelial cells of the blood vessel and L-selectin on the surface of the leukocyte bind to their respective carbohydrates, stopping the leukocyte movement. The leuko-

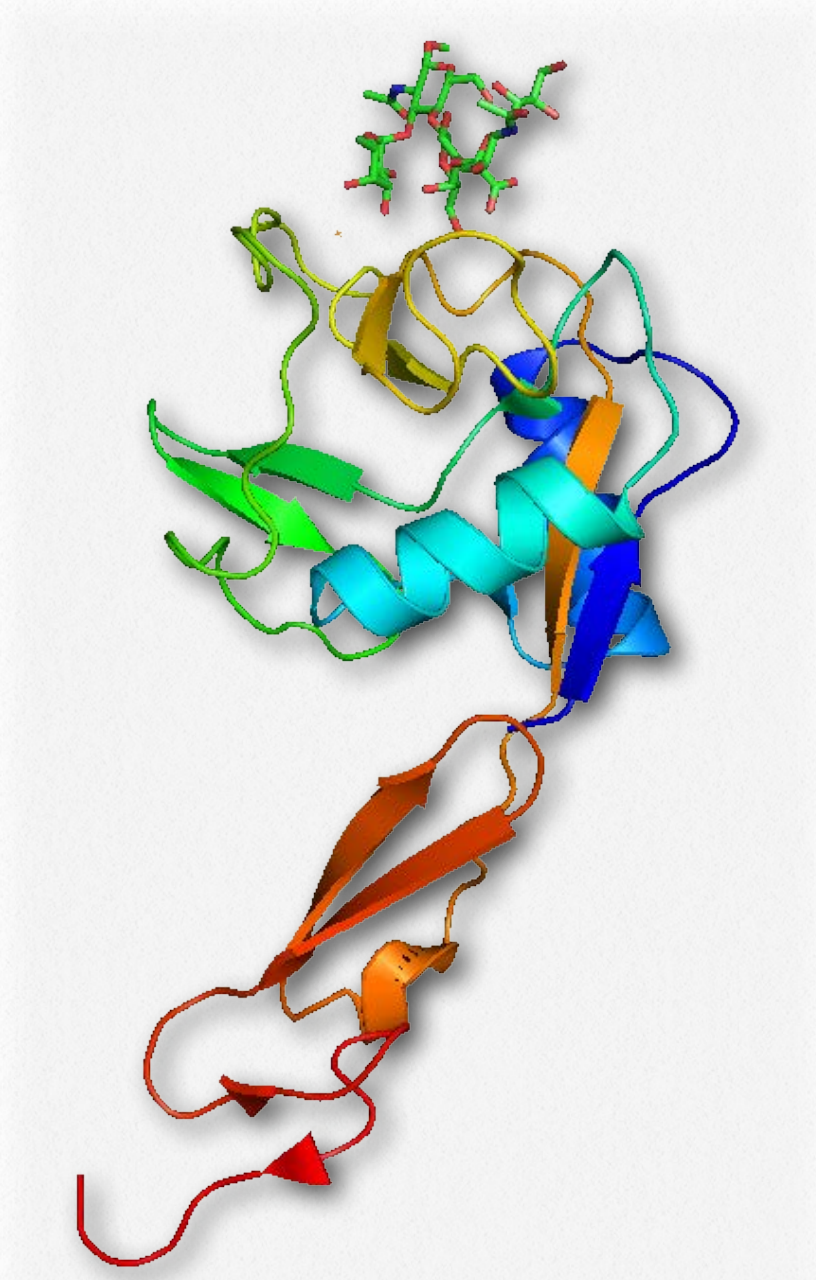

Figure 2.79 - Selectin bound to a sugar
Wikipedia

cyte then crosses the wall of the capillary and begins the immune response. Selectins are involved in the inflammatory processes of asthma, psoriasis, multiple scleroris, and rheumatoid arthritis.

Laminins

Laminins are extracellular matrix glycoproteins that a major components of the basal lamina and affect cell differentiation, migration, and adhesion. They are secreted into the extracellular matrix where they are incorporated and are essential for tissue maintenance and survival. When laminins are defective, muscles may not form properly and give rise to muscular dystrophy.

Laminins are associated with fibronectin, entactin, and perlecan proteins in type IV collagen networks and bind to integrin receptors in the plasma membrane. As a consequence, laminins contribute to cellular attachment, differentiation, shape, and movement. The proteins are trimeric in structure, having one α-chain, a β-chain, and a γ-chain. Fifteen combinations of different chains are known.

YouTube Lectures by Kevin
HERE & HERE

Vitronectin

Vitronectin is a glycoprotein (75kDa) found in blood serum (platelets), the extracellular matrix, and in bone. It promotes the process of cell adhesion and spreading and binds to several protease inhibitors (serpins). It is secreted from cells and is believed to play roles in blood clotting and the malignancy of tumors. One domain of vitronectin binds to plasminogen activator inhibitor and acts to stabilize it. Another domain of the protein binds to cellular integrin proteins, such as the vitronectin receptor that anchors cells to the extracellular matrix.

Catenins

Catenins are a family of proteins interacting with cadherin proteins in cell adhesion (Figure 2.69). Four main types of catenins are known, α-, β-, γ-, and δ-catenin. Catenins play roles in cellular organization before development occurs and help to regulate cellular growth. α-catenin and β-catenin are found at adherens junctions with cadherin and help cells to maintain epithelial layers. Cadherins are connected to actin filaments of the cytoskeleton and catenins play the critical role. Catenins are important for the process whereby cellular division is inhibited when cells come in contact with each other (contact inhibition). When catenin genes are mutated, cadherin cell adhesions can disappear and tumorigenesis may result. Catenins have been found to be associated with colorectal and numerous other forms of cancer.

Glycophorins

All of the membrane proteins described so far are notable for the connections they make to other proteins and cellular structures. Some membrane proteins, though, are designed to reduce cellular connections to proteins of other cells. This is particularly important for blood cells where "stickiness" is undesirable except where clotting is concerned.

Glycophorins (Figure 2.80) are membrane-spanning sialoglycoproteins of red blood cells. They are heavily glycosylated (60%).and rich in sialic acid, giving the cells a very hydrophilic (and negatively charged) coat, which enables them to circulate in the bloodstream without adhering to other cells or the vessel walls.

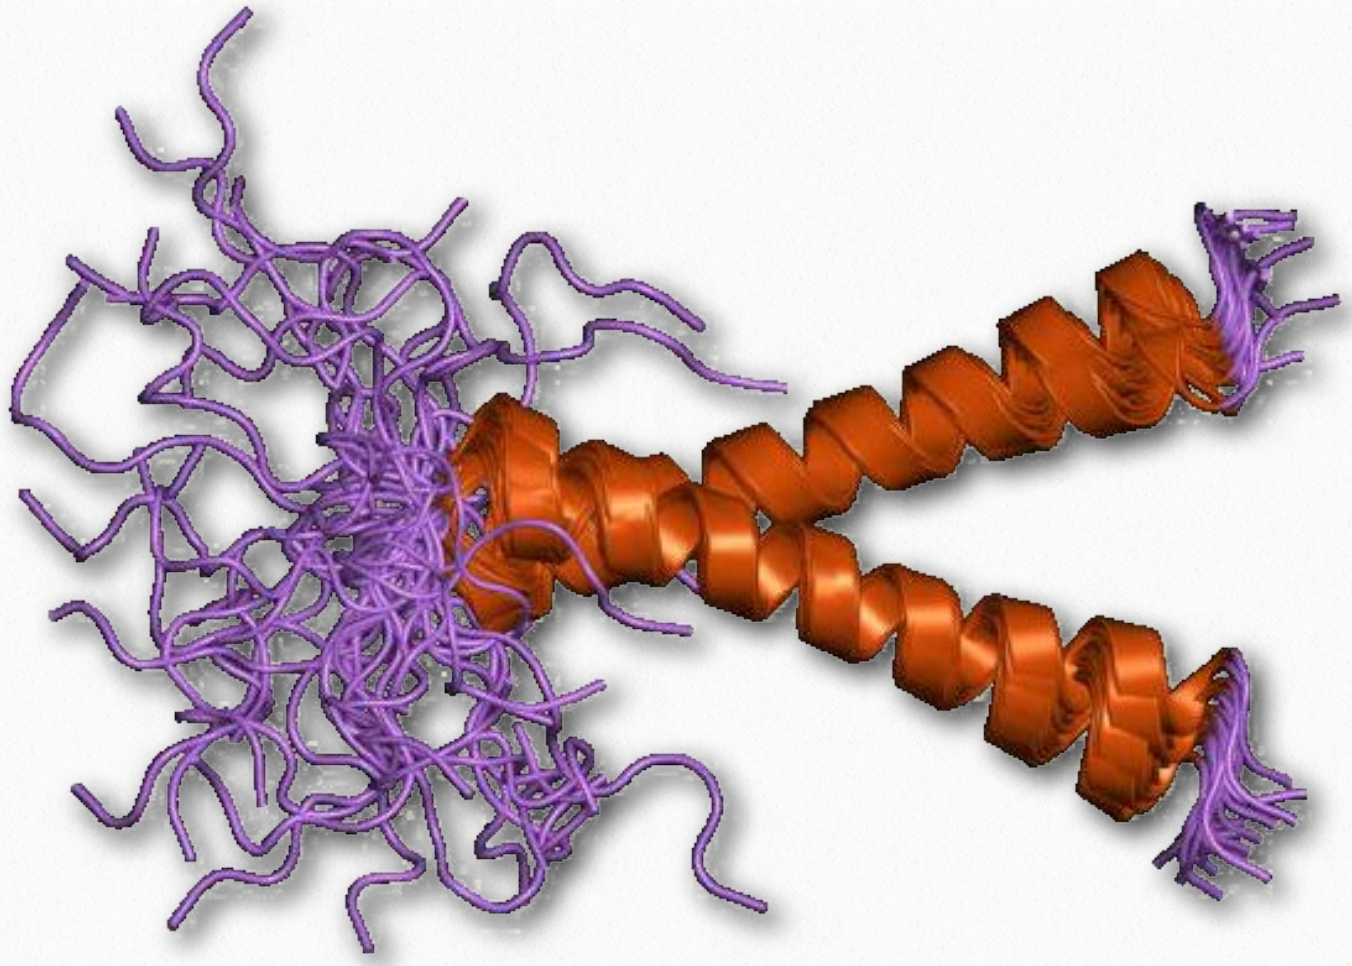

Figure 2.80 - Glycophorin a

Five glycophorins have been identified - four (A,B,C,and D) from isolated membranes and a fifth form (E) from coding in the human genome. The proteins are abundant, forming about 2% of the total membrane proteins in these cells. Glycophorins have important roles in regulating RBC membrane mechanical properties and shape. Because some glycophorins can be expressed in various non-erythroid tissues (particularly Glycophorin C), the importance of their interactions with the membrane skeleton may have a considerable biological significance.

Cooperativity and allosterism - quaternary structure

Quaternary structure, of course describes the interactions of individual subunits of a multi-subunit protein (Figure 2.81). The result of these interactions can give rise to important biological phenomena, such as cooperative binding of substrates to a protein and allosteric effects on the action of an enzyme.

Allosteric effects can occur by a series of mechanisms, but a common feature is that binding of an effector to an enzyme subunit causes (or locks) the enzyme in either a T-state (less activity) or an R-state (more activity). Effectors can be enzyme substrates (homotropic effectors) or non-substrates (heterotropic effectors). Allosterism will be covered in more depth in the Catalysis chapter HERE.

We begin our consideration of quaternary structure with a discussion of cooperativity, how it arises in the multi-subunit protein hemoglobin and how its properties contrast with those of the related, single subunit protein myoglobin.

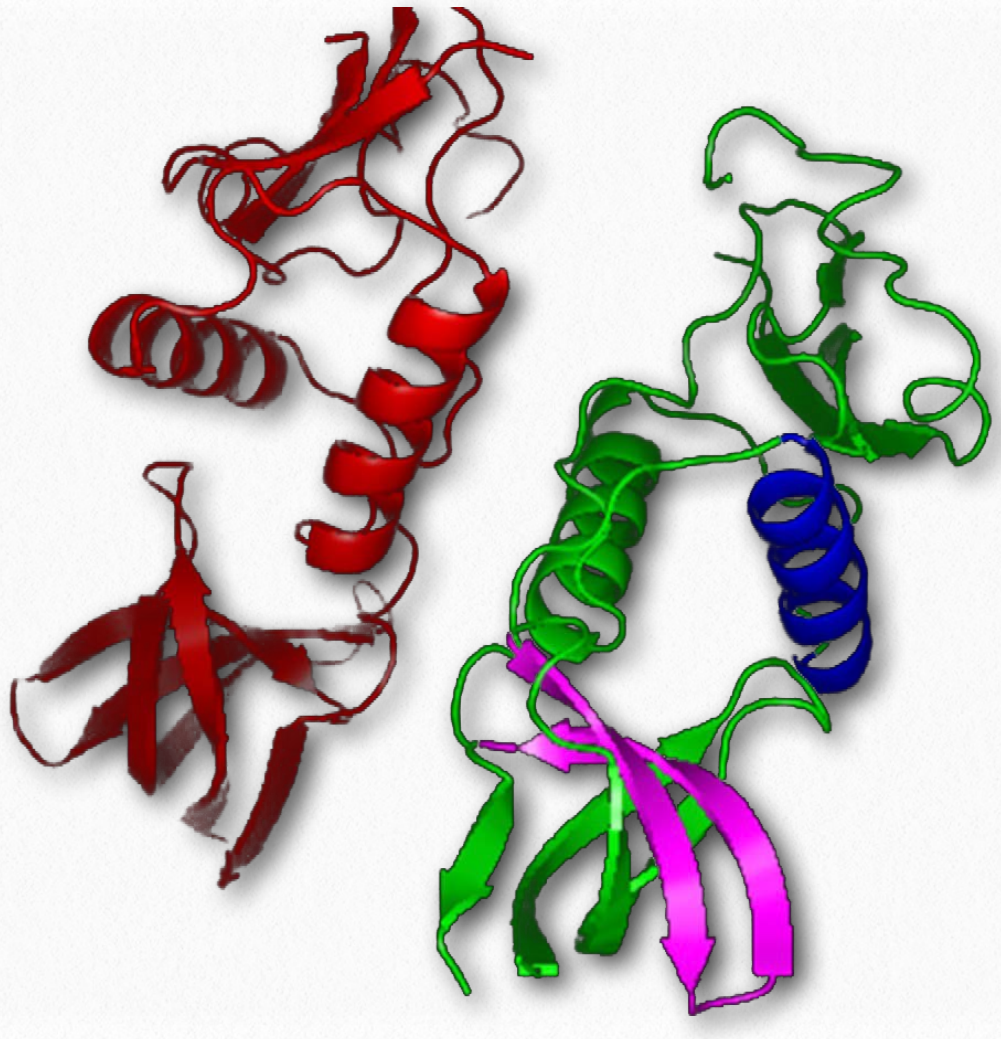

Figure 2.81 - Two polypeptide units of a protein interact in quaternary structure

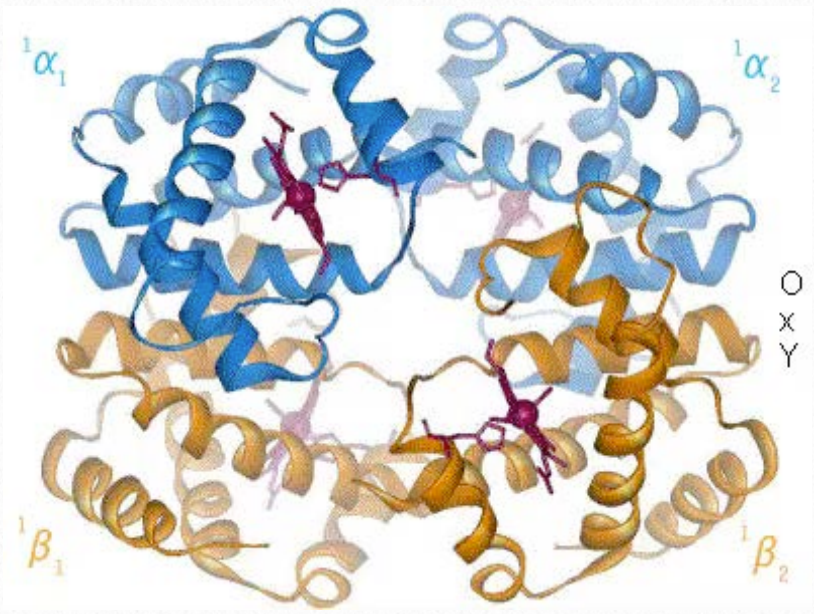
Wikipedia

Cooperativity

Cooperativity is defined as the phenomenon where binding of one ligand molecule by a protein favors the binding of additional molecules of the same type. Hemoglobin, for example, exhibits cooperativity when the binding of an oxygen molecule by the iron of the heme group in one of the four subunits causes a slight conformation change in the subunit. This happens because the heme iron is attached to a histidine side chain and binding of oxygen 'lifts' the iron along with the histidine ring (also known as the imidazole ring).

Since each hemoglobin subunit interacts with and influences the other subunits, they too are induced to change shape slightly when the first subunit binds to oxygen (a transition described as going from the T-state to the R-state). These shape changes favor each of the remaining subunits binding oxygen, as well. This is very important in the lungs where oxygen is picked up by hemoglobin, because the binding of the first oxygen molecule facilitates the rapid uptake of more oxygen molecules. In the tissues, where the oxygen concentration is lower, the oxygen leaves hemoglobin and the proteins flips from the R-state back to the T-state.

My blood has a proclivity
For co-op-ER-a-TIV-it-y
It's 'cause when in the lung environs
Ox-y-GEN binds to the irons
And changes hemoglobin's fate
Out of a T to an R-State



Movie 2.3 - Hemoglobin's structural changes on binding oxygen

Wikipedia

CO_2 transport

Cooperativity is only one of many fascinating structural aspects of hemoglobin that help the body to receive oxygen where it is needed and pick it up where it is abundant. Hemoglobin also assists in the transport of the product of cellular respiration (carbon dioxide) from the tissues producing it to the lungs where it is exhaled. Like the binding of oxygen to hemoglobin, binding of other molecules to hemoglobin affects its affinity for oxygen. The effect is particularly pronounced when comparing the oxygen binding characteristics of hemoglobin's four subunits with the oxygen binding of the related protein myoglobin's single subunit (Figure 2.83).

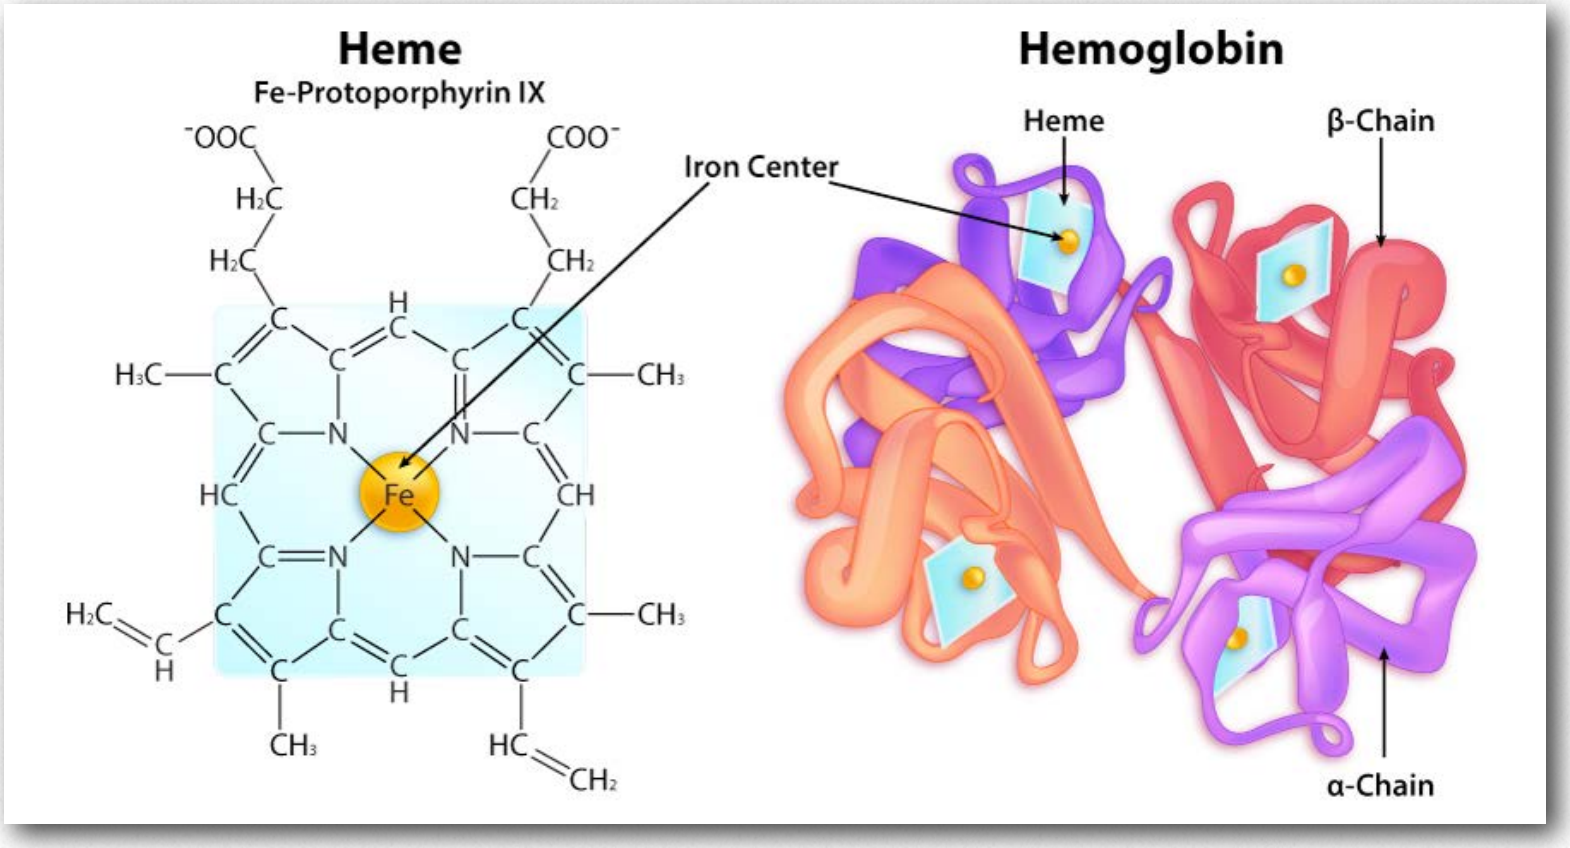


Figure 2.82 - Heme structure within hemoglobin

Image by Aleia Kim

Different oxygen binding

Like hemoglobin, myoglobin contains an iron in a heme group that binds to oxygen. The structure of the globin protein in myoglobin is very similar to the structure of the globins in hemoglobin and hemoglobin is thought to have evolved from myoglobin in evolutionary history. As seen in Figure 2.83, the binding curve of hemoglobin for oxygen is S-shaped (sigmoidal), whereas the binding curve for myoglobin is hyperbolic. What this tells us is that hemoglobin's affinity for oxygen is low at a low concentration oxygen, but

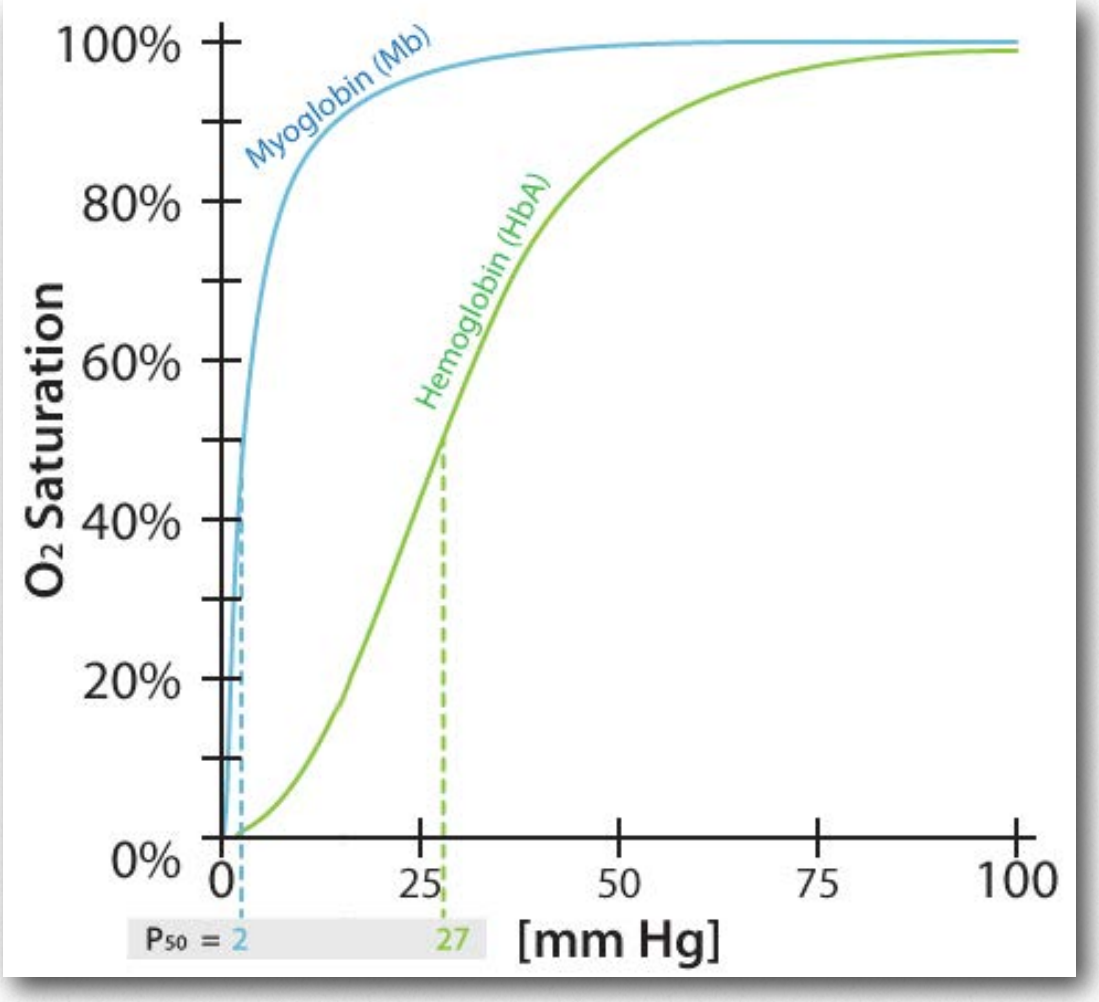

Figure 2.83 - Oxygen binding affinities for myoglobin and hemoglobin

Figure by Aleia Kim

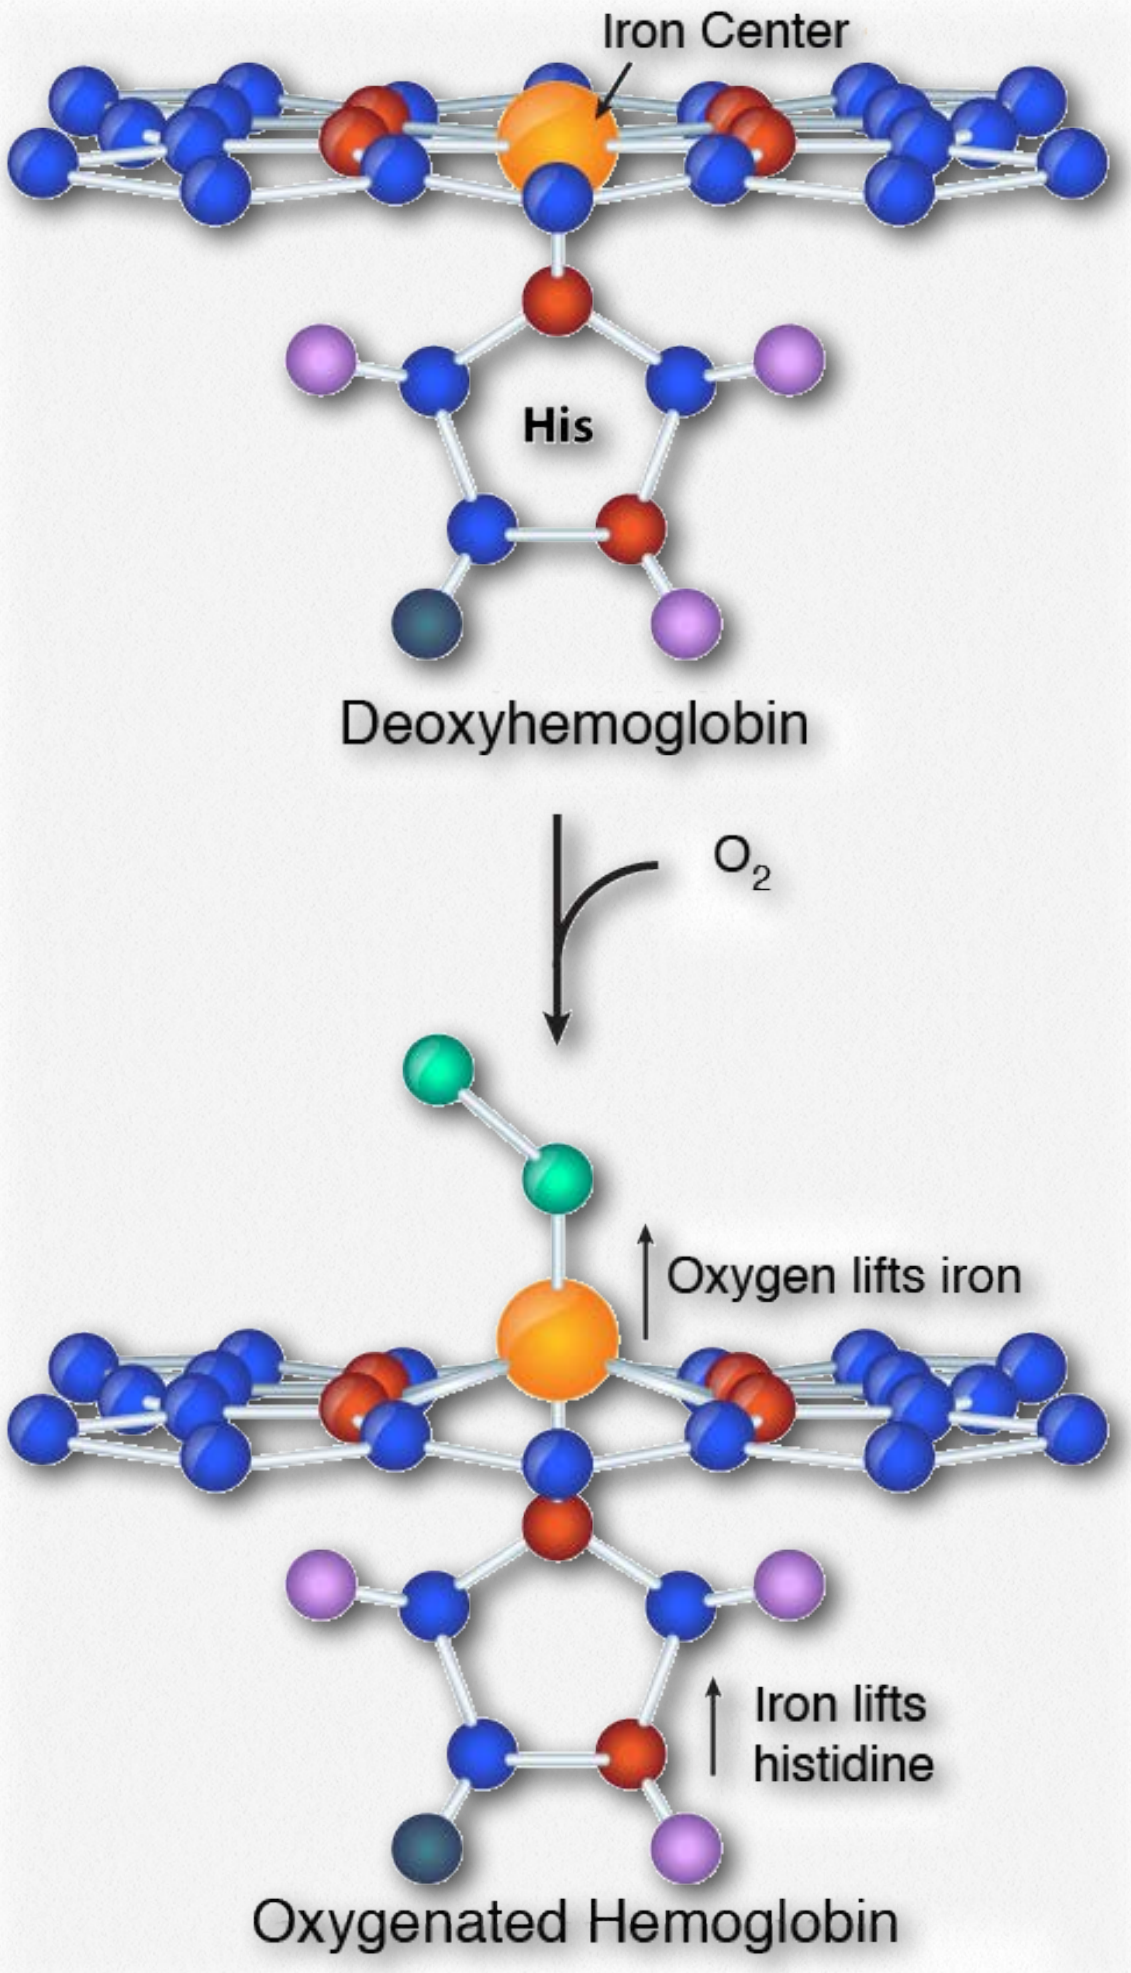

Figure 2.84 - Binding of oxygen at the heme center of hemoglobin

Image by Aleia Kim

increases as the oxygen concentration increases. Since myoglobin very quickly saturates with oxygen, even under low oxygen concentrations, it says that its affinity for oxygen is high and doesn't change.

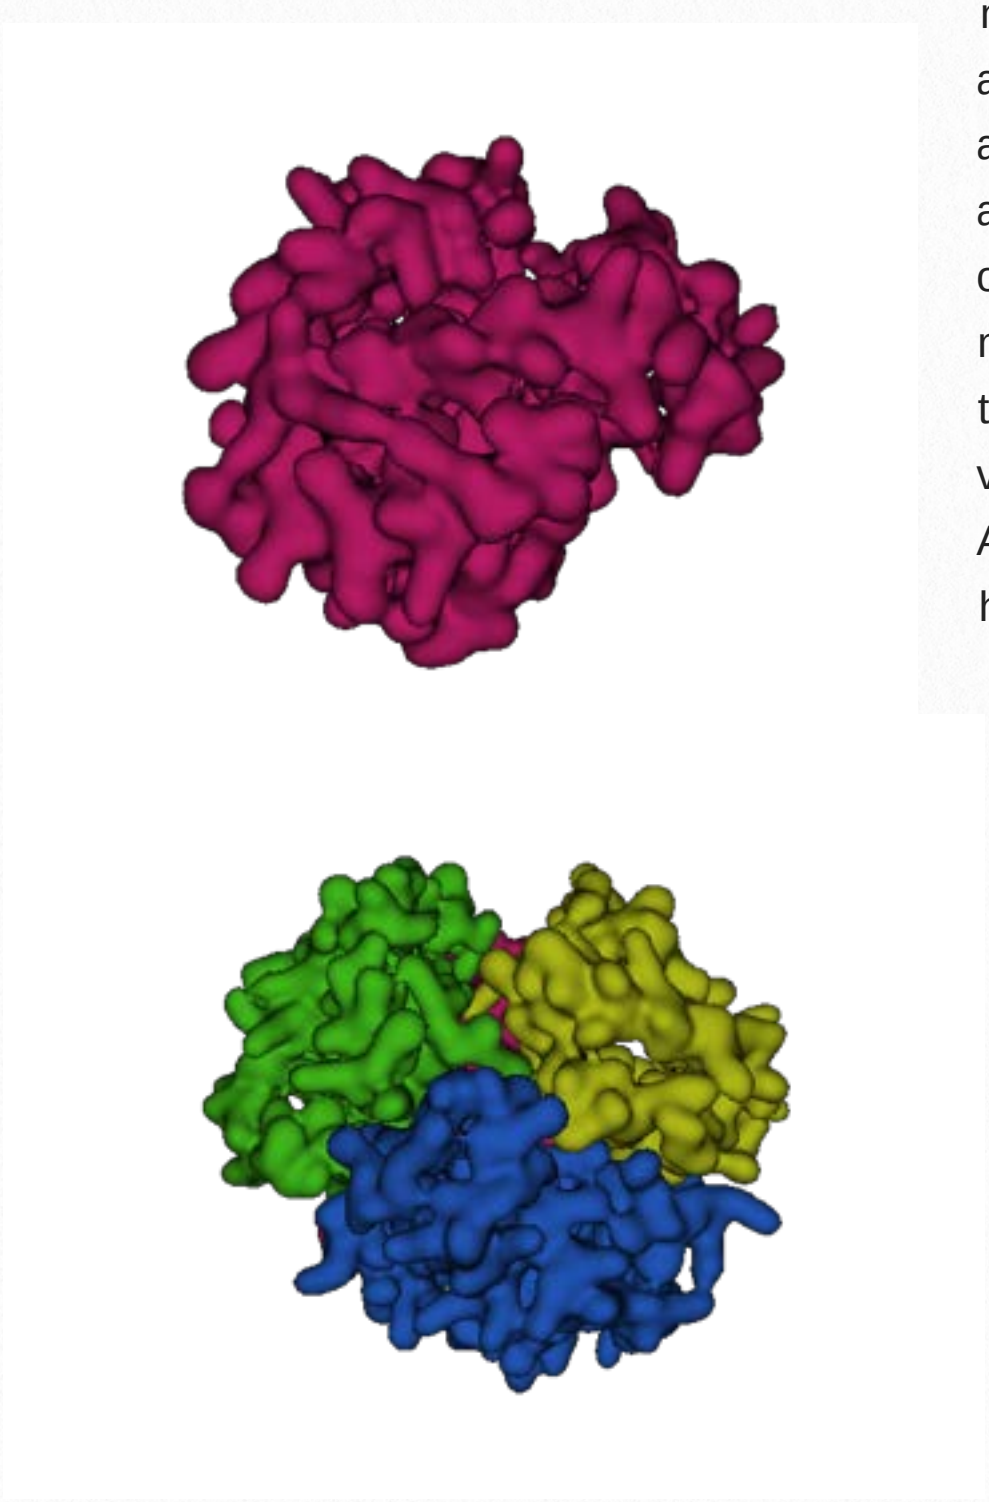
Because myoglobin has only a single subunit, binding of oxygen by that subunit can't affect any other subunits, since there are no other subunits to affect. Consequently,

YouTube Lectures by Kevin HERE & HERE

cooperativity requires more than one subunit. Therefore, hemoglobin can exhibit cooperativity, but myoglobin can't. It is worth noting that simply having multiple subunits does not mean cooperativity will exist. Hemoglobin is one protein that exhibits the characteristic, but many multisubunit proteins do not.

Storage vs. delivery

The lack of ability of



Interactive 2.2 - **Hemoglobin in the presence (top) and absence (bottom) of oxygen**

myoglobin to adjust its affinity for oxygen according to the oxygen concentration (low affinity at low oxygen concentration, such as in tissues and high affinity at high oxygen concentration, such as in the lungs) means it is better suited for storing oxygen than for delivering it according to the varying oxygen needs of and animal body. As we shall see, besides cooperativity, hemoglobin has other structural features that allow it to deliver oxygen precisely where it is needed most in the body.

Bohr effect

The Bohr Effect was first described over 100 years ago by Christian Bohr, father of the famous physicist, Niels Bohr. Shown graphically (Figures 2.86, 2.87, and 2.88), the observed effect is that hemoglobin's affinity for oxygen decreases as the pH decreases and as the concentration of carbon dioxide increases. Binding of the protons and carbon dioxide by amino

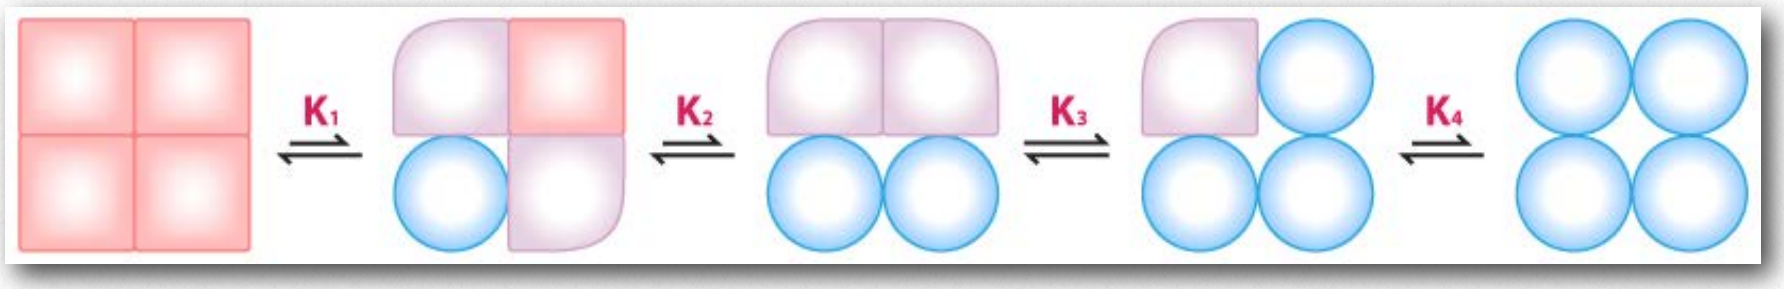


Figure 2.85 - Sequential model of binding. The sequential model is one way to explain hemoglobin's cooperativity. Squares represent no oxygen bound. Circles represent subunits bound with oxygen and rounded subunits correspond to units whose affinity for oxygen increases by interacting with a subunit that has bound oxygen.

Image by Aleia Kim

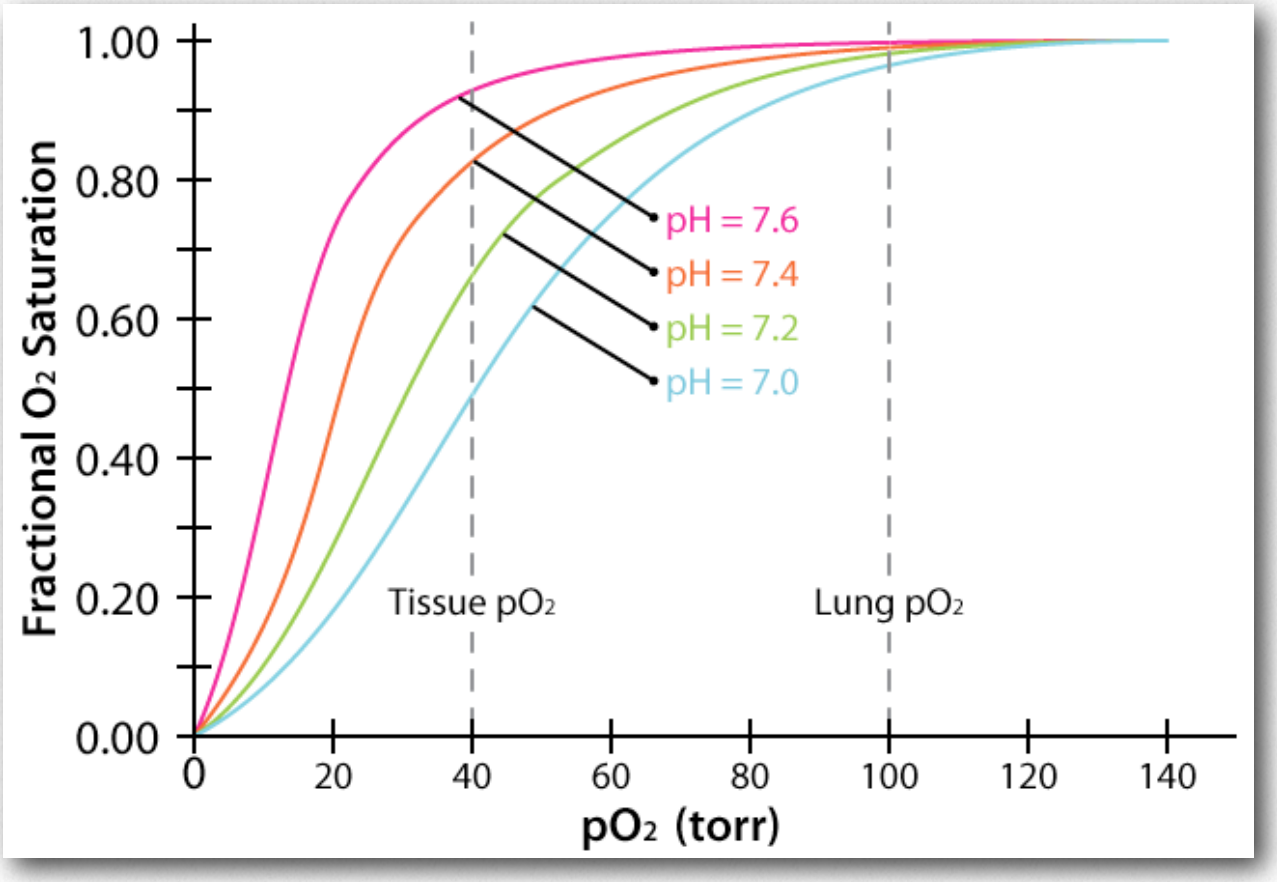

Figure 2.86 - The Bohr effect with respect to pH changes

Image by Aleia Kim

acid side chains in the globin proteins helps to facilitate structural changes in them. Most commonly, the amino acid affected by protons is histidine #146 of the β strands. When this happens, the ionized histidine can form an ionic bond with the side chain of aspartic acid #94, which has the effect of stabilizing the T-state (reduced oxygen binding state) and releasing oxygen. Other histidines and the amine of the amino terminal amino acids in the α-chains are also binding sites for protons.

2,3-BPG

Another molecule favoring the release of oxygen by hemoglobin is 2,3-bisphosphoglycerate (also called 2,3-BPG or just BPG - Figure 2.89). Like protons and carbon dioxide, 2,3-BPG is produced by actively respiring tissues, as a byproduct of glucose metabolism. The 2,3-BPG mole-

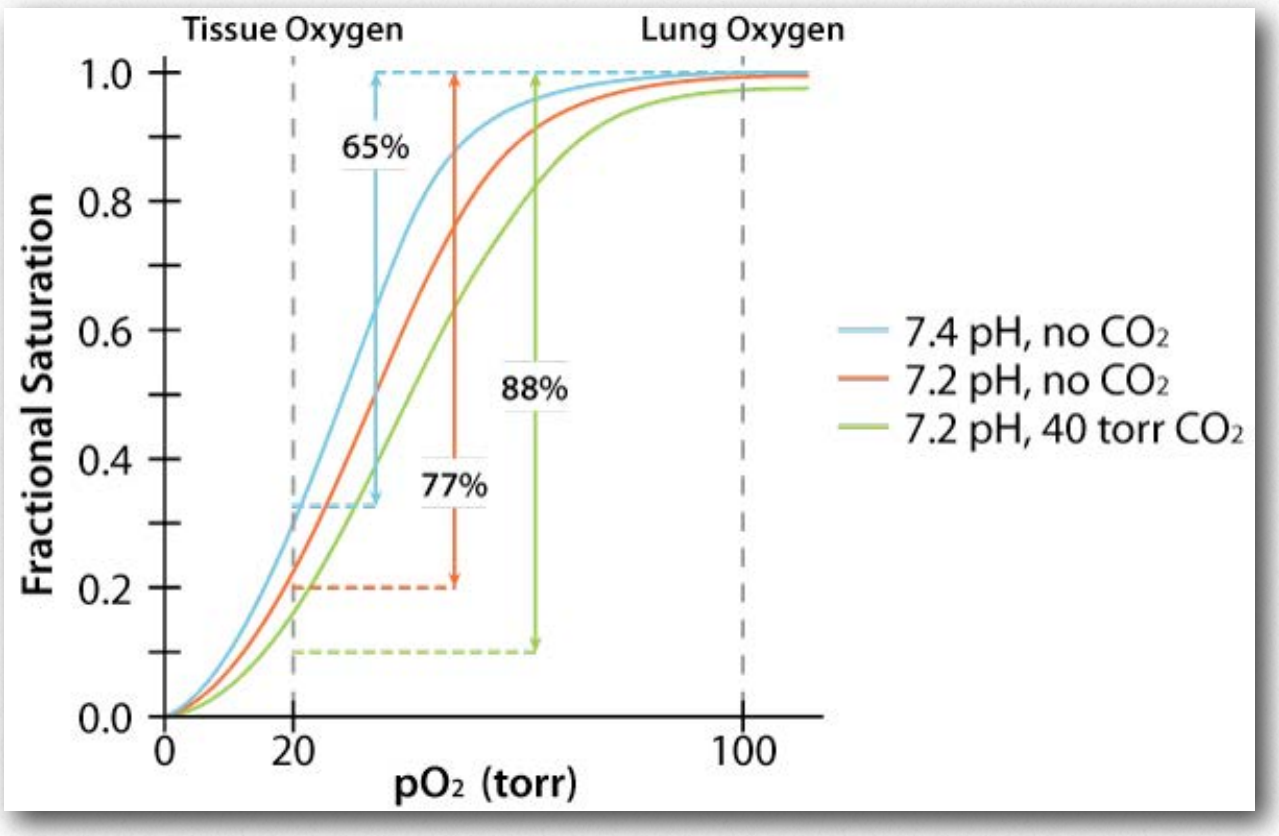

Figure 2.87 - Binding affinity of hemoglobin for oxygen under different conditions

Image by Aleia Kim

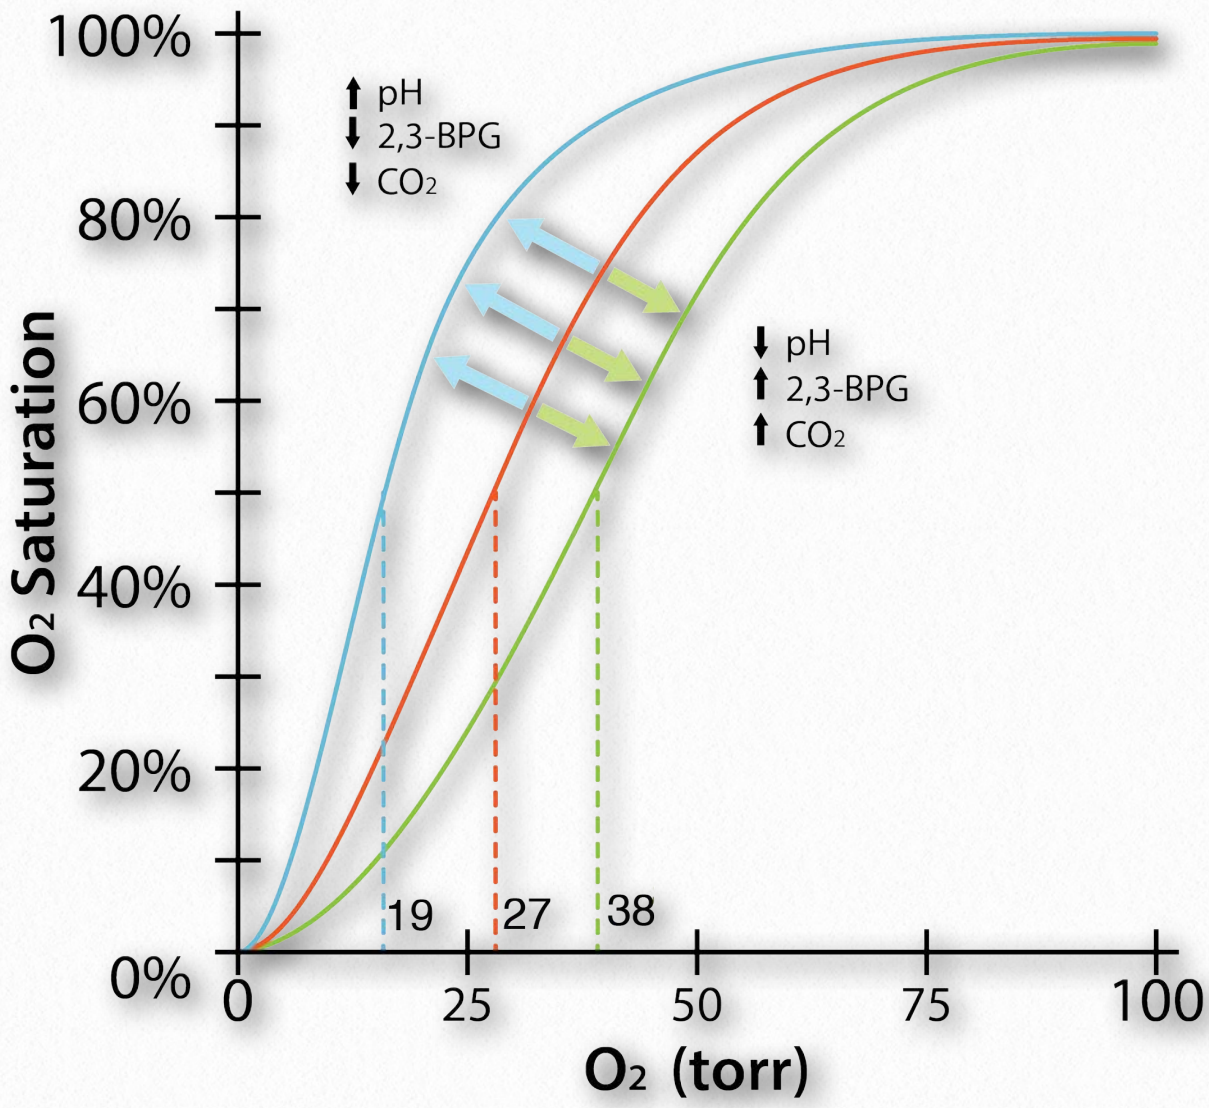

Figure 2.88 - The Bohr effect physiologically - oxygen binding curves for resting muscle (blue), active muscle (green) and reference muscle (orange) with respect to pH, 2,3-BPG, and CO_2

Image by Aleia Kim

cule fits into the 'hole of the donut' of adult hemoglobin (Figure 2.89). Such binding of 2,3-BPG favors the T-state (tight - low oxygen binding) of hemoglobin, which has a reduced affinity for oxygen. In the absence of 2,3-BPG, hemoglobin can more easily exist in the R-state (relaxed - higher oxygen binding), which has a high affinity for oxygen.

Smokers

Notably, the blood of smokers is higher in the concentration of 2,3-BPG than non-smokers, so more of their hemoglobin remains in the T-state and thus the oxygen carrying capacity of smokers is lower than non-smokers.

Another reason why smokers' oxygen carrying capacity is lower than that of non-smokers is that cigarette smoke contains carbon monoxide and this molecule, which has almost identical dimensions to molecular oxygen, effectively outcompetes with oxygen for binding to the iron atom of heme (Figure 2.90). Part of carbon monoxide's toxicity is due to its ability to bind hemoglobin and prevent oxygen from binding.

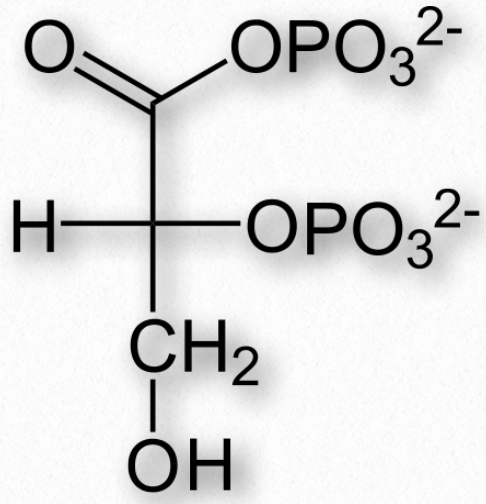

Figure 2.89 - The structure of 2,3 bisphosphoglycerate (2,3-BPG)

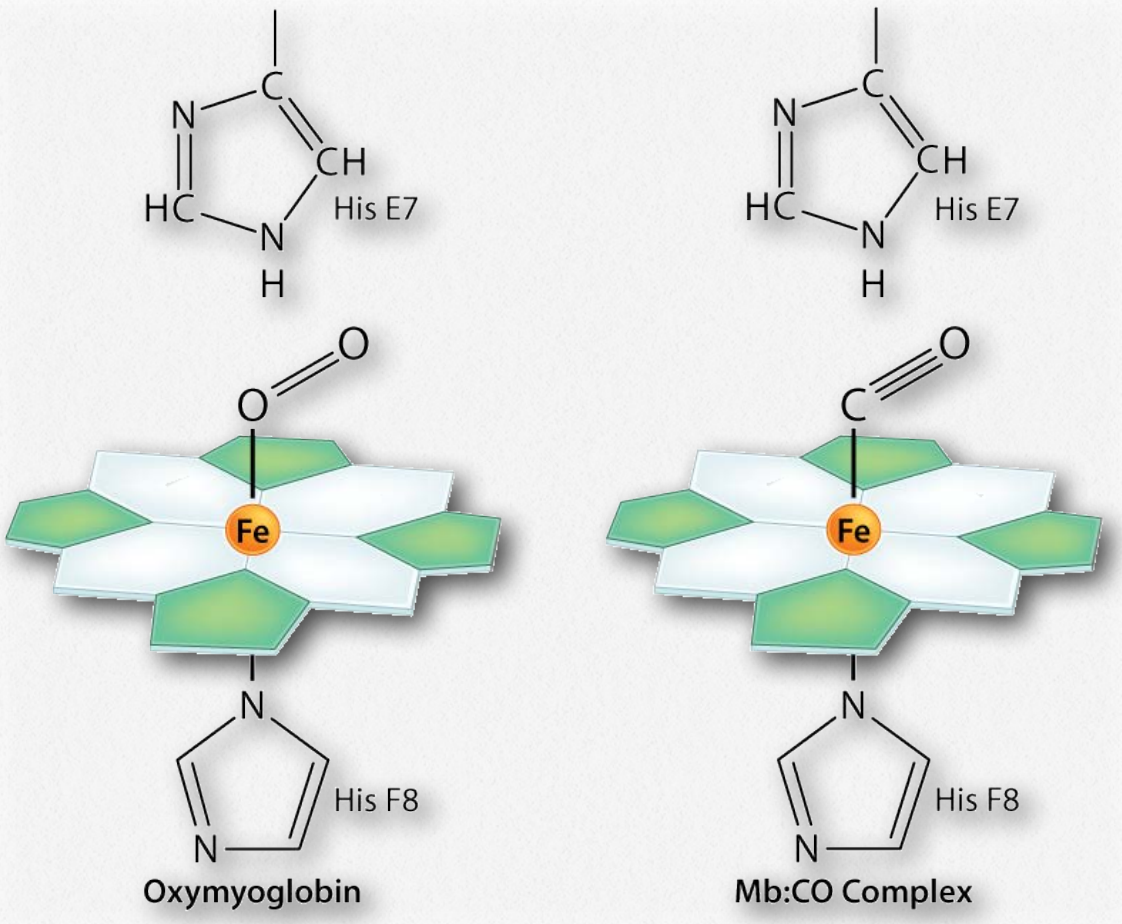

Figure 2.90 - Binding of oxygen (left) and carbon monoxide (right) by a heme group of hemoglobin

Image by Aleia Kim

back to the lungs by hemoglobin. The remainder travel as part of the bicarbonate buffering system or as dissolved CO_2. In the lungs, the process reverses itself. The lungs have a higher pH than respiring tissues, so protons are released from hemoglobin and CO_2 too is freed to be exhaled.

Carbon dioxide

Carbon dioxide binds to form a carbamate when binding the α-amine of each globin chain. The process of forming this structure releases a proton, which helps to further enhance the Bohr effect. Physiologically, the binding of CO_2 and H^+ has significance because actively respiring tissues (such as contracting muscles) require oxygen and release protons and carbon dioxide. The higher the concentration of protons and carbon dioxide, the more oxygen is released to feed the tissues that need it most.

About 40% of the released protons and about 20% of the carbon dioxide are carried

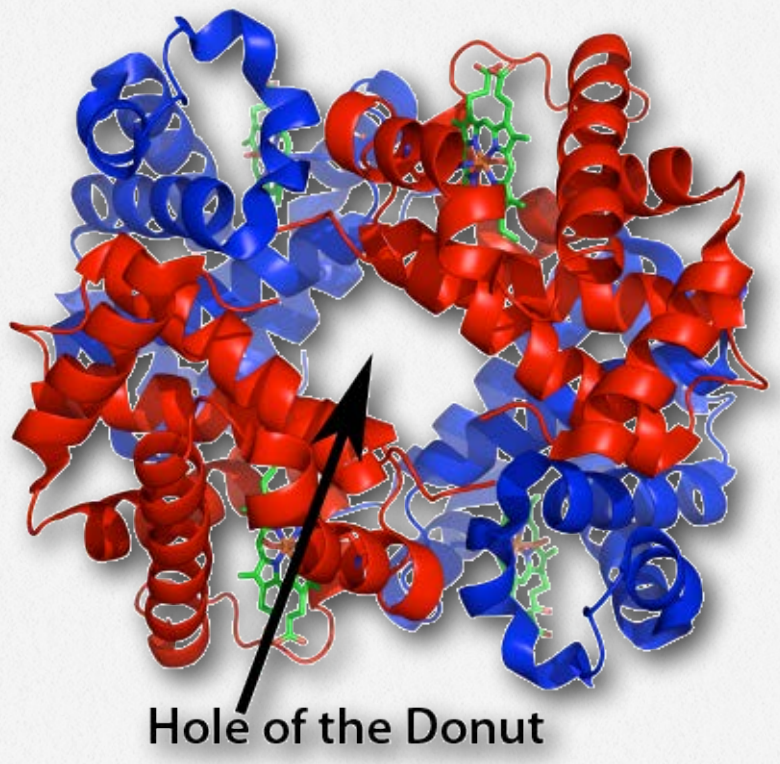

Figure 2.91 - Hemoglobin's hole of the donut for binding 2,3-BPG

Wikipedia

Fetal hemoglobin

Adult hemoglobin releases oxygen when it binds 2,3-

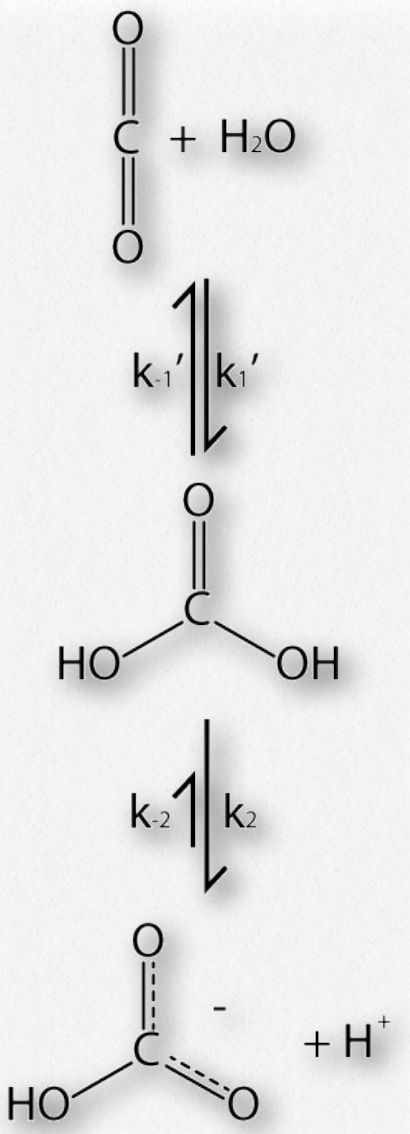

Figure 2.92 - Formation of bicarbonate from CO_2 in blood

BPG. This is in contrast to fetal hemoglobin, which has a slightly different configuration ($\alpha_2\gamma_2$) than adult hemoglobin ($\alpha_2\beta_2$). Fetal hemoglobin has a greater affinity for oxygen than maternal hemoglobin, allowing the fetus to obtain oxygen effectively from the mother's blood. Part of the reason for fetal hemoglobin's greater affinity for oxygen is that it doesn't bind 2,3-BPG. Consequently, fetal hemoglobin remains in the R-state much more than adult hemoglobin and because of this, fetal hemoglobin has greater affinity for oxygen than adult hemoglobin and can take oxygen away from adult hemoglobin. Thus, the fetus can get oxygen from the mother.

Sickle cell disease

Mutations to the globin genes coding for hemoglobin can sometimes have deleterious consequences. Sickle cell disease (also called sickle cell anemia) is a genetically transmitted disease that arises from such mutations. There are different forms of the disease. It is a recessive trait, meaning that to be afflicted with it, an individual must inherit two copies of the mutated gene.

The predominant form of hemoglobin in adults is hemoglobin A, designated HbA (two α chains and two β chains). The mutant form is known as HbS. The most common mutation is an A to T mutation in the middle of the codon for the seventh amino acid (some

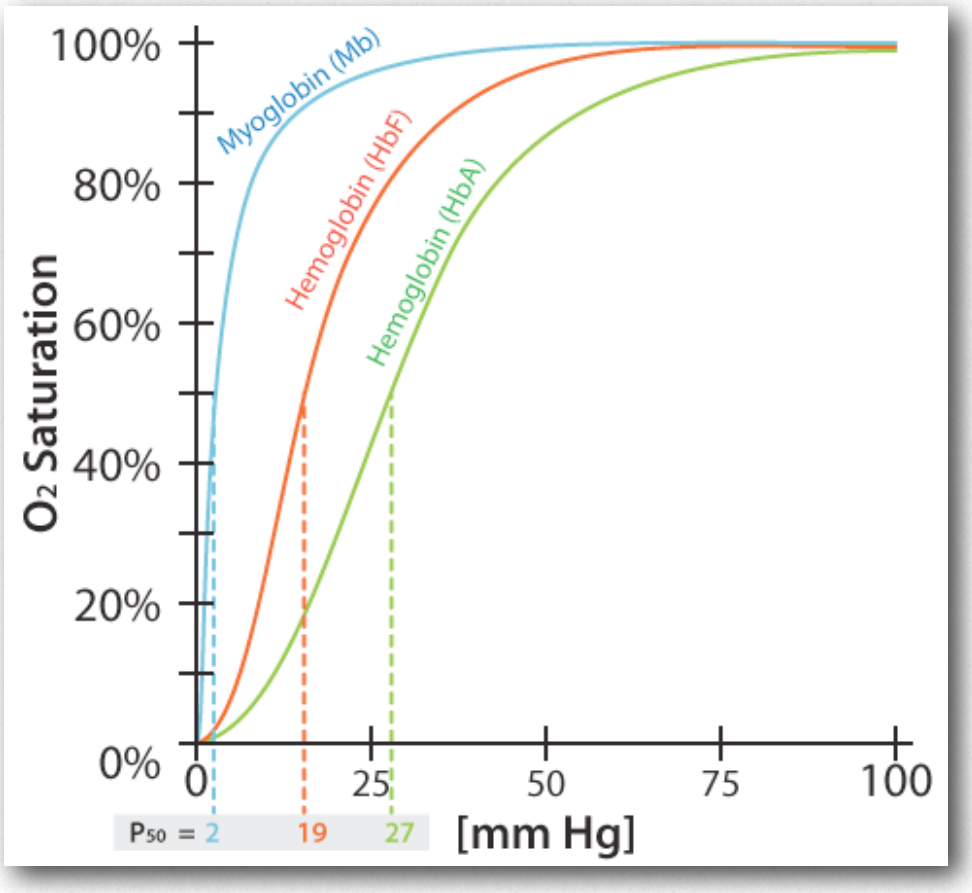

Figure 2.93 - Comparison of oxygen binding of myoglobin (blue), fetal hemoglobin (orange), and adult hemoglobin (green)

Wikipedia

counting schemes call it the sixth amino acid) of the β-chain. This results in conversion of a GAG codon to GTG and thus changes the amino acid specified at that position from a glutamic acid to a valine. This minor change places a small hydrophobic patch of amino acids on the surface of the β-globin chains.

Polymerization

Under conditions of low oxygen, these hydrophobic patches will associate with each other to make long polymers of hemoglobin molecules. The result is that the red blood cells containing them will change shape from being rounded to forming the shape of a sickle (Figure 2.94). Rounded red blood cells readily make it through tiny capillaries, but sickle-shaped cells do not.

Worse, they block the flow of other blood cells. Tissues where these blockages occur are already low in oxygen, so stopping the flow of blood through them causes them to go quickly anaerobic, causing pain and, in some cases, death of tissue. In severe circumstances,

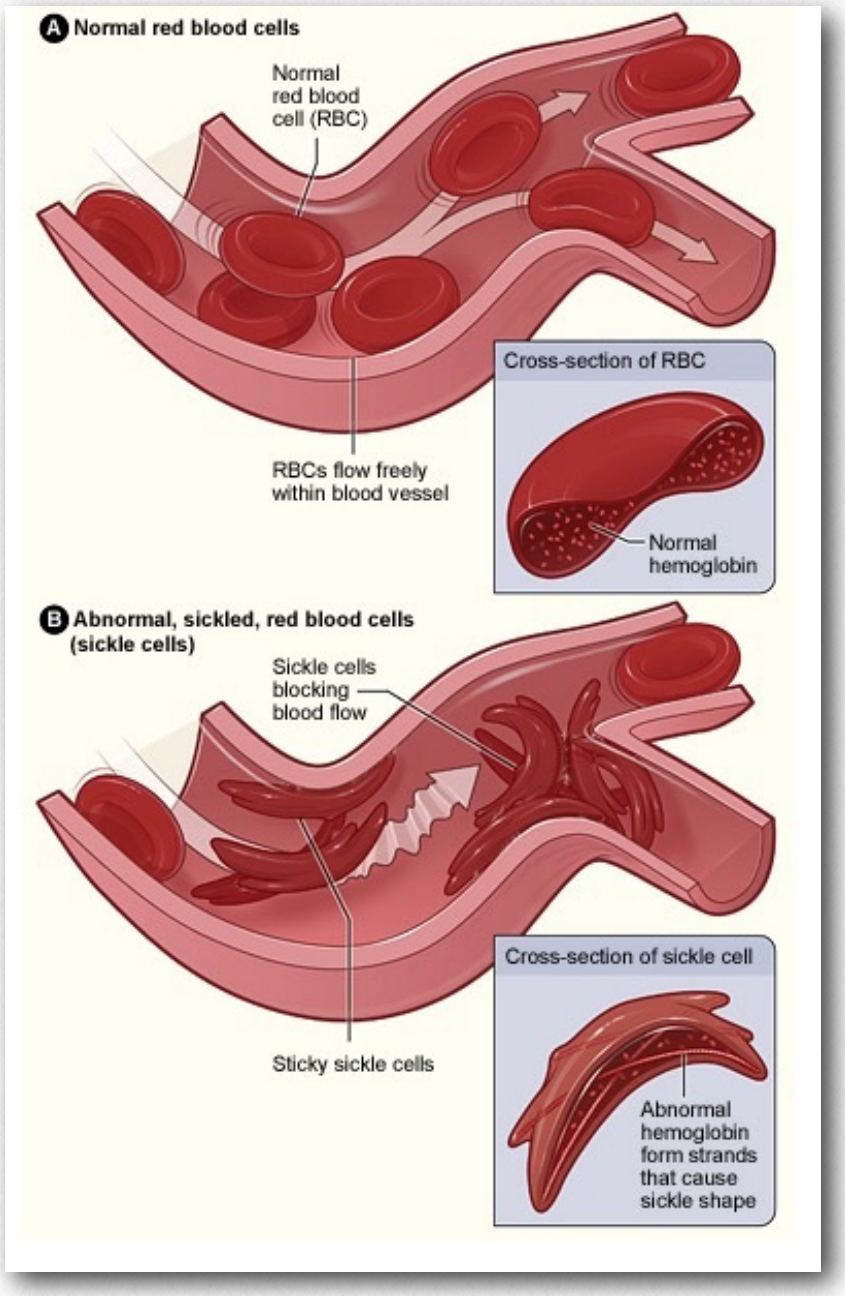

Figure 2.95 - Movement of blood in capillaries. Top - normal red blood cells. Bottom - sickled red blood cells

death may result. The disease is referred to as an anemia because the sickling of the red blood cells targets them for removal by the blood monitoring system of the body, so a person with the disease has chronically reduced numbers of red blood cells.

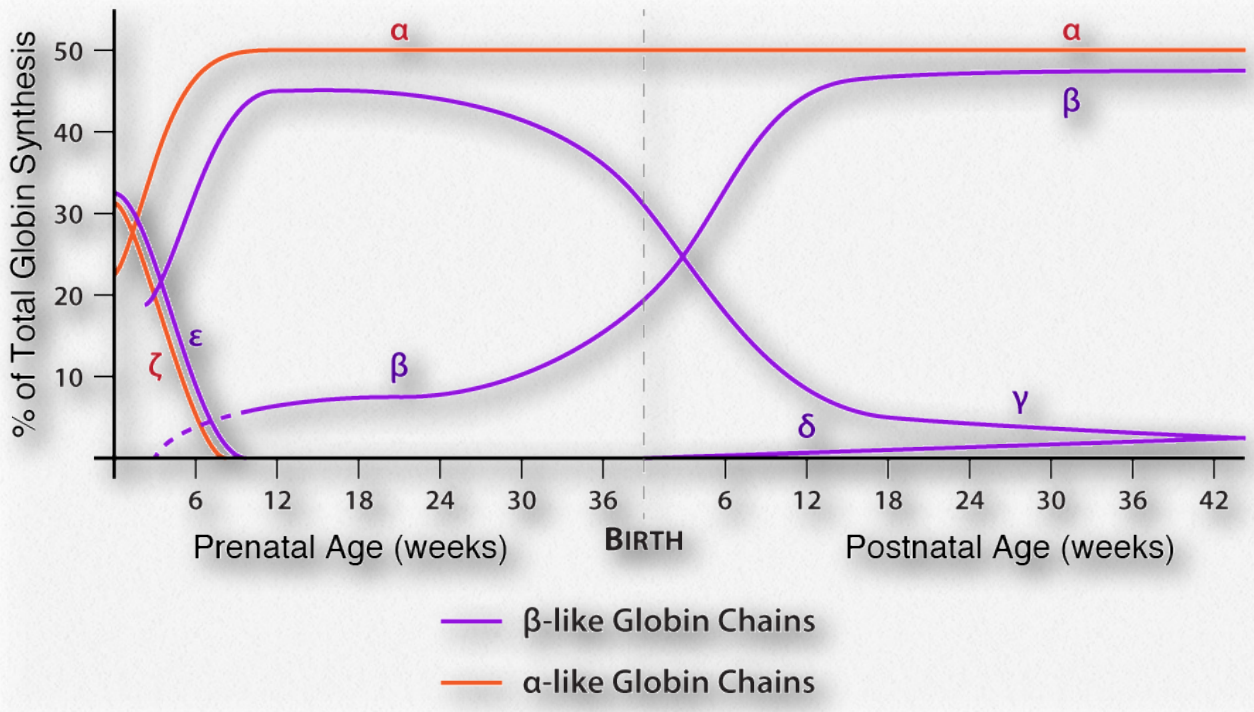

Figure 2.96 - Pattern of expression of six different globins of hemoglobin - α,β,γ,ε,δ, and ζ

Image by Aleia Kim

Heterozygote advantage

Interestingly, there appears to be a selective advantage to people who are heterozygous for the disease in areas where malaria is prominent. Heterozygotes do not suffer obvious ill effects of the disease, but their red blood cells appear to be more susceptible to rupture when infected. As a consequence, the parasite gets less of a chance to reproduce and the infected person has a greater chance of survival.

The protective effect of the mutant gene, though, does not extend to people who suffer the full blown disease (homozygotes for the mutant gene). Treatments for the disease include transfusion, pain management, and avoidance of heavy exertion. The drug hydroxyurea has been linked to reduction in number and severity of attacks, as well as an increase in survival time[1,2]. It appears to work by reactivating expression of the fetal hemoglobin gene, which typically is not synthesized to any significant extent normally after about 6 weeks of age.

Oxygen binding

Animals have needs for oxygen that differ from all other organisms. Oxygen, of course, is the terminal electron acceptor in animals and is necessary for electron transport to work. When electron transport is functioning, ATP generation by cells is many times more efficient than when it is absent. Since abundant ATP is essential for muscular contraction and animals move around a lot - to catch prey, to exercise, to escape danger, etc., hav-

ing an abundant supply of oxygen is important.

This is particularly a concern deep inside tissues where diffusion of oxygen alone (as occurs in insects) does not deliver sufficient quantities necessary for long term survival. The issue is not a problem for plants since, for the most part, their motions are largely related to growth and thus don't have rapidly changing needs/demands for oxygen that animals have. Unicellular organisms have a variety of mechanisms for obtaining oxygen and surviving without it. Two other important oxygen binding proteins besides hemoglobin are myoglobin and hemocyanin.

YouTube Lectures by Kevin HERE & HERE

Myoglobin

Myoglobin is the primary oxygen-storage protein found in animal muscle tissues. In contrast to hemoglobin, which circulates throughout the body, myoglobin protein is only found in muscle tissue and appears in the blood only after injury. Like hemoglobin, myoglobin binds oxygen at a prosthetic heme group it contains.

The red color of meat arises from the heme of myoglobin and the browning of meat by cooking it comes from oxidation of the ferrous (Fe^{++}) ion of myoglobin's heme to the ferric (Fe^{+++}) ion via oxidation in the cooking process. As meat sits in our atmosphere (an oxygen-rich environment), oxidation of Fe^{++} to Fe^{+++} occurs, leaving the brown color noted above. If meat is stored in a carbon monoxide (CO) environment, CO binds to the heme group and reduces the amount of oxidation, keeping meat looking red for a longer period of time.

High affinity

Myoglobin (Figure 2.97) displays higher affinity for oxygen at low oxygen concentrations than hemoglobin and is therefore able to absorb oxygen delivered by hemoglobin under these conditions. Myoglobin's high affinity for oxygen makes it better suited for oxygen storage than delivery. The protein exists as a single subunit of globin (in contrast to hemoglobin, which contains four subunits) and is related to the

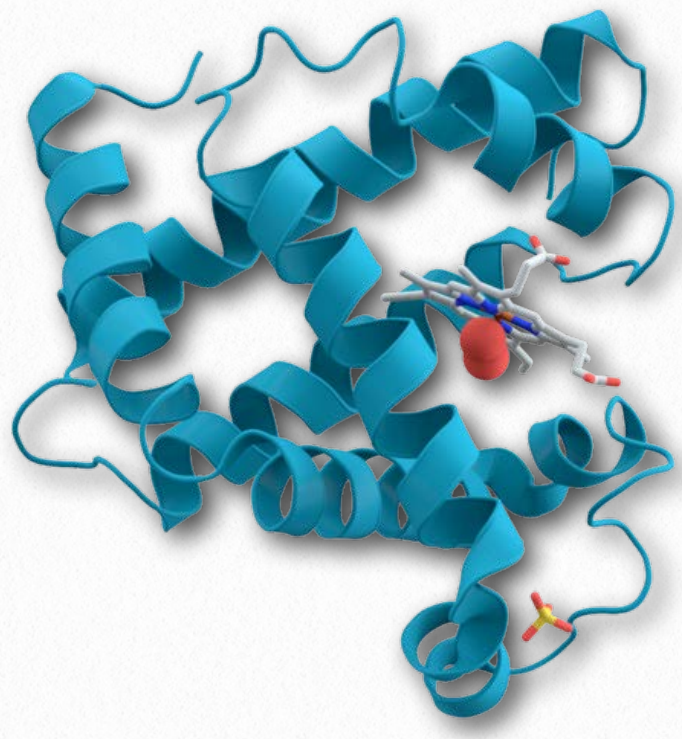

Figure 2.97 - Myoglobin bound to oxygen

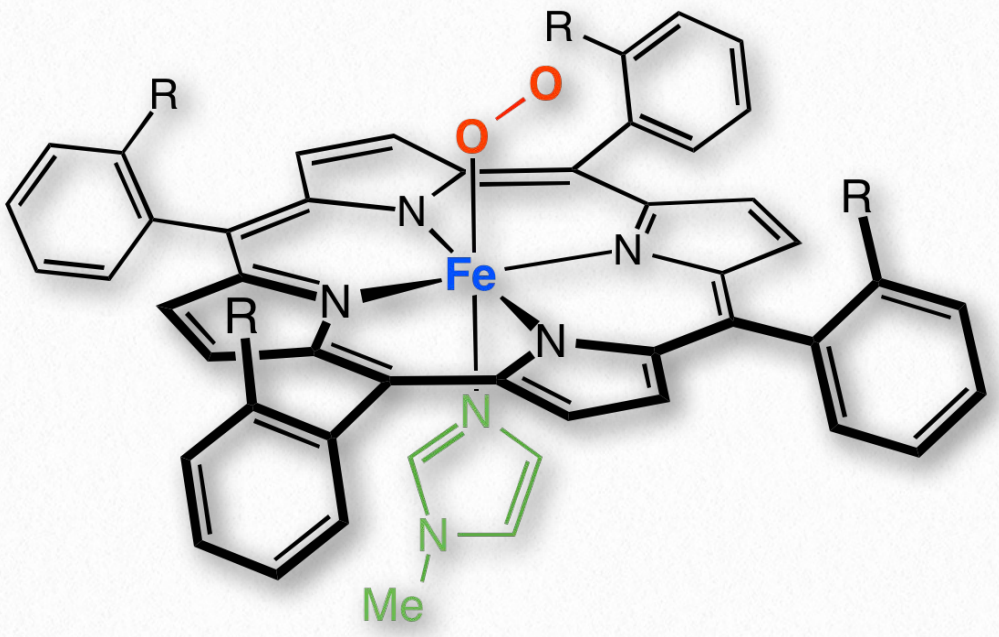

Figure 2.98 - Oxygen bound at heme of myoglobin

Wikipedia

subunits found in hemoglobin. Mammals that dive deeply in the ocean, such as whales and seals, have muscles with particularly high abundance of myoglobin. When oxygen concentration in muscles falls to low levels, myoglobin releases its oxygen, thus functioning as an oxygen “battery” that delivers oxygen fuel when needed and holding onto it under all other conditions. Myoglobin holds the distinction of being the first protein for which the 3D structure was determined by X-ray crystallography by John Kendrew in 1958, an achievement for which he later won the Nobel Prize.

Hemocyanin

Hemocyanin is the protein transporting oxygen in the bodies of molluscs and arthropods. It is a copper-containing protein found not within blood cells of these organisms, but rather is suspended in the circulating hemolymph they possess. The oxygen binding site of hemocyanin contains a pair of copper(I) cations directly coordinated to the protein by the imidazole rings of six histidine side chains.

Most, but not all hemocyanins bind oxygen non-cooperatively and are less efficient than hemoglobin at transporting oxygen. Notably, the hemocyanins of horseshoe crabs and some other arthropods do, in fact, bind oxygen cooperatively. Hemocyanin contains many subunit proteins, each with two copper atoms that can bind one oxygen molecule (O_2). Subunit proteins have atomic masses of about 75 kilodaltons (kDa). These may be arranged in dimers or hexamers depending on species.

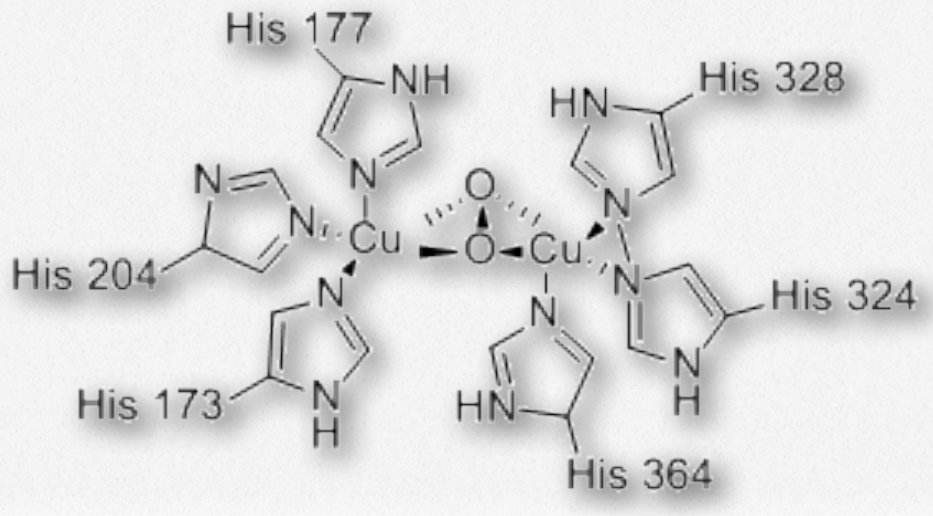

Figure 2.99 - Oxygen binding in hemocyanin

Wikipedia

Figure 2.100 - Hemocyanin (purple) in a red rock crab

Wikipedia

Superstructures comprised of dimer or hexamer complexes are arranged in chains or clusters and have molecular weights of over 1500 kDa.

Hemoglobin's Moving Around

To the tune of "*Santa Claus is Coming to Town*"

Metabolic Melodies Website HERE

Oh isn't it great?
What proteins can do
Especially ones that bind to O2
Hemoglobin's moving around

Inside of the lungs
It picks up the bait
And changes itself from T to R state
Hemoglobin's moving around

The proto-porphyrin system
Its iron makes such a scene
Arising when an O2 binds
Pulling up on histidine

The binding occurs
Cooperatively
Thanks to changes qua-ter-nar-y
Hemoglobin's moving around

It exits the lungs
Engorged with O2
In search of a working body tissue
Hemoglobin's moving around

The proton concentration
Is high and has a role
Between the alpha betas
It finds imidazole

To empty their loads
The globins decree
"We need to bind 2,3BPG"
Hemoglobin's moving around

The stage is thus set
For grabbing a few
Cellular dumps of CO2
Hemoglobin's moving around

And then inside the lungs it
Discovers ox-y-gen
And dumps the CO2 off
To start all o'er agin

So see how this works
You better expect
To have to describe the Bohr effect
Hemoglobin's moving around

The Bloody Things

To the tune of "*Coke ® It's The Real Thing*"

Metabolic Melodies Website **HERE**

I'm gonna put some oxygens
beside my porphyrin rings
To nudge the irons up a notch
and yank on histidines
The globins' shapes will change a bit,
oh what a sight to see
The way they bind to oxygen
co-op-er-AH-tive-ly

And as I exit from the lungs
to swim in the bloodstream
Metabolizing cells they all
express their needs to me
To them I give up oxygen
and change from R to T
While my amines, they hang onto
the protons readily

But that's not all the tricks I know,
there's more that's up my sleeve
Like gaps between sub-U-nits that
hold 2,3-BPG
When near met-a-bo-LI-zing cells,
I bind things that diffuse
The protons and bicarbonates
from lowly cee oh twos

CHORUS
That's the way it is
When your cells are at play
Go say hip hip hooray
For the bloody things

Recording by David Simmons
Lyrics by Kevin Ahern

Heme

To the tune of "*Jean*"

Metabolic Melodies Website HERE

Heme, heme, colored supreme
Deepest red I've ever seen
When my oxygen's low
Hemoglobin will know
Give up your oxygen, heme

Heme, heme porphyrin ring
Bonded to five histidines
When an oxygen binds
To your iron it climbs
Tugging its histidine, heme

Then the globin arranges itself a new way
And the three other units tell their hemes OK
They can go on a bindin' - oh-two they're findin'

Then heme, heme leaving the lungs
Travels inside the bloodstream
When it finds a tissue
That is lacking oh-two
It gives what it needs, bloody heme

Heme, you keep me alive
Binding coop'ratively
Go release what I need
Christian Bohr has decreed
Tissues adore you, lovely heme

Lyrics by Kevin Ahern

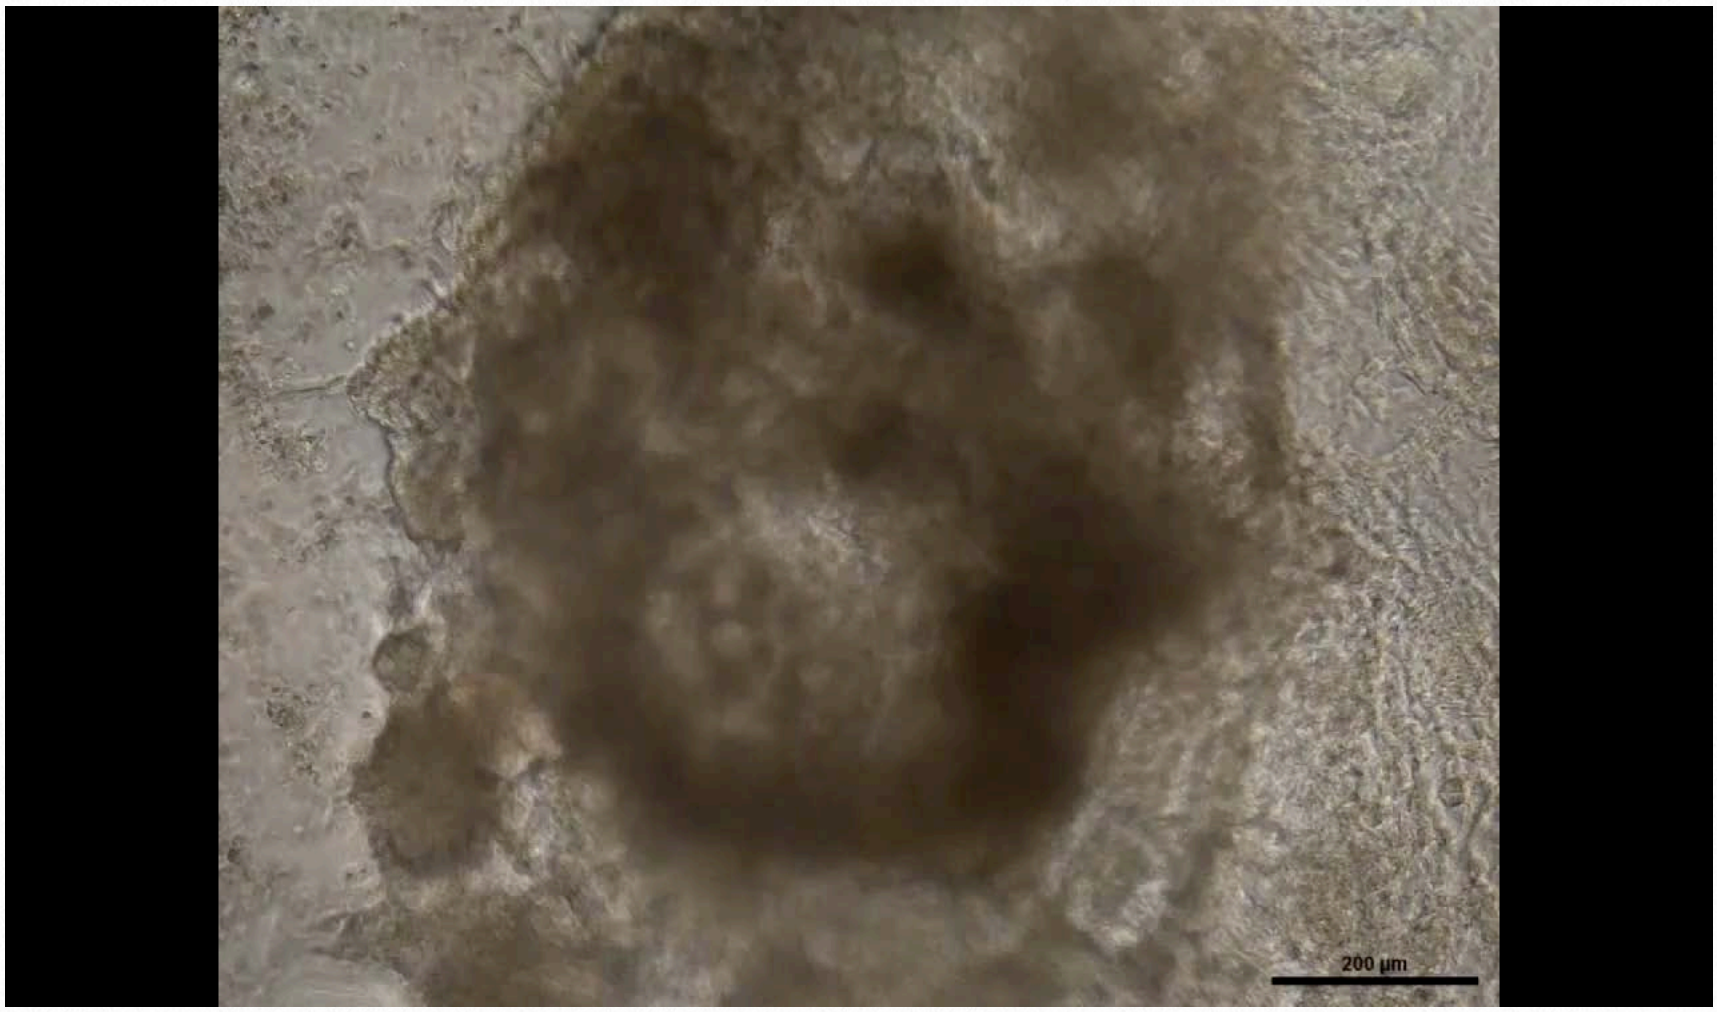
Structure and Function: Protein Function II



To this point, the proteins we have discussed have not been catalysts (enzymes). The majority of proteins in cells, however, catalyze reactions. In this section we begin our discussion of a subclass of proteins that catalyze reactions releasing energy and convert it into mechanical force. These operate at the cellular and organismal level and are known as motor proteins. Motor proteins rely on globular structural proteins, so it is important that we describe how these cellular "railways" are assembled before discussing the motor proteins themselves. There are two relevant fibrous structures serving as rails for motor proteins. They are 1) microfilaments (composed of an actin polymer) and 2) microtubules (composed of a polymer of tubulin.

YouTube Lectures by Kevin
HERE & HERE

Actin

The monomeric unit of actin is called G-actin (globular actin) and the polymer is known as F-actin (filamentous actin). Filaments of F-actin comprise the smallest filaments of cells

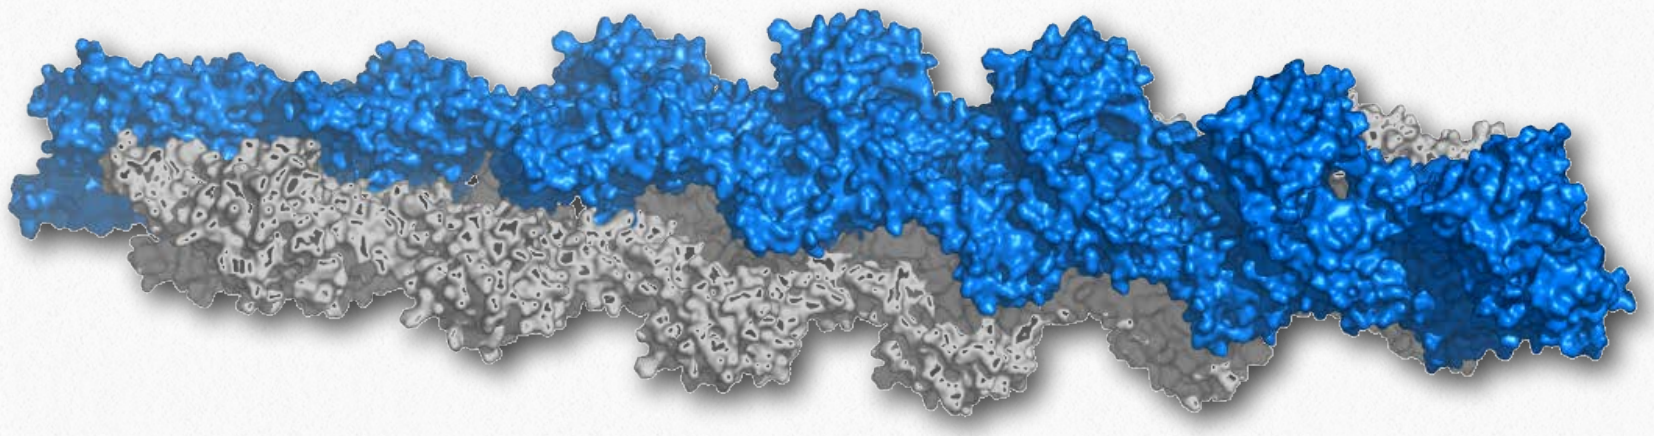


Figure 2.101 - Model of actin filaments

Wikipedia

known as microfilaments (Figure 2.101). Actin is essential for muscular contraction and also has diverse roles in cellular signaling and maintenance of cell junctions. In conjunction with other proteins, actin has numerous interactions with the cell membrane. The β- and γ-forms of actin are components of the cytoskeleton and facilitate motility inside of cells. α-actin is important in muscle tissues, where it is used by myosin in the mechanical process of contraction (See HERE).

Monomeric and polymeric forms of actin play roles in cellular activities relating to motion. Two parallel F-actin strands can pair with each other and create a double helical structure with 2.17 subunits per turn of the helix. Helical F-actin in muscles contains tropomyosin, which covers the actin binding sites for myosin in resting muscles to prevent contraction. Other proteins bound to actin muscle filaments include the troponins (I, T, and C).

Actin cellular action

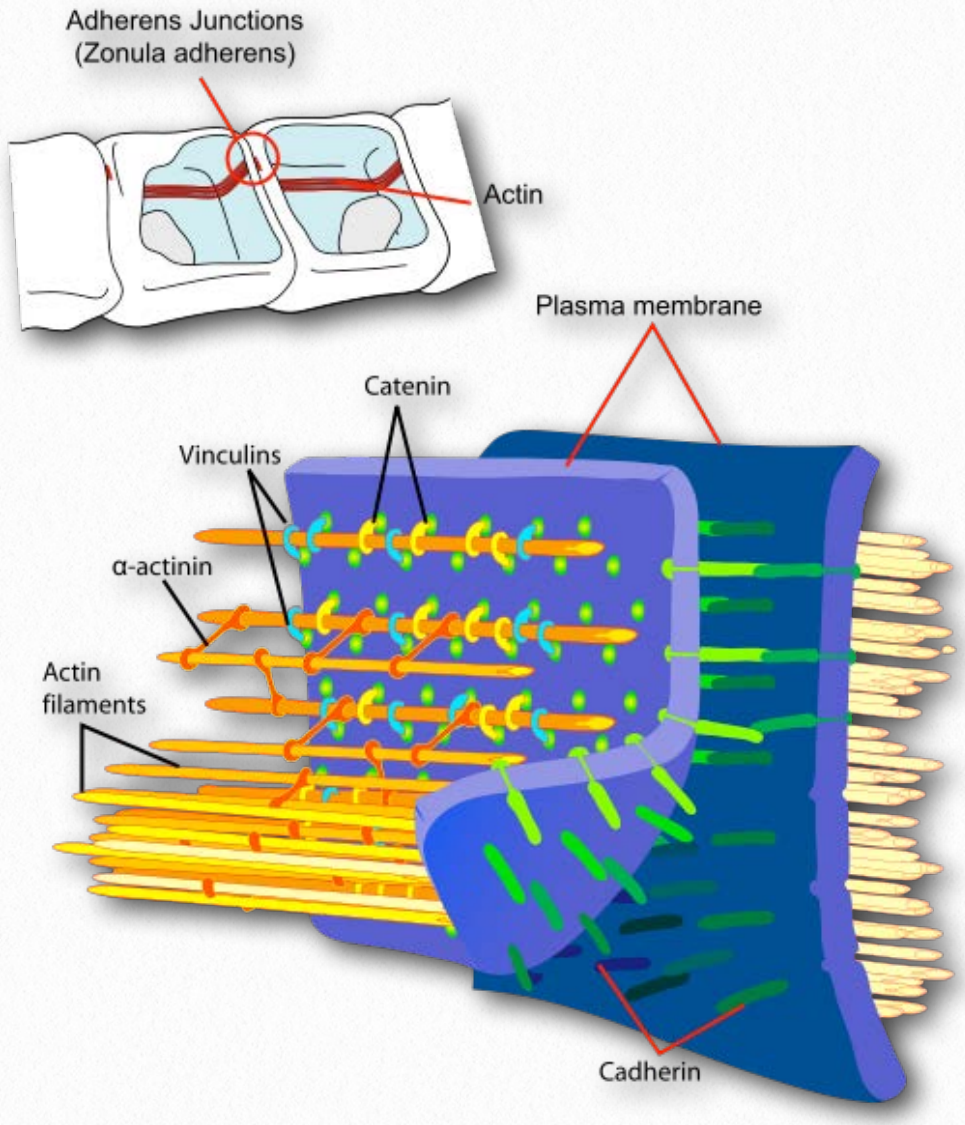

Figure 2.102 - Attachment of actin at the cell membrane complex known as the adherens junction

Wikipedia

Examples of actin action at the cellular level include cell motility, cytokinesis, intracellular transport of vesicles and organelles, and cell shape. Each actin monomer is bound to a molecule of ATP or ADP and the presence of one of these is essential for proper G-actin functioning.

The role of ATP

In the monomer, actin is more commonly bound to ATP, whereas in the filaments, it is typically bound to ADP. Actin is an inefficient ATPase, breaking the molecule down slowly, but the catalysis speeds up as much as 40,000 fold when the monomer begins to polymerize. Actin also has a binding site for divalent cations - either calcium or magnesium.

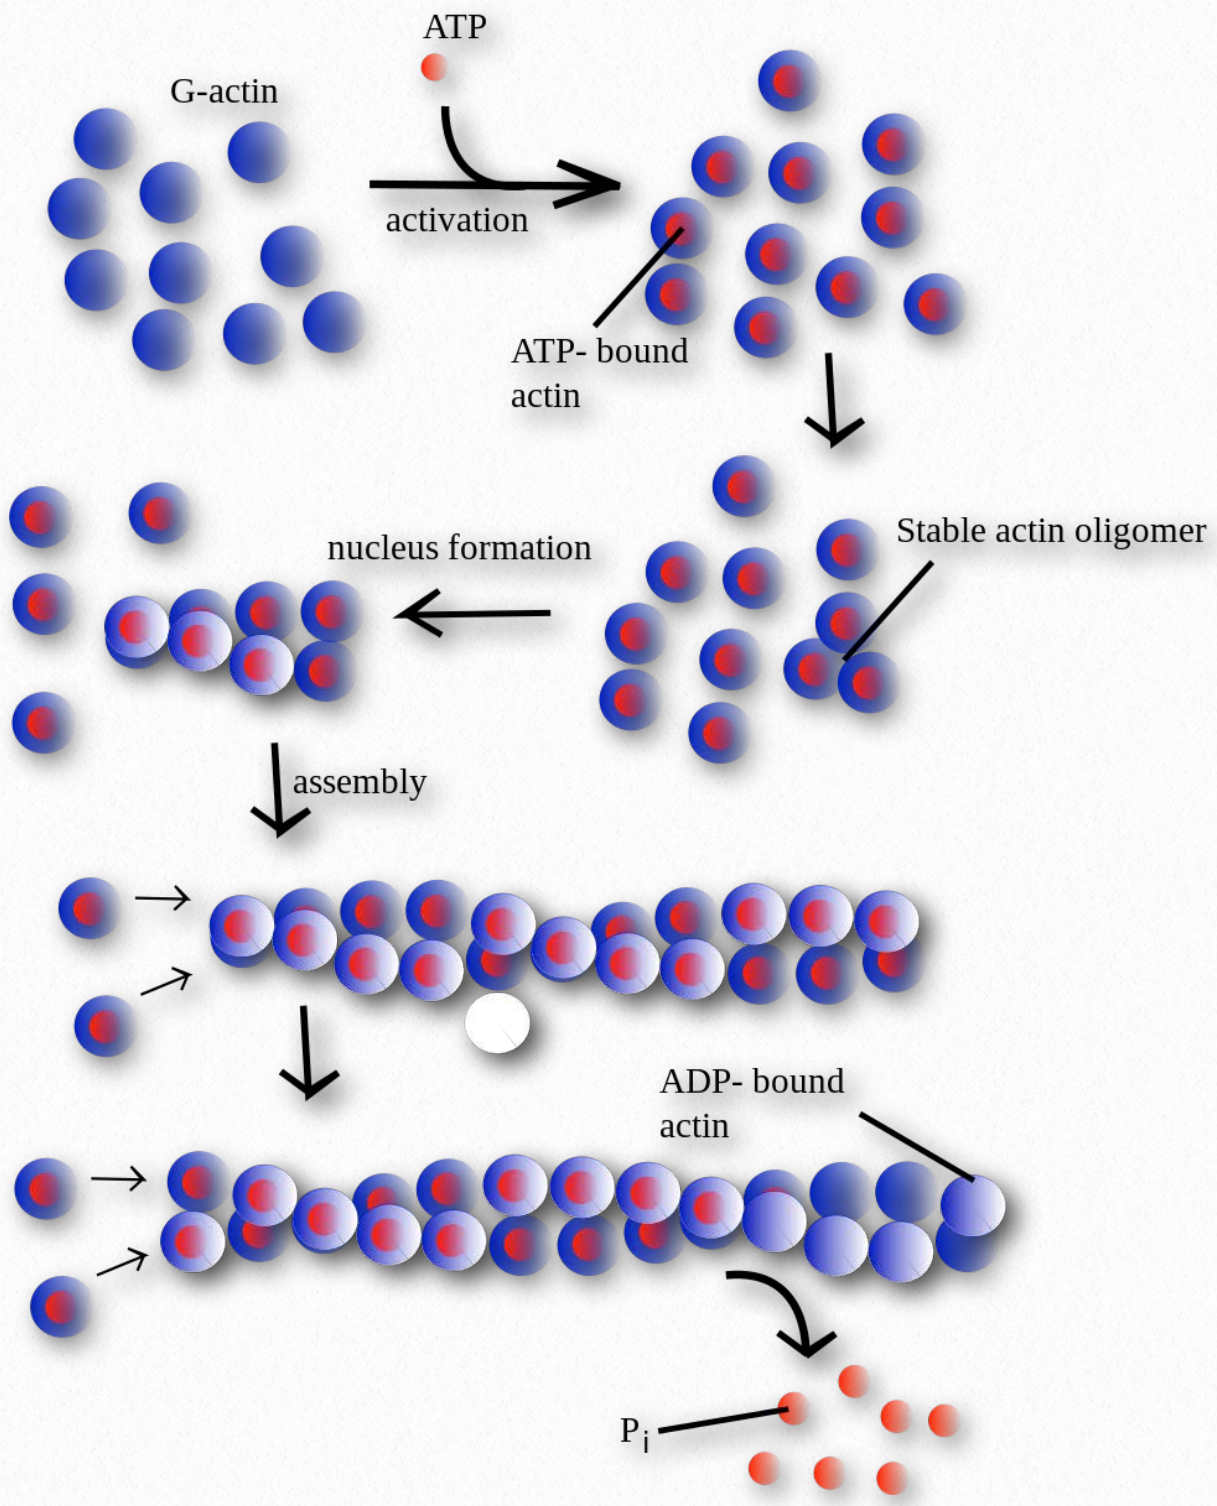

Figure 2.103 - Polymerization of G-actin monomers into F-actin polymers

Wikipedia

F-Actin binds to structural proteins at the adherens junction (Figure 2.102). These include α-actinin, vinculin (provides a membrane connection and connections to the catenins and cadherin).

Polymerization

Polymerization of actin begins with a nucleating event (Figure 2.103). One factor known to affect the process is known as the Arp 2/3 complex. It does this by mimicking an actin dimer, starting an autocatalytic process of actin assembly. The Arp 2/3 complex plays

roles both in the initiation of polymerization of new actin filaments as well as the formation of branches in the filaments.

Two proteins play roles in modulating polymer growth. Thymosin functions on the end of actin filaments to control growth. Profilin works on G-actin monomers exchanging ADP for ATP, promoting addition of monomers to a growing chain.

F-actin filaments are held together by relatively weak bonds compared to the covalent bonds of the monomers of nucleic acids, thus allowing for easier disassembly when desired.

Actin's amino acid sequence is optimized, having diverged only a relatively small amount (20%) between algae and humans. Mutations in the actin gene result in muscular diseases and/or deafness.

Tubulin

Tubulin proteins are the monomeric building blocks of eukaryotic microtubules (Figure 2.104 & 2.105). Bacterial (TubZ) and archaeon (FtsZ) equivalents are known. The α-tubulin and β-tubulin proteins polymerize to make microtubule structures in the cytoplasm of cells. Microtubules are major components of the cytoskeleton of eukaryotic cells, providing structural support, transport within the cell, and functions necessary for segregation of DNAs during cell division.

Dimerization of the α-tubulin and β-tubulin proteins is necessary for polymerization and requires that the subunits bind to GTP. Microtubules only grow in one direction. β-tubulin is found on the plus end of the tubule (growth end = plus end) and α-tubulin is exposed on the other end (non-growth end = minus end). Dimers of α-tubulin/β-tubulin are incorporated into growing microtubules in this orientation. If a dimer is bound to GDP

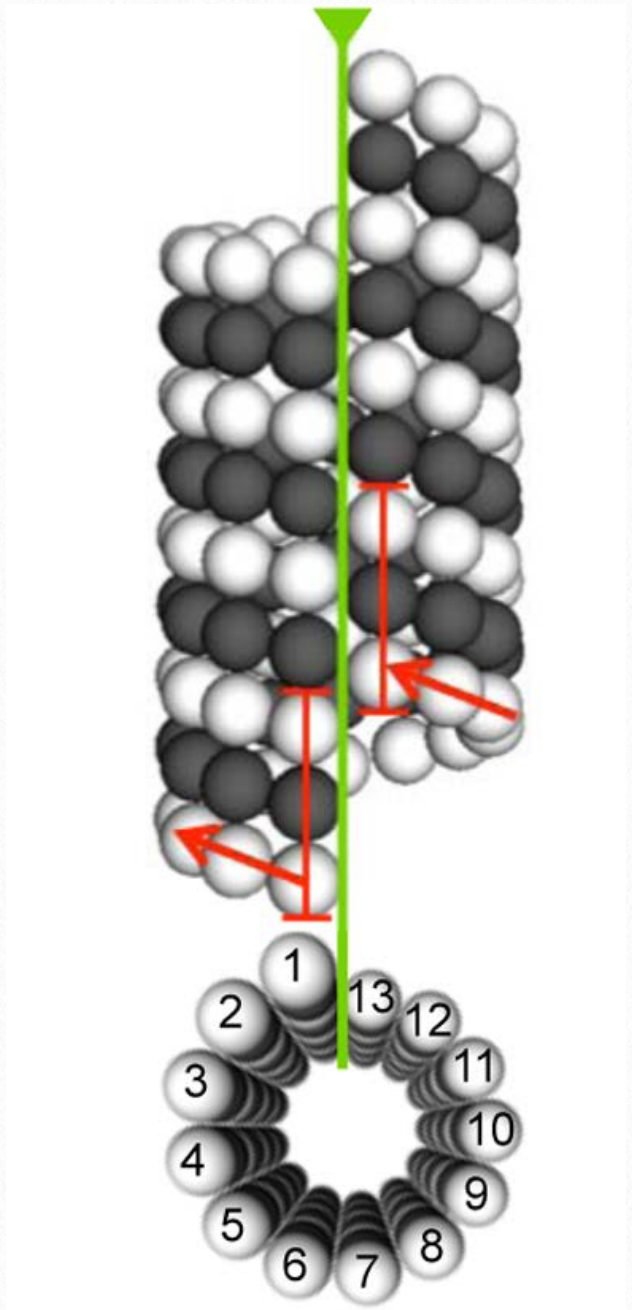

Figure 2.104 **Microtubule structure**

Wikipedia

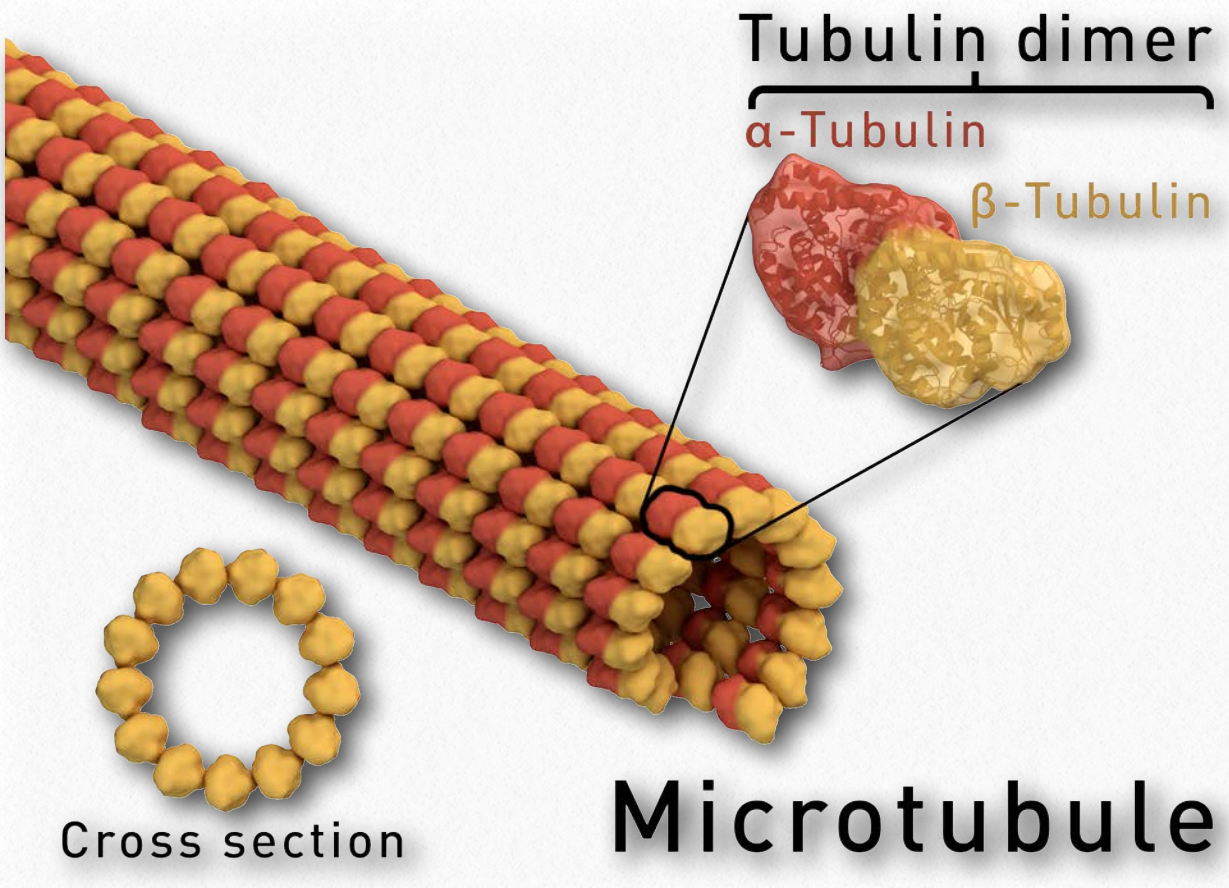

Figure 2.105 - Microtubule anatomy

Wikipedia

instead of GTP, it tends to be unstable and fall apart, whereas those bound to GTP stably assemble into microtubules.

Microtubules

Microtubules, along with microfilaments and intermediate filaments (see HERE) constitute the cytoskeleton of cells. Found in the cytoplasm, they are found in eukaryotic cells, as well as some bacteria. Microtubules help to give cells structure. They comprise the inner structure of flagella and cilia and provide rail-like surfaces for the transport of materials within cells.

Polymerization of α-tubulin and β-tubulin to form microtubules occurs after a nucleating event. Individual units get arranged in microtubule organizing centers (MTOCs), an exam-

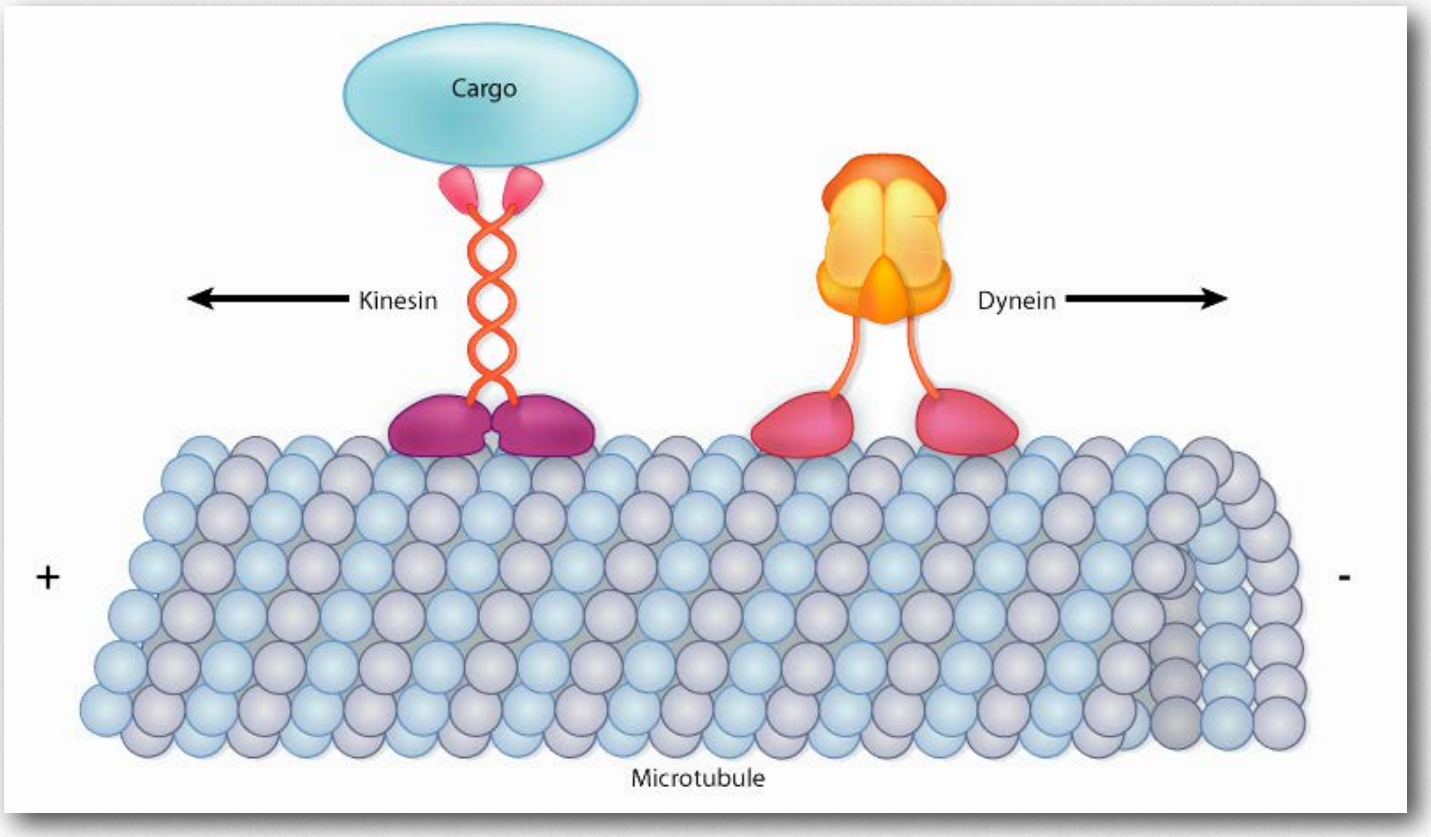

Figure 2.106 - Kinesin and dynein "walk" along microtubules, but move in opposite directions

Image by Aleia Kim

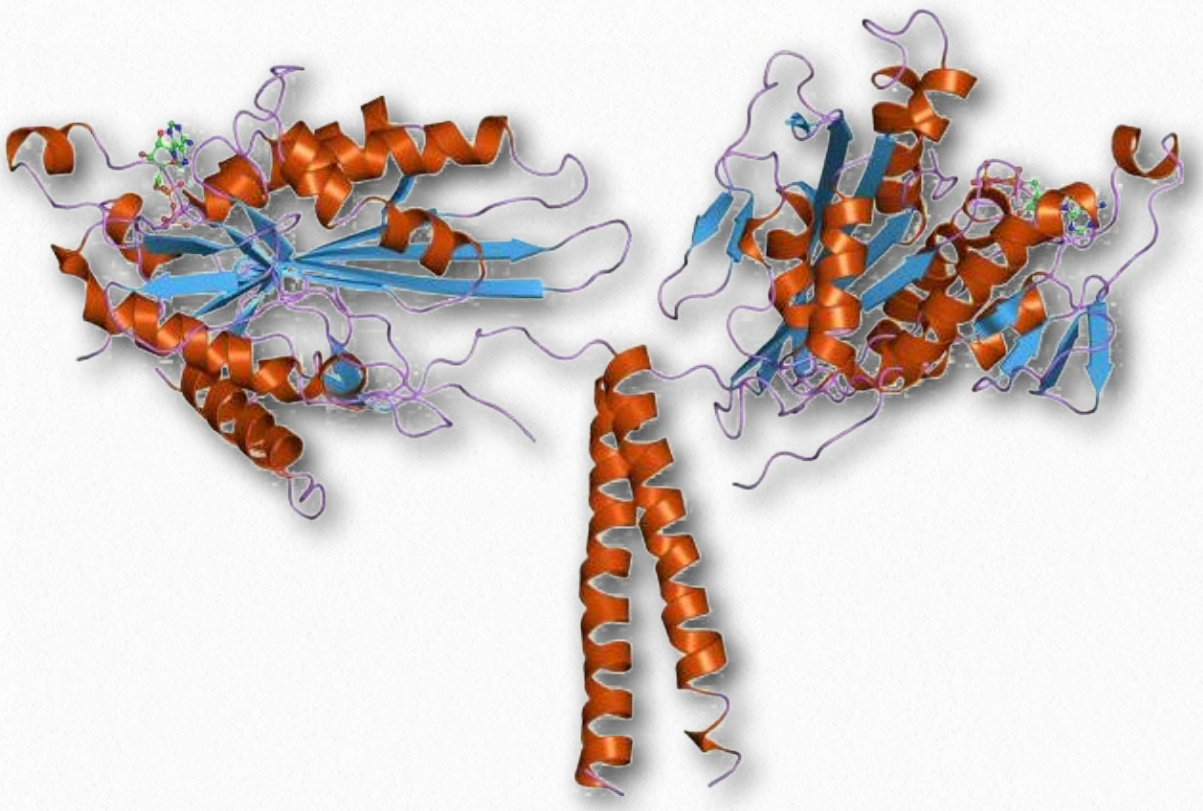

Figure 2.107 - Kinesin. "Feet" are at the top.

ple of which is the centrosome. Centrosomes are focal points of connection of microtubules. Basal bodies of cilia and flagella also help to organize microtubules.

Motor proteins

From the transport of materials within a cell to the process of cytokinesis where one cell splits into two in mitosis, a cell has needs for motion at the molecular level. Secretory vesicles and organelles must be transported. Chromosomes must be separated in mitosis and meiosis.

The proteins dynein and kinesin (Figure 2.106) are necessary for intracellular movement. These motor proteins facilitate the movement of materials inside of cells along microtubule "rails". These motor proteins are able to move along a portion of the cytoskeleton by converting chemical energy into motion with the hydrolysis of ATP. An exception is flagellar rotation, which uses energy provided from a gradient created by a proton pump.

Kinesins and dyneins

As noted, kinesins and dyneins navigate in cells on microtubule tracks (Figure 2.108 & Movie

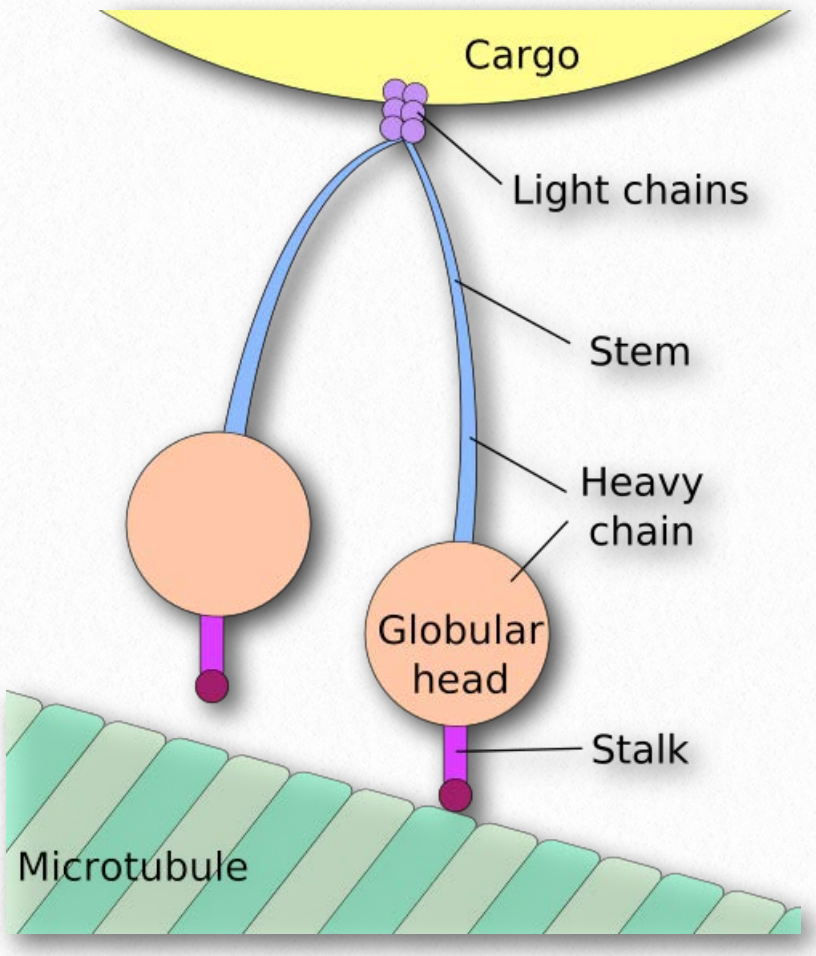

Figure 2.108 - Nomenclature of dynein. The "feet" of Figure 2.105 are the stalk and globular head of the structure here.
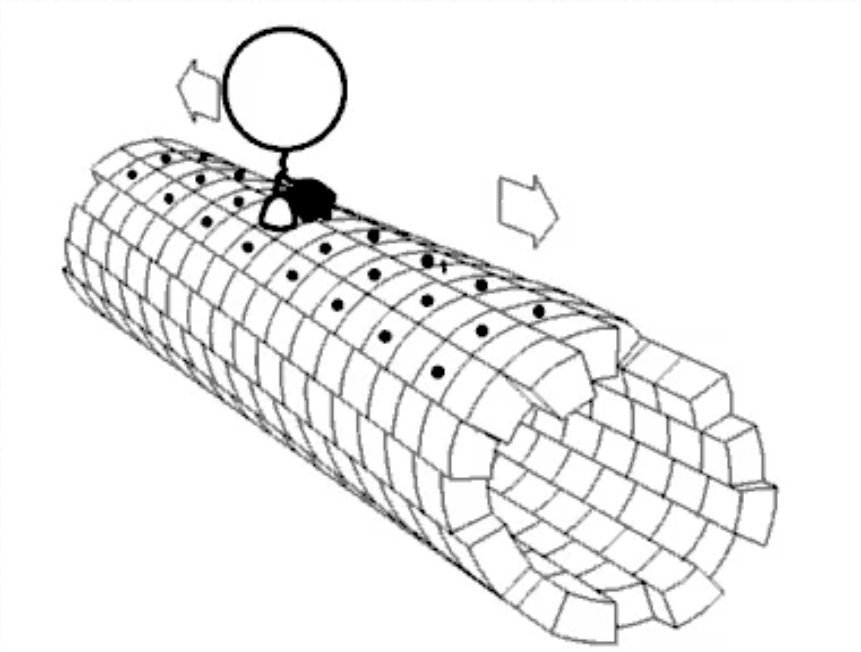
Wikipedia



Movie 2.4 The motor protein kinesin walking down a microtubule

Wikipedia

2.4). Most kinesins move in the direction of the synthesis of the microtubule (+ end movement), which is generally away from the cell center and the opposite direction of movement of dyneins, which are said to do retrograde transport toward the cell center. Both proteins provide movement functions necessary for the processes of mitosis and meiosis. These include spindle formation, chromosome separation, and shuttling of organelles, such as the mitochondria, Golgi apparatuses, and vesicles.

Kinesins are comprised of two heavy chains and two light chains. The head motor domains of heavy chains (in the feet) use energy of ATP hydrolysis to do mechanical work for the movement along the microtubules. There are at least fourteen distinct kinesin families and probably many related ones in addition.

Dyneins are placed into two groups - cytoplasmic and axonemal (also called ciliary or flagellar dyneins - Figure 2.109). Dyneins are more complex in structure than kinesins with many small polypeptide units. Notably, plants do not have dynein motor proteins, but do contain kinesins.

Myosin

An important group of motor proteins in the cell is the myosins. Like kinesins and dyneins, myosins use energy from hydrolysis of ATP for movement. In this case, the movement is mostly not along microtubules, but rather along microfilaments comprised of a polymer of actin (F-actin). Movement of myosin on actin is best known as the driving force for muscular contraction. Myosins

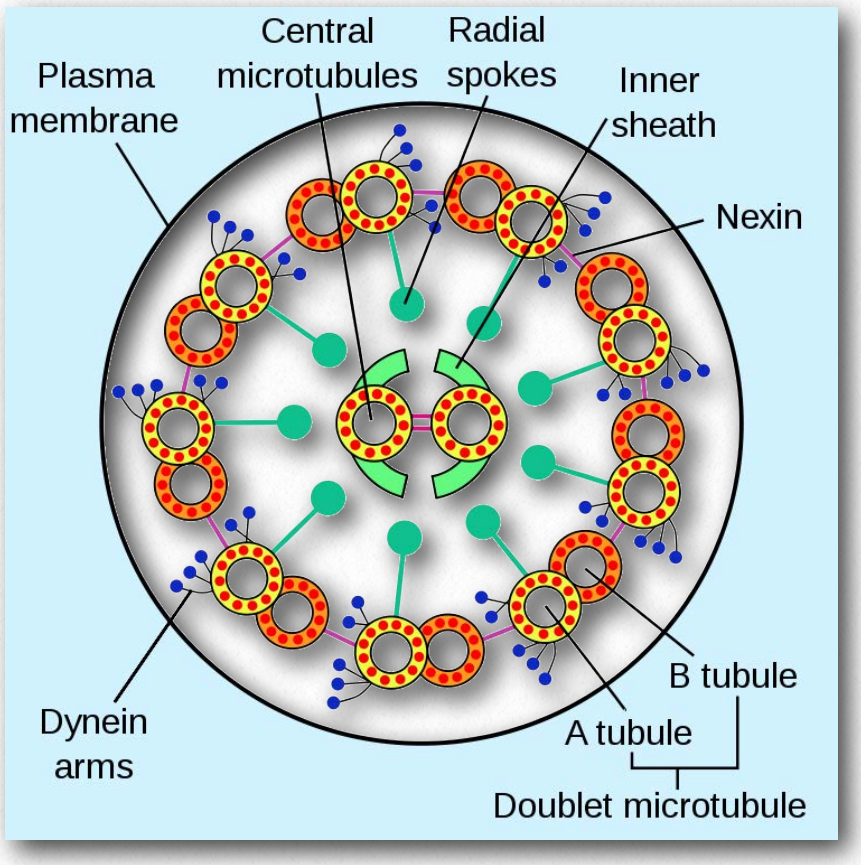


Figure 2.109 - Dynein in an axoneme

Wikipedia

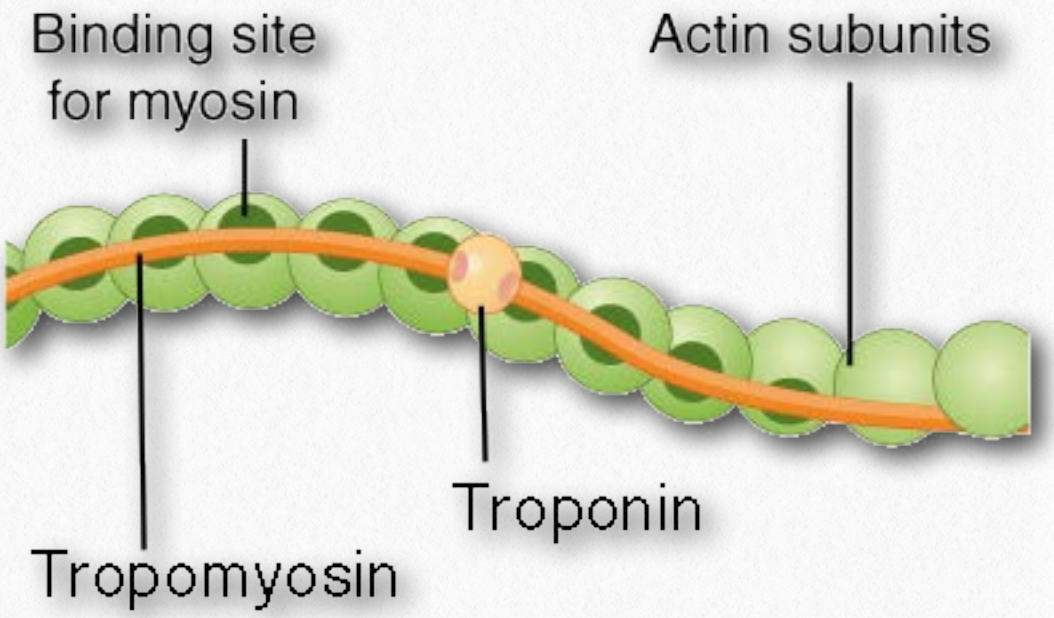

Figure 2.110 - Actin filament anatomy

Wikipedia

are a huge family of proteins, all of which bind to actin and all of which involve motion. Eighteen different classes of myosin proteins are known. Myosin II is the form responsible for generating muscle contraction. It is an elongated protein formed from two heavy chains with motor heads and two light chains. Each myosin motor head binds actin and has an ATP binding site. The myosin heads bind and hydrolyze ATP. This hydrolysis produces the energy necessary for myosin to walk toward the plus end of an actin filament.

YouTube Lectures by Kevin HERE & HERE

Non-muscle myosin IIs provide contraction needed to power the action of cytokinesis. Other myosin proteins are involved in movement of non-muscle cells. Myosin I is involved in intracellular organization. Myosin V performs vesicle and organelle transport. Myosin XI provides movement along cellular microfilament networks to facilitate organelle and cytoplasmic streaming in a particular direction.

Structure

Myosins have six subunits, two heavy chains and four light chains. Myosin proteins have domains frequently described as a head and a tail (Figure 2.111). Some also describe an intermediate hinge region as a neck. The head portion of myosin is the part that binds to actin. It uses energy from ATP hydrolysis to move along the actin filaments. In muscles, myosin proteins form aggregated structures referred to as thick filaments. Movements are directional.

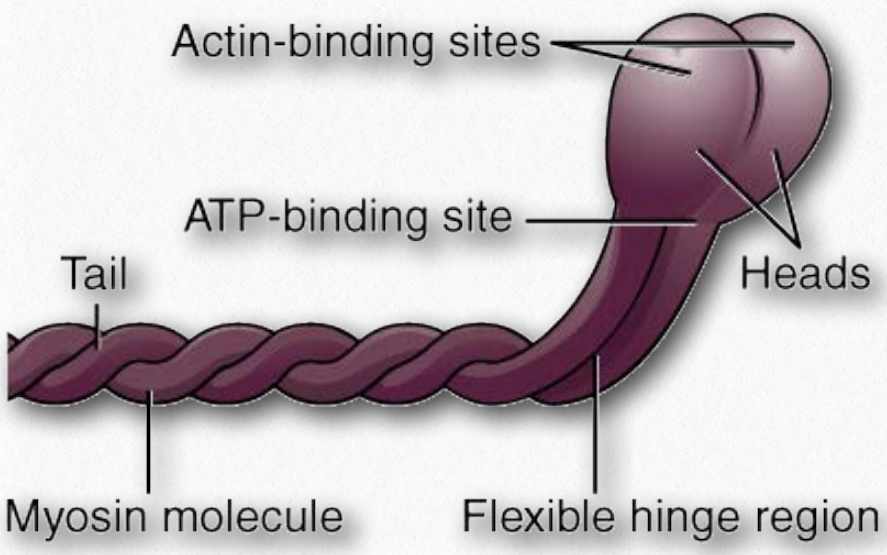

Figure 2.111 - Myosin protein anatomy

Wikipedia

Structural considerations of muscular contraction

Before we discuss the steps in the process of muscular contraction, it is important to describe anatomical aspects of muscles and nomenclature.

There are three types of muscle tissue - skeletal (striated), smooth, and (in vertebrates) cardiac. We shall concern ourselves mostly here with skeletal muscle tissue. Muscles may be activated by the central nervous system or, in the case of smooth and cardiac muscles, may contract involuntarily. Skeletal muscles may be slow twitch or fast twitch.

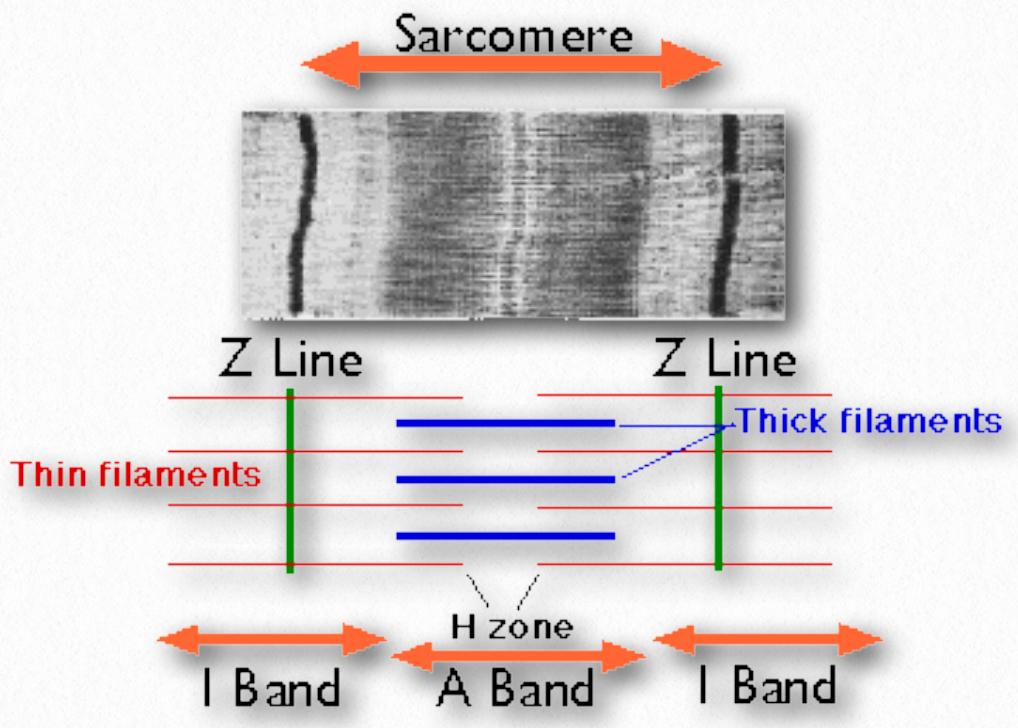

Figure 2.112 - Structural components of muscle. Wikipedia

Sarcomeres

Sarcomeres are described as the basic units comprising striated muscles and are comprised of thick (myosin) and thin (actin) filaments and a protein called titin. The filaments slide past each other in muscular contraction and then backwards in muscular relaxation. They are not found in smooth muscles.

Under the microscope, a sarcomere is the region between two Z-lines of striated muscle tissue (Figure 2.112). The Z-line is the distinct, narrow, dark region in the middle of an I-band. Within the sarcomere is an entire A-band with its central H-zone. Within the H-zone are located tails of myosin fibers, with the head pointed outwards from there projecting all the way to the I-band. The outside of the A-band is the darkest and it gets lighter moving towards the center.

Within the I-band are located thin filaments that are not occupied with thick myosin filaments. The A-band contains intact thick filaments overlaying thin filaments except in the central H zone, which contains only thick filaments. In the center of the H-zone is a line, known as the M-line. It contains connecting elements of the cellular cytoskeleton.

Figure 2.113 - **Skeletal muscle longitudinal section.**

Wikipedia

In muscular contraction, myosin heads walk along pulling their tails over the actin thin filaments, using energy from hydrolysis of ATP and pulling them towards the center of the sarcomere.

Sarcolemma

The sarcolemma (also known as the myolemma) is to muscle cells what the plasma membrane is to other eukaryotic cells - a barrier between inside and outside. It contains a lipid bilayer and a glycocalyx on the outside of it. The glyocalyx contains polysaccharides and connects with the basement membrane. The basement membrane serves a s scaffolding to connect muscle fibers to. This connection is made by transmembrane proteins bridging the actin cytoskeleton on the inside of the cell with the basement membrane on the outside. On the ends of the muscle fibers, each sarcolemma fuses with a tendon fiber and these, in turn, adhere to bones.

Sarcoplasmic reticulum

The sarcoplasmic reticulum (Figure 2.114) is a name for the structure found within muscle cells that is similar to the smooth endoplasmic reticulum found in other cells. It contains a specialized set of proteins to meet needs unique to muscle cells. The organelle largely serves as a calcium “battery,” releasing stored calcium to initiate muscular contraction when stimulated and taking up calcium when signaled at the end of the contraction cycle. It accomplishes these tasks using calcium ion channels for release of the ion and specific calcium ion pumps to take it up.

Movement direction

All myosins but myosin VI move towards the + end (the growing end) of the microfila-

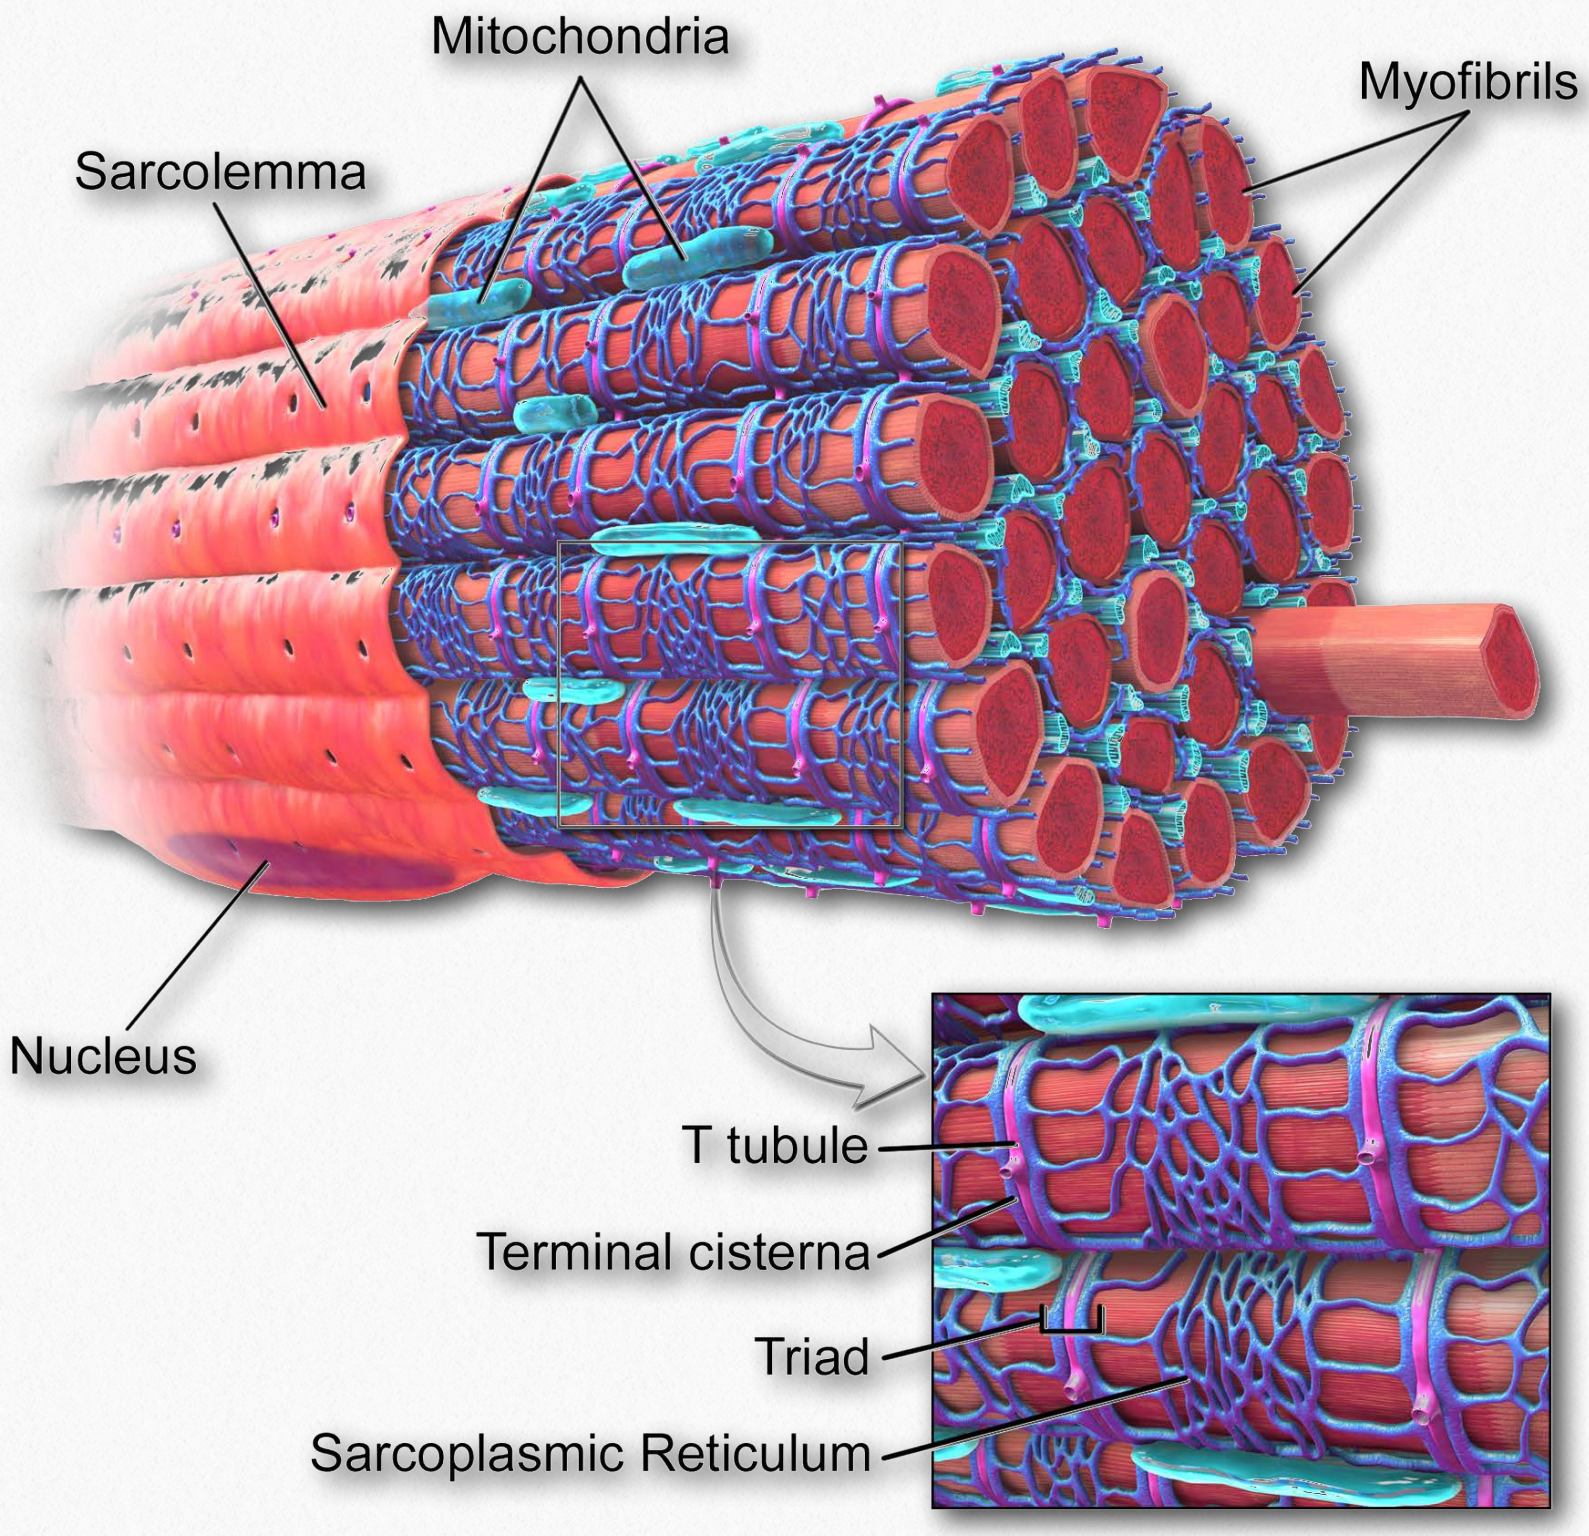

Figure 2.114 - Anatomy of a muscle fiber

Wikipedia

ment. The neck portion serves to link the head and the tail. It also a binding site for myosin light chain proteins that form part of a macromolecular complex with regulatory functions. The tail is the point of attachment of molecules or other "cargo" being moved. It can also connect with other myosin subunits and may have a role to play in controlling movement.

Muscular contraction

The sliding filament model has been proposed to describe the process of muscular tension/contraction. In this process a repeating set of actions slide a thin actin filament over a thick myosin filament as a means of creating tension/ shortening of the muscle fiber.

Steps in the process occur as follows:

A. A signal from the central nervous system (action potential) arrives at a motor neuron, which it transmits towards the neuromuscular junction (see more on the neurotransmission part of the process HERE)

B. At the end of the axon, the nerve signal stimulates the opening of calcium channels at the axon terminus causing calcium to flow into the terminal.

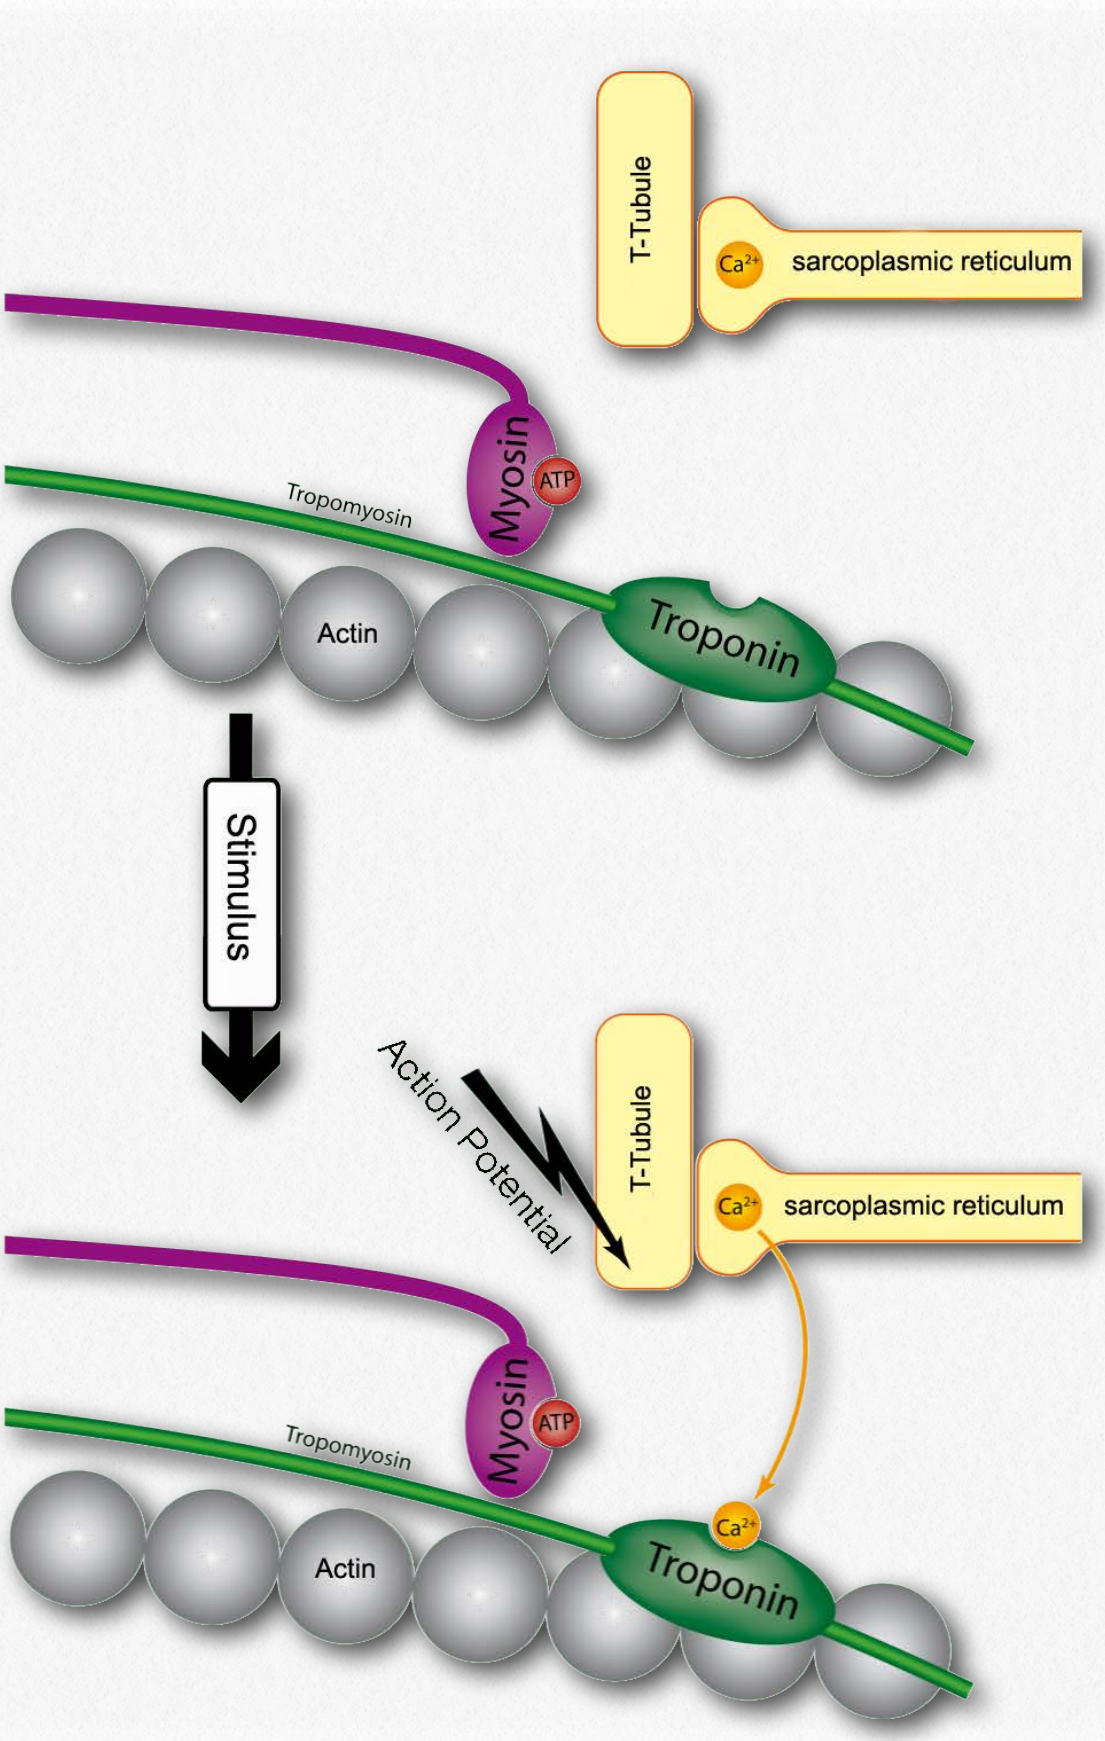

Figure 2.115 - 1. Activation of a muscle cell by release of calcium (step H)

Wikipedia

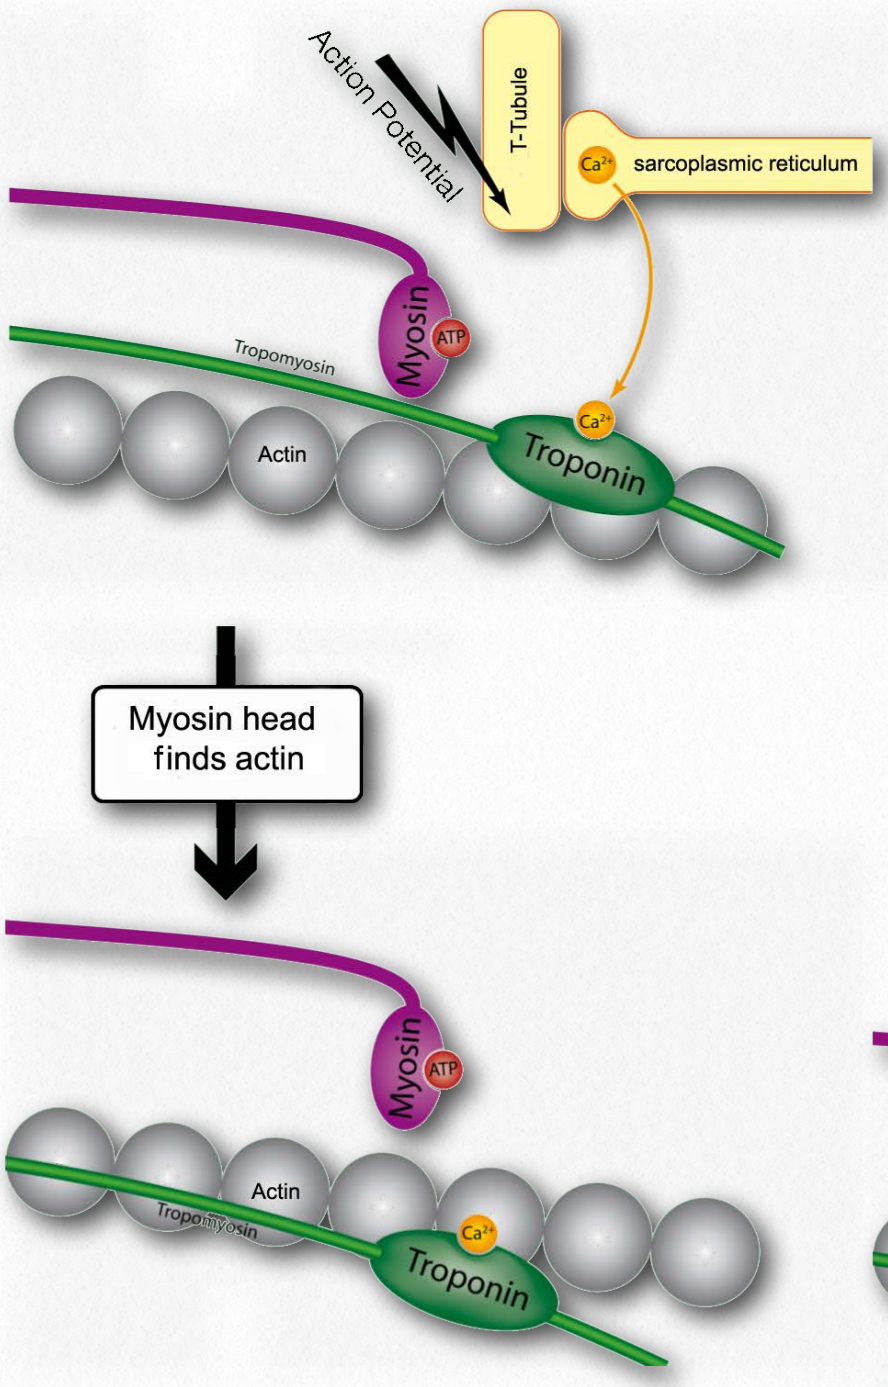

Figure 2.116 - 2. Calcium binding by troponin allows myosin to access actin sites (I).

Wikipedia

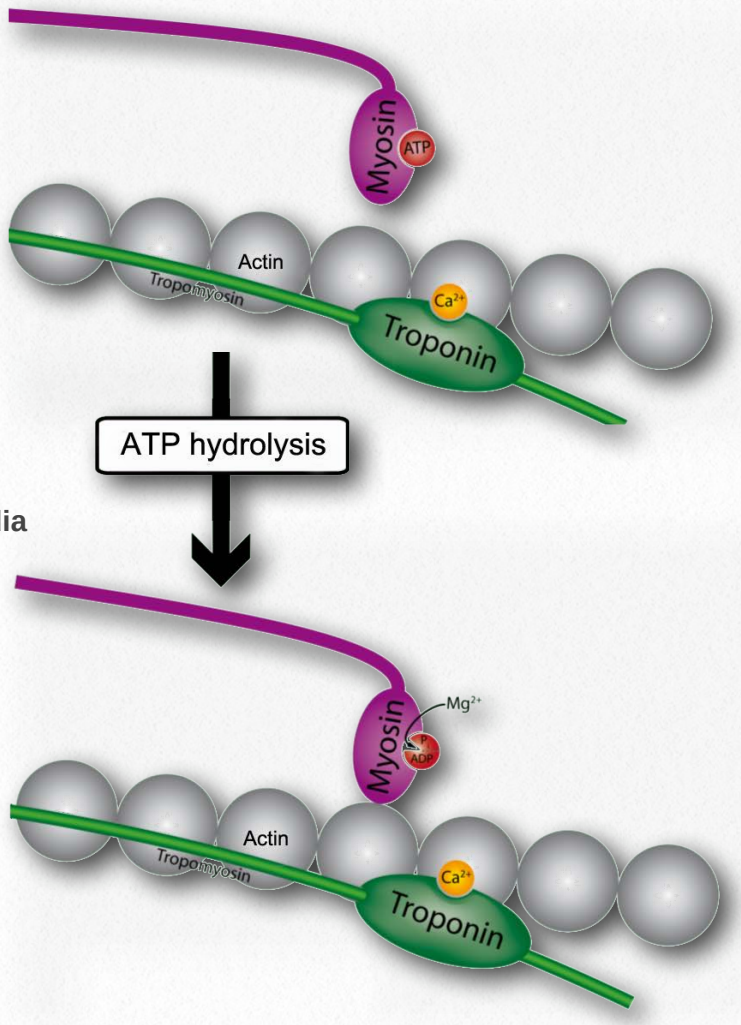

Figure 2.117 - 3. ATP cleavage by myosin allows actin attachment (J)

Wikipedia

apse and then binds to nicotinic acetylcholine receptors on the neuromuscular junction, activating them.

E. Activation of the receptor stimulates opening gates of sodium and potassium channels, allowing sodium to move into the cell and potassium to exit. The polarity of the membrane of the muscle cell (called a sarcolemma - Figure 2.111) changes rapidly (called the end plate potential).

F. Change in the end plate potential results in opening of voltage sensitive ion channels specific for sodium or potassium only to

C. Movement of calcium into the axon of the nerve causes acetylcholine (a neurotransmitter) in synaptic vesicles to fuse with the plasma membrane. This causes the acetylcholine to be expelled into the synaptic cleft between the axon and the adjacent skeletal muscle fiber.

D. Acetylcholine diffuses across the syn-

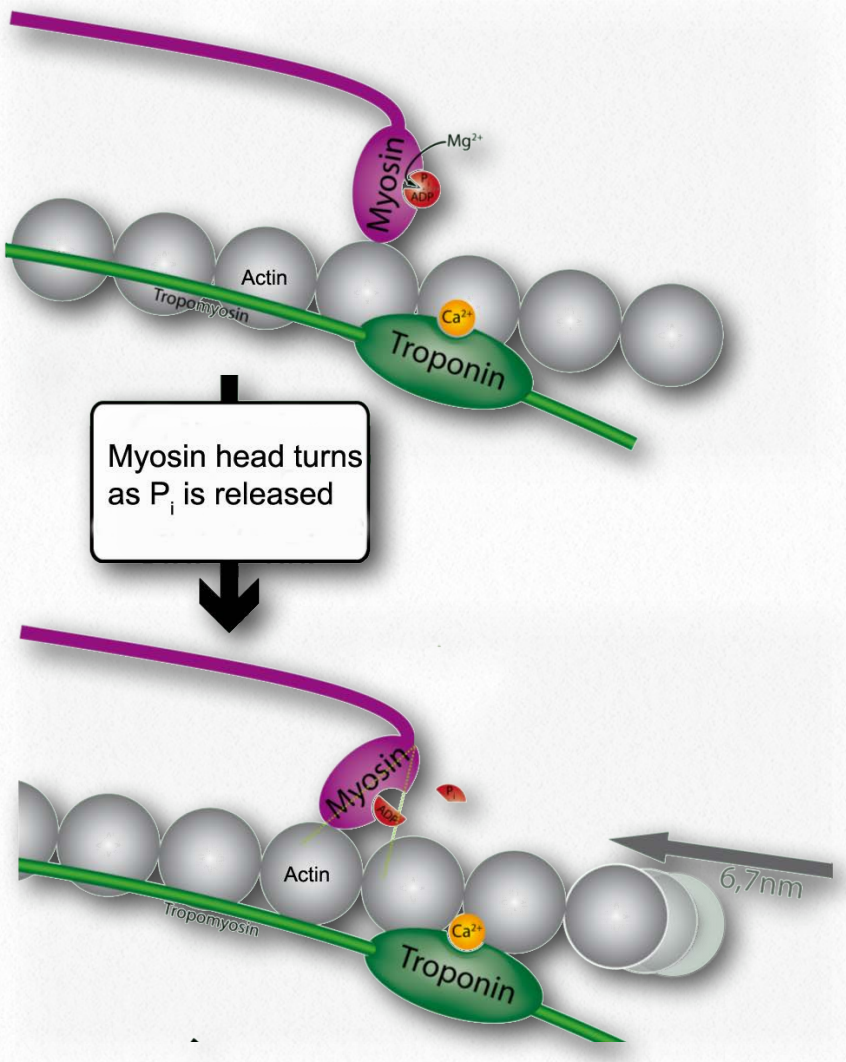

Figure 2.118 - 4. Release of P_i causes myosin hinge to bend. Thin filament pulled left (K).

Wikipedia

open, creating an action potential (voltage change) that spreads throughout the cell in all directions.

G. The spreading action potential depolarizes the inner muscle fiber and opens calcium channels on the sarcoplasmic reticulum (Figure 2.115).

H. Calcium released from the sarcoplasmic reticulum binds to troponin on the actin filaments (Figure 2.115).

I. Troponin alters the structure of the tropomyosin to which is it bound. This causes tropomyosin to move slightly, allowing access to myosin binding sites on the microfilament (also called thin filament) that it was covering (Figure 2.116).

J. Myosin (bound to ATP) cleaves the ATP to ADP and P_i, which it holds onto in its head region and then attaches itself to the exposed binding sites on the thin filaments causing inorganic phosphate to be released from the myosin followed by ADP (Figure 2.117).

K. Release of ADP and P_i is tightly coupled to

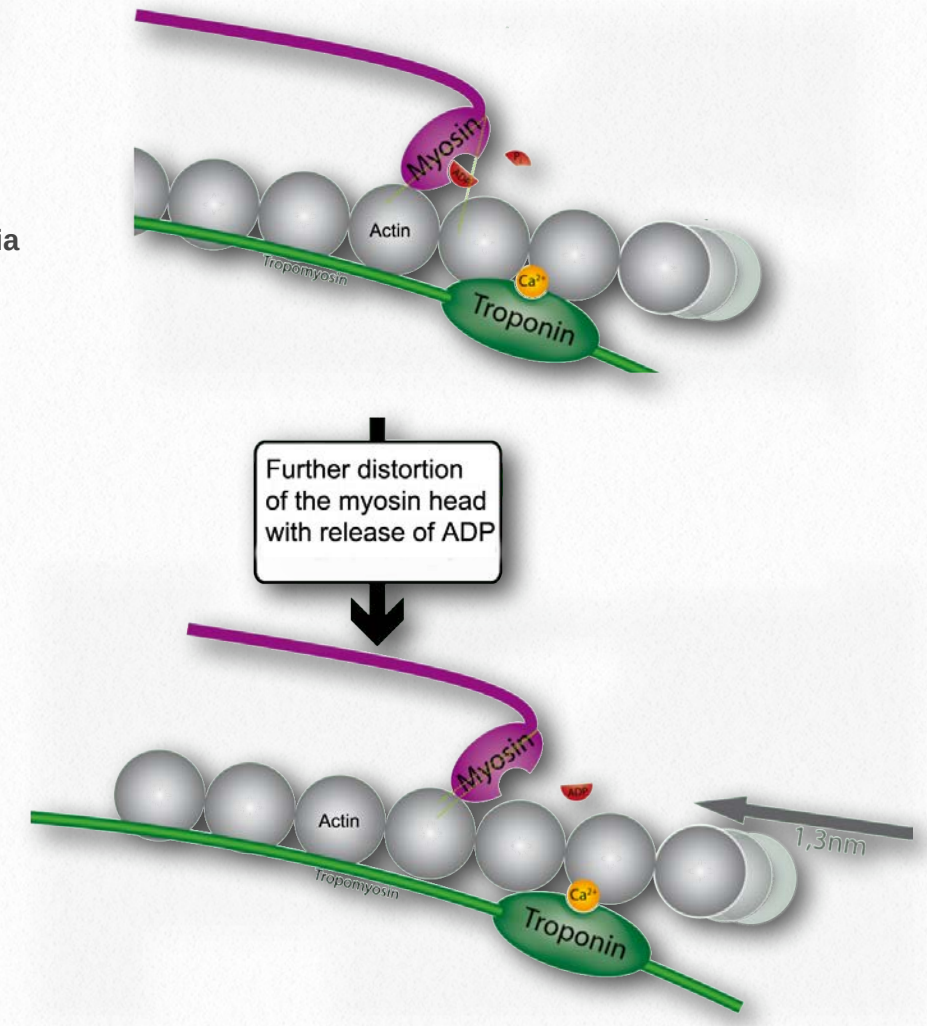

Figure 2.119 - 5. Release of ADP favors further bending of hinge and movement of thin filament leftward (K).

Wikipedia

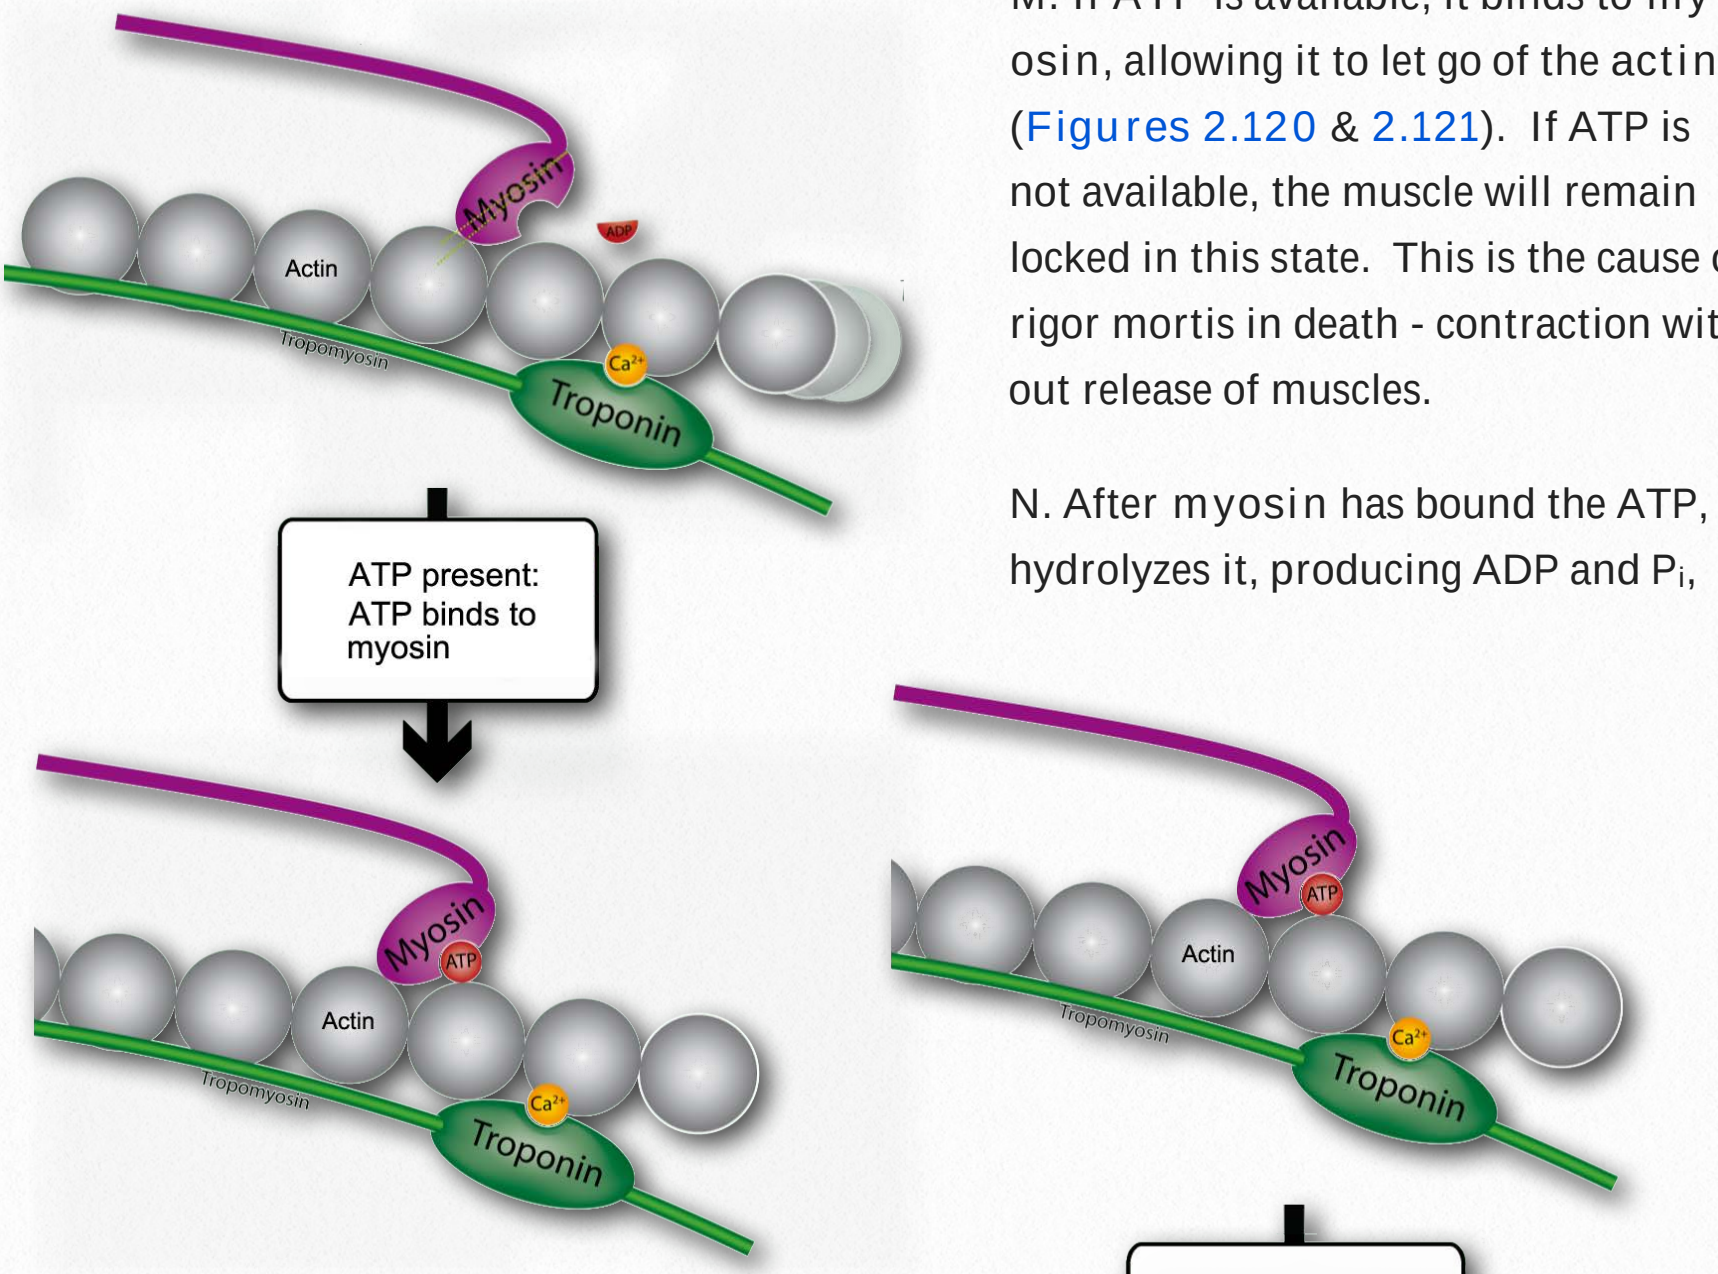

Figure 2.120 - When ATP is present, it binds to myosin (M).

Wikipedia

M. If ATP is available, it binds to myosin, allowing it to let go of the actin (Figures 2.120 & 2.121). If ATP is not available, the muscle will remain locked in this state. This is the cause of rigor mortis in death - contraction without release of muscles.

N. After myosin has bound the ATP, it hydrolyzes it, producing ADP and P_i,

a bending of the myosin hinge, resulting in what is called the power stroke. This causes the thin filament to move relative to the thick fibers of myosin (Figures 2.118 & 2.119).

L. Such movement of the thin filaments causes the Z lines to be pulled closer to each other. This results in shortening of the sarcomere as a whole (Figure 2.122) and narrowing of the I band and the H zones (Figure 2.123).

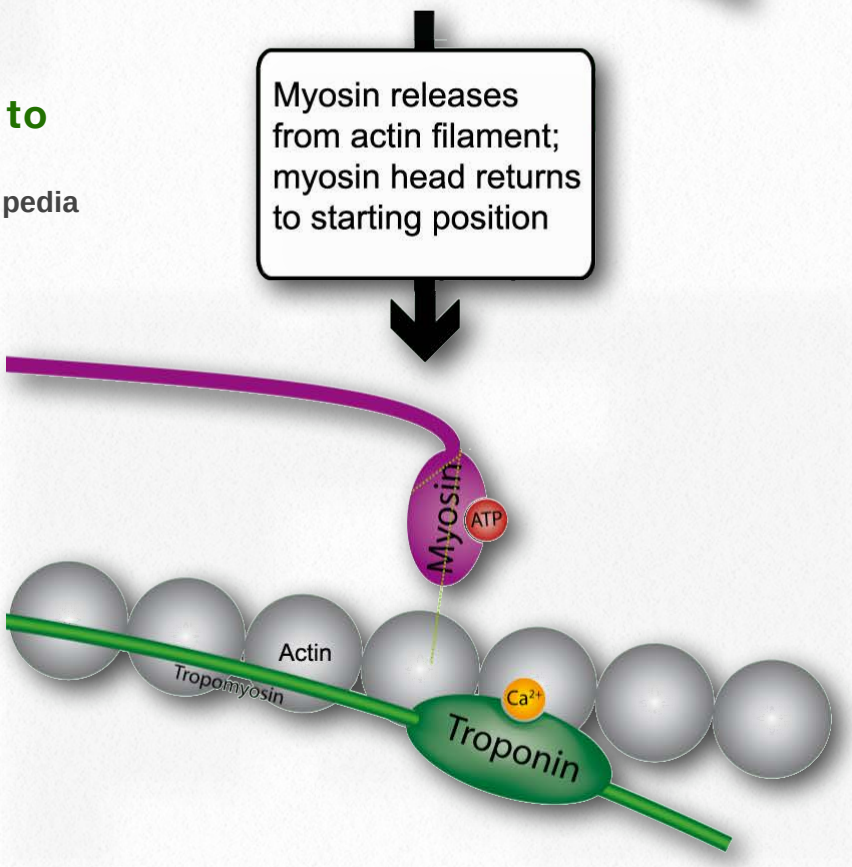

Figure 2.121 - Binding of ATP favors release of myosin from actin site (N)

Wikipedia

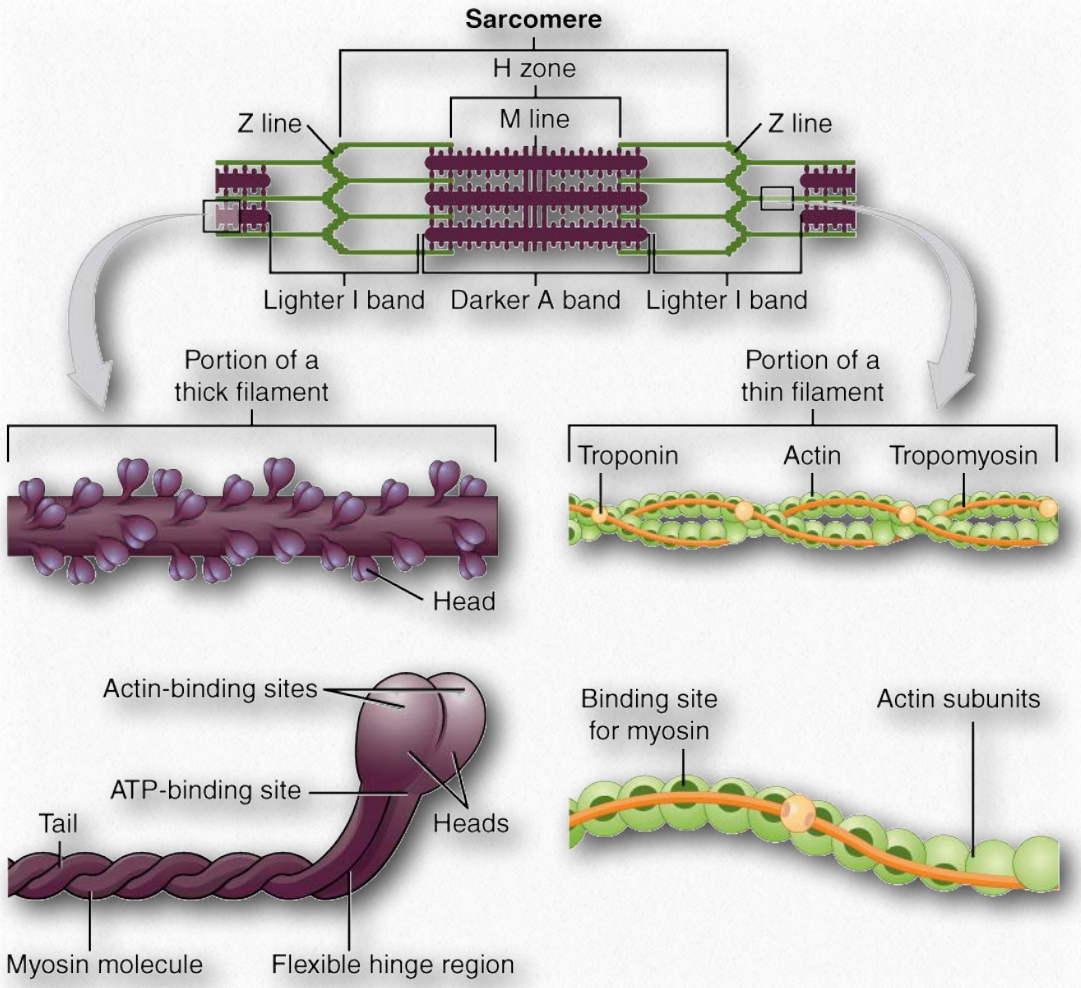

Figure 2.122 - Sarcomere Anatomy

Wikipedia

which are held by the head. Hydrolysis of ATP resets the hinge region to its original state, unbending it. This unbent state is also referred to as the cocked position.

O. If tropomyosin is still permitting access to binding sites on actin, the process repeats so long as ATP is available and calcium remains at a high enough concentration to permit it to bond to troponin.

Relaxation of the muscle tension occurs as the action potential in the muscle cell dissipates. This happens because all of the following things happen 1) the nerve signal stops; 2) the neurotransmitter is degraded by the enzyme acetylcholinesterase; and 3) the calcium concentration declines because it is taken up by the sarcoplasmic reticulum.

It should be noted that the sarcoplasmic reticulum is always taking

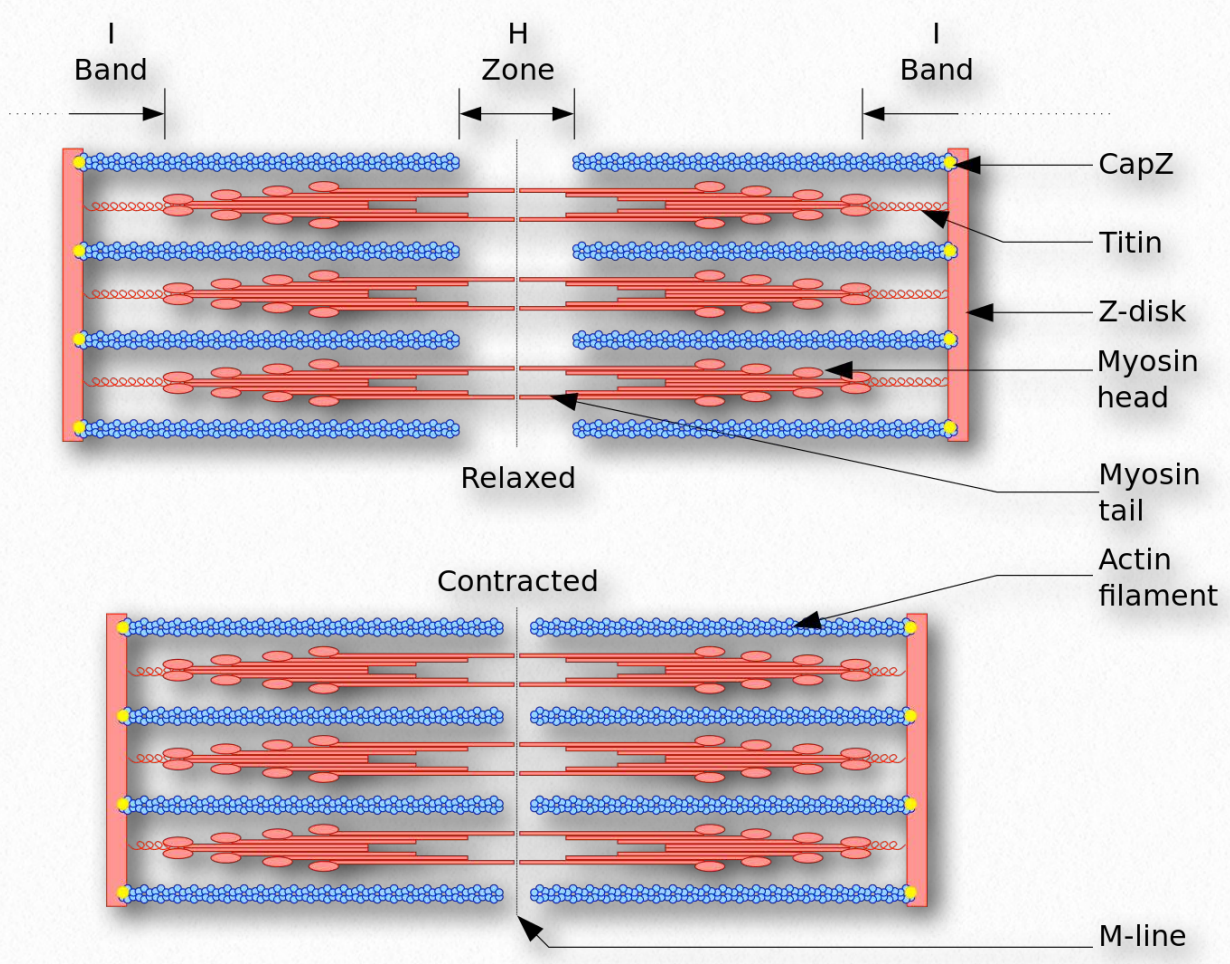

Figure 2.123 - The Sliding Filament Model of Muscular Contraction

Wikipedia

up calcium. Only when its calcium gates are opened by the action potential is it unable to reduce cellular calcium concentration. As the action potential decreases, then the calcium gates close and the sarcoplasmic reticulum "catches up" and cellular calcium concentrations fall. At that point troponin releases calcium, tropomyosin goes back to covering myosin binding sites on actin, myosin loses its attachment to actin and the thin filaments slide back to their original positions relative to the myosin thick filaments.

Tropomyosin

Tropomyosins are proteins that interact with actin thin filaments to help regulate their roles in movement, both in muscle cells and non-muscle cells (Figure 2.124). Tropomyosins interact to form head-to-toe dimers and perch along the α-helical groove of an actin filament. The isoforms of tropomyosin that are in muscle cells control interactions between myosin and the actin filament within the sarcomere and help to regulate contraction of the muscle. In other cells, non-muscle tropomyosins help to regulate the cytoskeleton's functions.

The interactions of tropomyosin with the cytoskeleton are considerably more complicated than what occurs in muscle cells. Muscle cells have five tropomyosin isoforms, but in the cytoskeleton of non-muscle cells, there are over 40 tropomyosins.

Troponin

The troponins involved in muscular contraction are actually a complex of three proteins known as troponin I, troponin C, and tro-

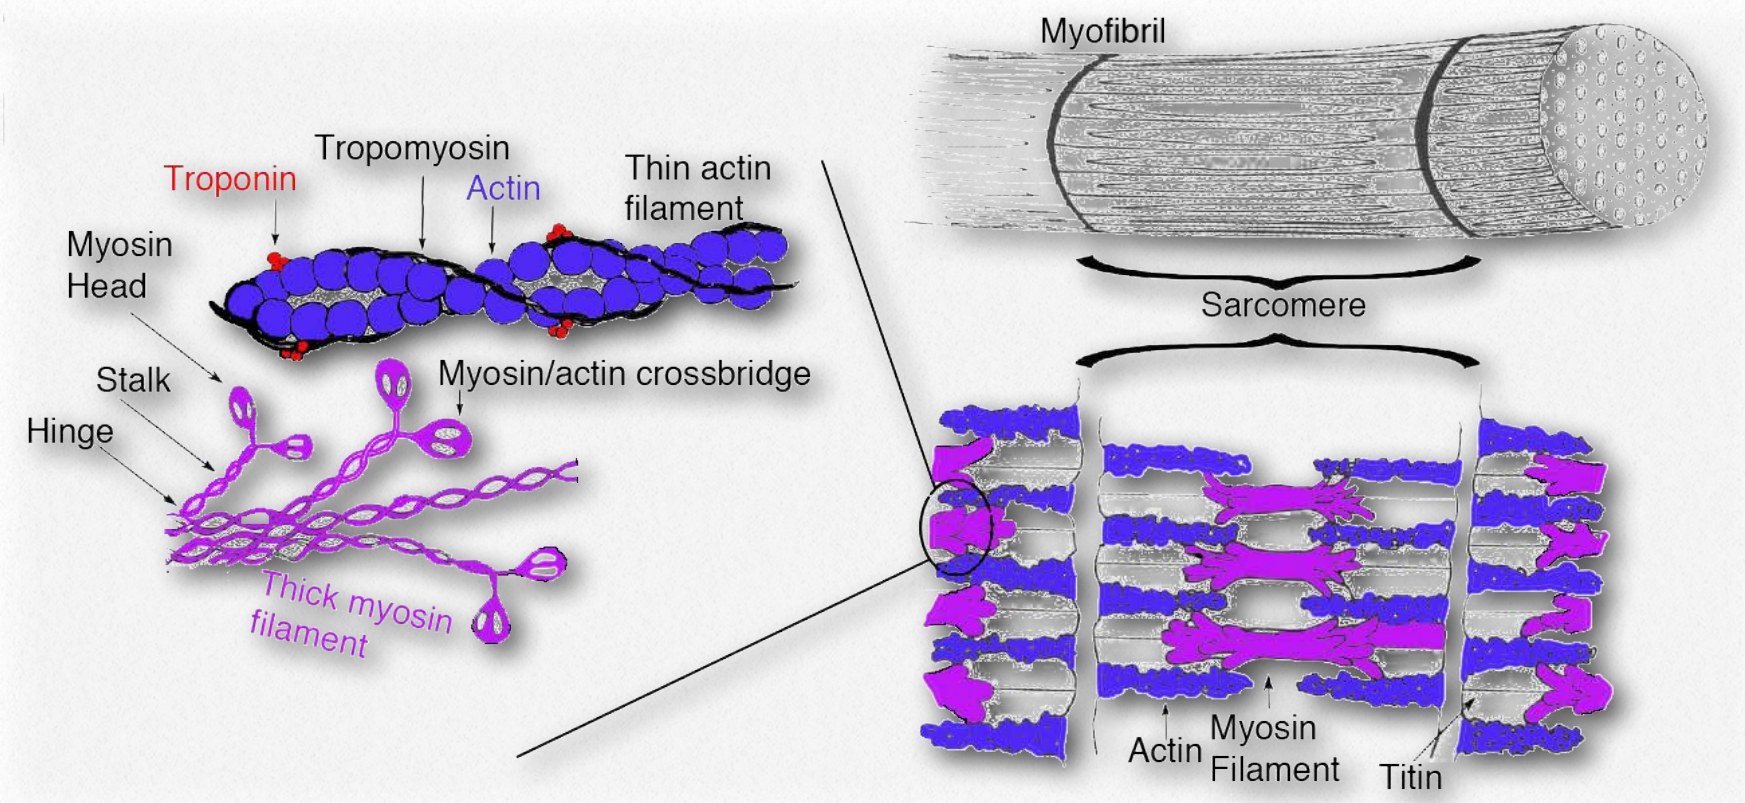

Figure 2.124 - Tropomyosin and troponin in muscle anatomy

Wikipedia

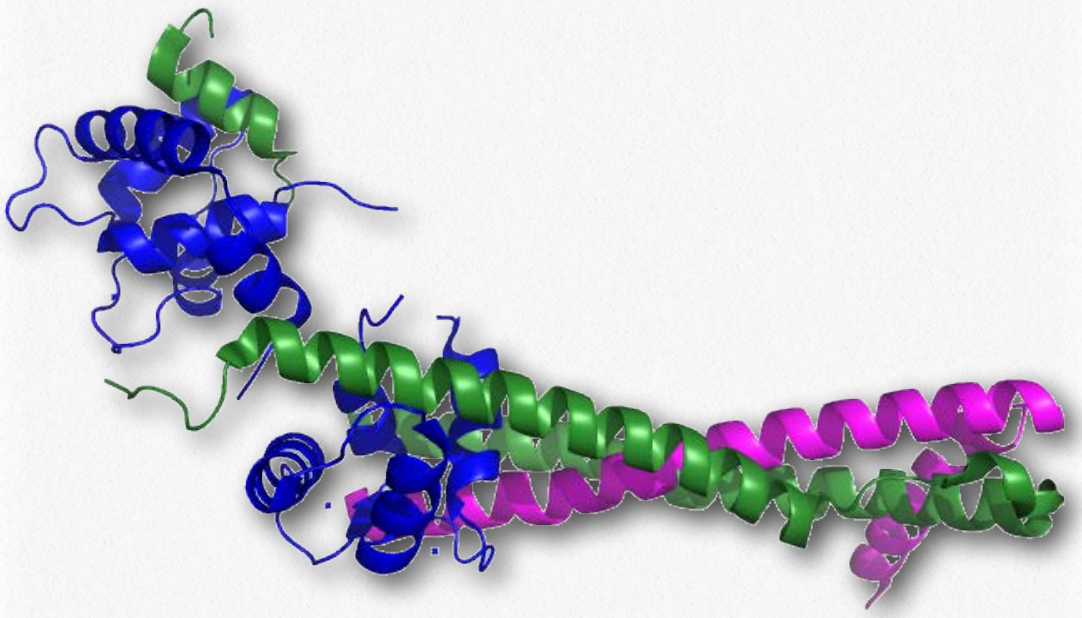

Figure 2.125 - Troponin complex of muscle. Blue = troponin C, magenta = troponin T , green = troponin I

ponin T (Figure 2.125). They associate with each other and with tropomyosin on actin filaments to help regulate the process of muscular contraction. Troponin I prevents binding of myosin's head to actin and thus prevents the most important step in contraction. Troponin C is a unit that binds to calcium ions. Troponin T is responsible for binding all three proteins to tropomyosin. Troponins in the bloodstream are indicative of heart disorders. Elevation of troponins in the blood occurs after a myocardial infarction and can remain high for up to two weeks.

Actinin

Actinin is a skeletal muscle protein that attaches filaments of actin to Z-lines of skeletal muscle cells. In smooth muscle cells, it also connects actin to dense bodies.

Titin

Titin (also known as connectin) is the molecular equivalent of a spring that provides striated muscle cells with elasticity. It is the third most abundant protein in muscle cells. The protein is enormous, with 244 folded individual protein domains spread across 363 exons (largest known number), with the largest known exon (17,106 base pairs long), and it is the largest protein known (27,000 to 33,000 amino acids, depending on splicing).

Unstructured sequences

The folded protein domains are linked together by unstructured sequences. The unstructured regions of the protein allow for unfolding when stretching occurs and refolding upon relaxation. Titin connects the M and Z lines in the sarcomere (Figure 2.123). Tension created in titin serves to limit the range of motion of the sarcomere, giving rise to what is called passive stiffness.

tin proteins and these appear to relate to differences in the mechanical characteristics of each muscle.

Energy backup for muscle energy

Myoglobin was described as a molecular batter for oxygen. Muscle cells have a better of their own for ATP. The is important for animals, but not for plants because a plant's need for energy is different than an animal's. Plants do not need to access energy sources as rapidly as animals do, nor do they have to maintain a constant internal temperature. Plants can neither flee predators, nor chase prey. These needs of animals are much more immediate and require that energy stores be accessible on demand.

Muscles, of course, enable the motion of animals and the energy required for muscle contraction is ATP. To have stores of energy readily available, muscles have, in addition to ATP, creatine phosphate for energy and glycogen for quick release of glucose to make more energy. The synthesis of creatine phosphate is a prime example of the effects of concentration on the synthesis of high energy molecules. For example, creatine phosphate has an energy of hydrolysis of -43.1 kJ/mol whereas ATP has an energy of hydrolysis of -30.5 kJ/mol. Creatine phosphate, however, is made from creatine and ATP in the reaction shown in Figure 2.126. How is this possible?

The $\Delta G^{\circ\prime}$ of this reaction is +12.6 kJ/mol, reflecting the energies noted above. In a resting muscle cell, ATP is abundant and ADP is low, driving the reaction downward, creating creatine phosphate. When muscular contraction commences, ATP levels fall and ADP levels climb. The above reaction then reverses and proceeds to synthesize ATP immediately. Thus, creatine phosphate acts like a battery, storing energy when ATP levels are high and releasing it almost instantaneously to create ATP when its levels fall.

The Muscle Energy Song

To the tune of "*I Will*"

Metabolic Melodies Website HERE

For running and for jumping
You need some energy
Chemically the body stores it
In the form of ATP

If backup should be needed
Reserves are there in wait
Muscles brimming with supplies of
Tiny creatine phosphate

Ready whenever you are ever
Wanting to exercise
Steady as ever when whatever
Energy needs arise

The action is exacting
For leaping in the air
Myofibrils all contracted
Using energy extracted

From reactions that react in me
Using A-T-P
You see

Lyrics by Kevin Ahern

Structure and Function: Nucleic Acids

Information molecules

The nucleic acids, DNA and RNA, may be thought of as the information molecules of the cell. In this section, we will examine the structures of DNA and RNA, and how these structures are related to the functions these molecules perform.

We will begin with DNA, which is the hereditary information in every cell, that is copied and passed on from generation to generation. The race to elucidate the structure of DNA was one of the greatest stories of 20th century science. Discovered in 1869 by Friedrich Miescher, DNA was identified as the genetic material in experiments in the 1940s led by Oswald Avery, Colin MacLeod, and Maclyn McCarty. X-ray diffraction work of Rosalind Franklin and the observations of Erwin Chargaff were combined by James Watson and Francis Crick to form a model of DNA that we are familiar with today. Their famous paper, in the April 25, 1953 issue of Nature, opened the modern era of molecular biology. Arguably, that one-page paper has had more scientific impact per word than any other research arti-

cle ever published. Today, every high school biology student is familiar with the double helical structure of DNA and knows that G pairs with C and A with T.

> It's taught in school of DNA
> The race for structure underway
> Gave rise to competition huge
> Along with data subterfuge
> In view of this we should extend
> New authorship to make amends
> A fairer order could be picked
> Franklin, Wilkins, Watson, Crick

The double helix, made up of a pair of DNA strands, has at its core, bases joined by hydrogen bonds to form base pairs - adenine always paired with thymine, and guanine invariably paired with cytosine. Two hydrogen bonds are formed between adenine and thymine, but three hydrogen bonds hold together guanine and cytosine (Figure 2.127).

The complementary structure immediately suggested to Watson and Crick how DNA might be (and in fact, is) replicated and it further explains how information is DNA is transmitted to RNA for the synthesis of proteins. In addition to the hydrogen bonds between bases of each strand, the double helix is held together by hydrophobic interactions of the

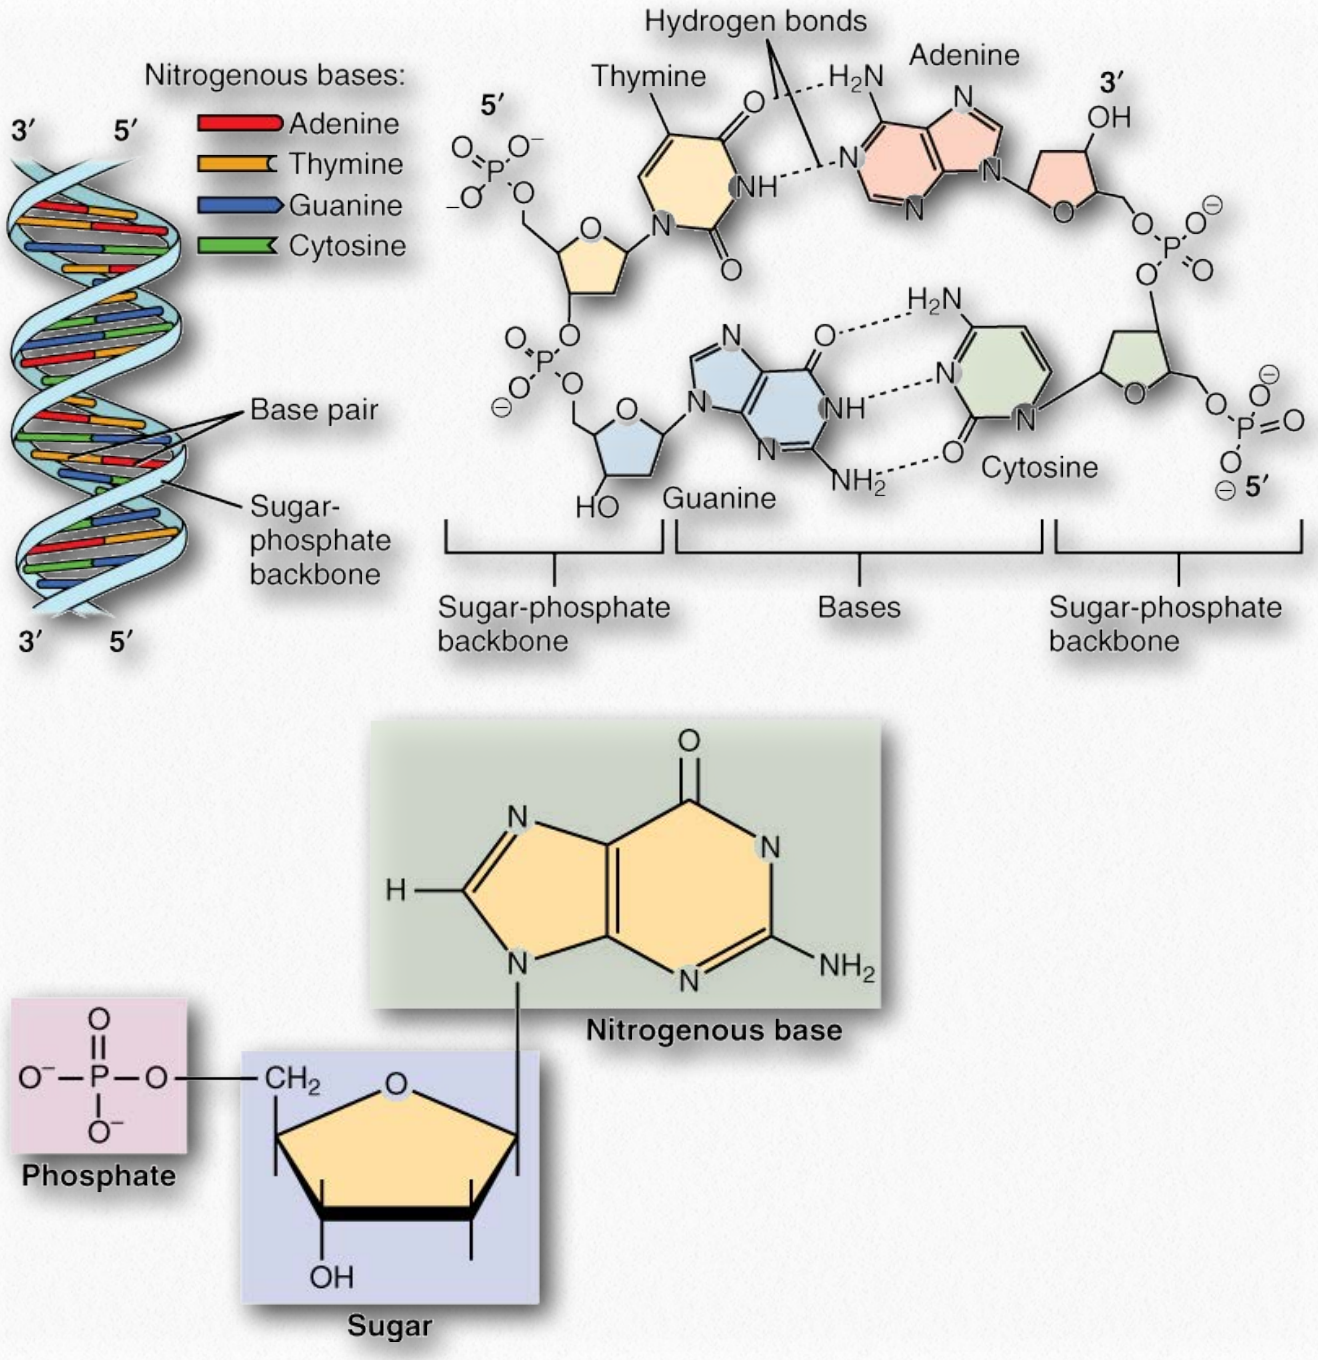

Figure 2.127 - A DNA duplex with base pairs, a closeup of base pairing, and a closeup of a nucleotide

Wikipedia

stacked, non-polar bases. Crucially, the sequence of the bases in DNA carry the information for making proteins. Read in groups of three, the sequence of the bases directly specifies the sequence of the amino acids in the encoded protein.

Structure

A DNA strand is a polymer of nucleoside monophosphates held together by phosphodiester bonds. Two such paired strands make up the DNA molecule, which is then twisted into a helix. In the most common B-form, the DNA helix has a repeat of 10.5 base pairs per turn, with sugars and phosphate forming the covalent phosphodiester "backbone" of the molecule and the adenine, guanine, cytosine, and thymine bases oriented in the middle where they form the now familiar base pairs that look like the rungs of a ladder.

Building blocks

The term nucleotide refers to the building blocks of both DNA (deoxyribonucleoside triphosphates, dNTPs) and RNA (ribonucleoside triphosphates, NTPs). In order to discuss this important group of molecules, it is necessary to define some terms.

Nucleotides contain three primary structural components. These are a nitrogenous base, a pentose sugar, and at least one phosphate. Molecules that contain only a sugar and a nitrogenous base (no phosphate) are called nucleosides. The nitrogenous bases found in nucleic acids include adenine and guanine (called purines) and cytosine, uracil, or thymine (called pyrimidines).

There are two sugars found in nucleotides - deoxyribose and ribose (Figure 2.128). By convention, the carbons on these sugars are labeled 1' to 5'. (This is to distinguish the carbons on the sugars from those on the

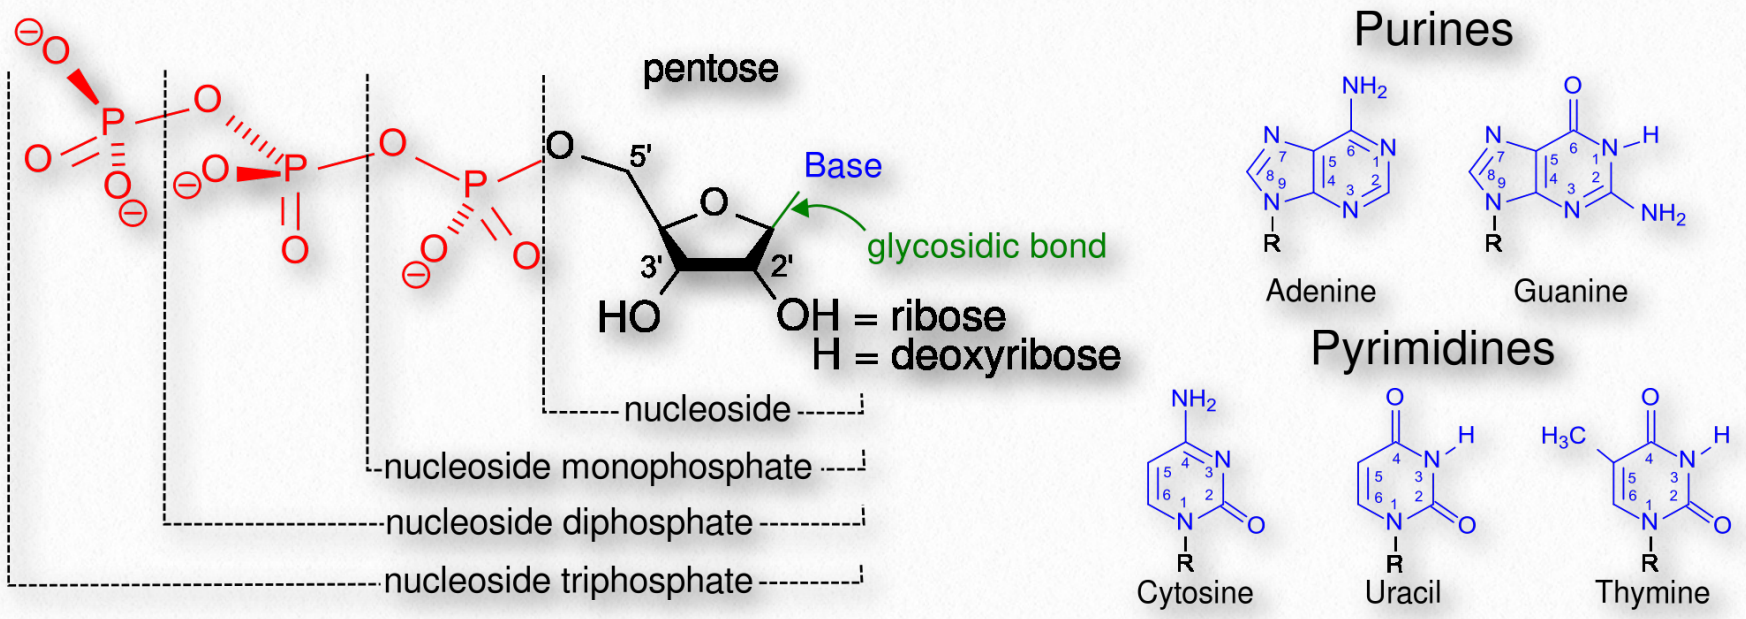

Figure 2.128 - Nucleotides, nucleosides, and bases

bases, which have their carbons simply labeled as 1, 2, 3, etc.) Deoxyribose differs from ribose at the 2' position, with ribose having an OH group, where deoxyribose has H.

Nucleotides containing deoxyribose are called deoxyribonucleotides and are the forms found in DNA. Nucleotides containing ribose are called ribonucleotides and are found in RNA. Both DNA and RNA contain nucleotides with adenine, guanine, and cytosine, but with very minor exceptions, RNA contains uracil nucleotides, whereas DNA contains thymine nucleotides. When a base is attached to a sugar, the product, a nucleoside, gains a new name.

uracil-containing = uridine (attached to ribose) / deoxyuridine (attached to deoxyribose)

thymine-containing - ribothymidine (attached to ribose) / thymidine (attached to deoxyribose)

cytosine-containing = cytidine (attached to ribose - Figure 2.129) / deoxycytidine (attached to deoxyribose)

guanine-containing = guanosine (attached to ribose) / deoxyguanosine (attached to deoxyribose)

adenine-containing = adenosine (attached to ribose) / deoxyadenosine (attached to deoxyribose)

YouTube Lectures by Kevin HERE & HERE

Of these, deoxyuridine and ribothymidine are the least common. The addition of one or more phosphates to a nucleoside makes it a nucleotide. Nucleotides are often referred to as nucleoside phosphates, for this reason. The number of phosphates in the nucleotide is indicated by the appropriate prefixes (mono, di or tri).

Figure 2.129 Cytidine

Thus, cytidine, for example, refers to a nucleoside (no phosphate), but cytidine monophosphate refers to a nucleotide (with one phosphate). Addition of second and third phosphates to a nucleoside monophosphate requires energy, due to the repulsion of negatively charged phosphates and this chemical energy is the basis of the high energy triphosphate nucleotides (such as ATP) that fuel cells.

Ribonucleotides as energy sources

Though ATP is the most common and best known cellular energy source, each of the four ribonucleotides plays important roles in providing energy. GTP, for example, is the energy source for protein synthesis (translation) as well as for a handful of metabolic reactions. A bond between UDP and glucose

makes UDP-glucose, the building block for making glycogen. CDP is similarly linked to several different molecular building blocks important for glycerophospholipid synthesis (such as CDP-diacylglycerol).

The bulk of ATP made in cells is not from directly coupled biochemical metabolism, but rather by the combined processes of electron transport and oxidative phosphorylation in mitochondria and/or photophosphorylation that occurs in the chloroplasts of photosynthetic organisms. Triphosphate energy in ATP is transferred to the other nucleosides/nucleotides by action of enzymes called kinases. For example, nucleoside diphosphokinase (NDPK) catalyzes the following reaction

$$ATP + NDP \rightleftarrows ADP + NTP$$

where 'N' of "NDP" and "NTP corresponds to any base. Other kinases can put single phosphates onto nucleosides or onto nucleoside monophosphates using energy from ATP.

Deoxyribonucleotides

Individual deoxyribonucleotides are derived from corresponding ribonucleoside diphosphates *via* catalysis by the enzyme known as ribonucleotide reductase (RNR). The deoxyribonucleoside diphosphates are then converted to the corresponding triphosphates (dNTPs) by the addition of a phosphate group. Synthesis of nucleotides

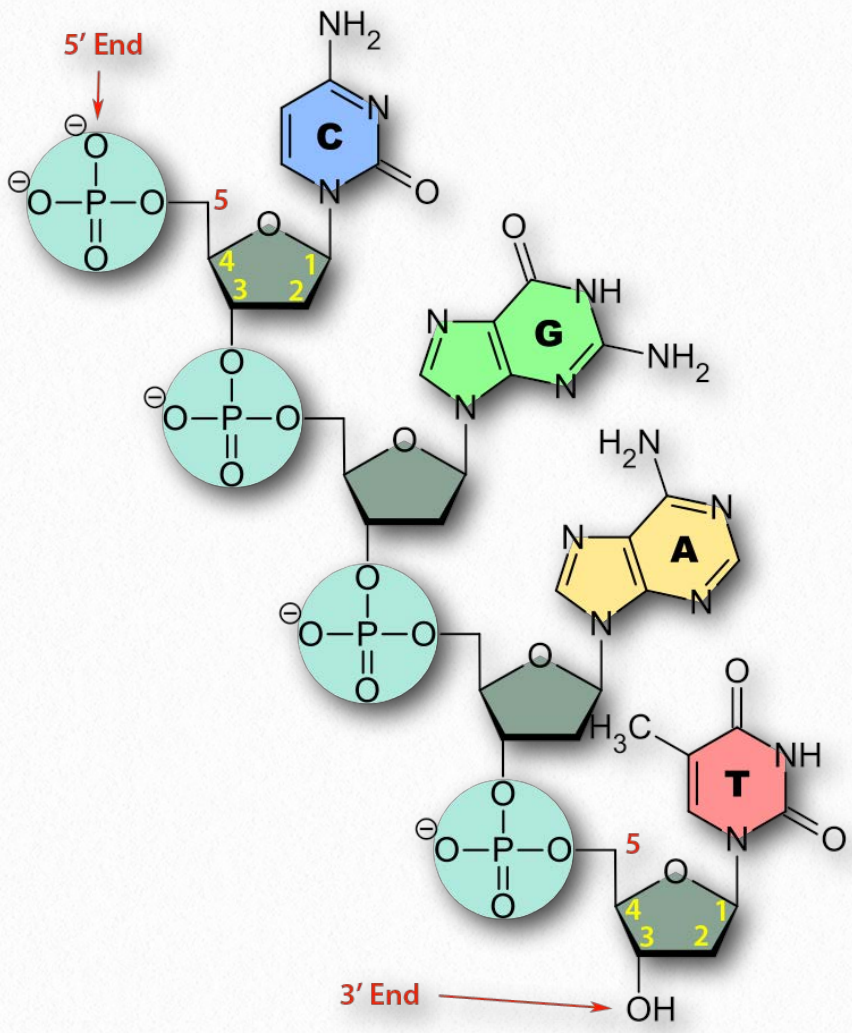

Figure 2.130 - 5'-3' Polarity of a DNA strand

containing thymine is distinct from synthesis of all of the other nucleotides and will be discussed later.

Building DNA strands

Each DNA strand is built from dNTPs by the formation of a phosphodiester bond, catalyzed by DNA polymerase, between the 3'OH of one nucleotide and the 5' phosphate of the next. The result of this directional growth of the strand is that the one end of the strand has a free 5' phosphate and the other a free 3' hydroxyl group (Figure 2.130). These are designated as the 5' and 3' ends of the strand.

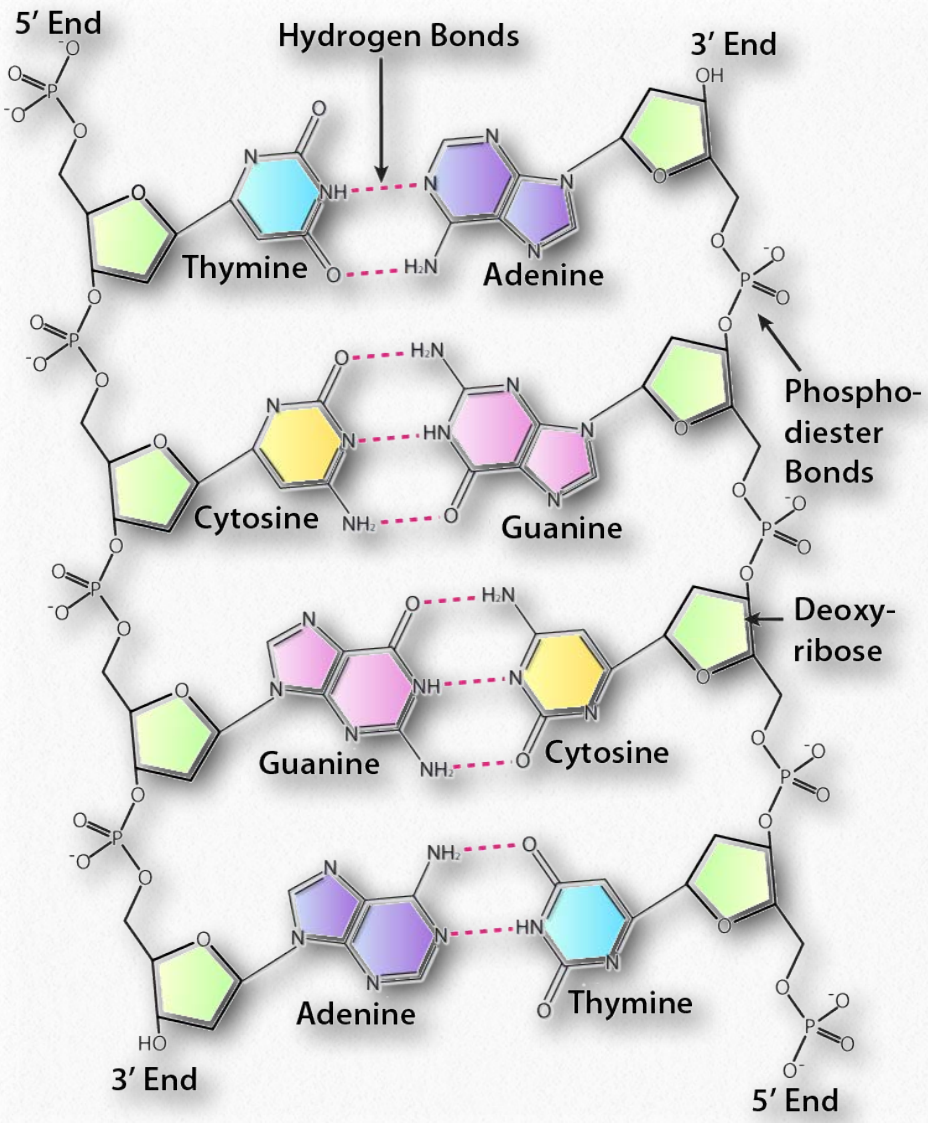

Figure 2.131 - Anti-parallel orientation of a DNA duplex, phosphodiester backbone, and base pairing

Image by Aleia Kim

Figure 2.131 shows two strands of DNA (left and right). The strand on the left, from 5' to 3' reads T-C-G-A, whereas the strand on the right, reading from 5' to 3' is T-C-G-A. The strands in a double-stranded DNA are arranged in an anti-parallel fashion with the 5' end of one strand across from the 3' end of the other.

Hydrogen bonds

Hydrogen bonds between the base pairs hold a nucleic acid duplex together, with two hydrogen bonds per A-T pair (or per A-U pair in RNA) and three hydrogen bonds per G-C pair. The B-form of DNA has a prominent major groove and a minor groove tracing the path of the helix (Figure 2.132). Proteins, such as transcription factors bind in these grooves and access the hydrogen bonds of the base pairs to "read" the sequence therein.

Other forms of DNA besides the B-form (Movie 2.5) are known (Figure 2.133). One of these, the A-form, was identified by Rosalind Franklin in the same issue of Nature as Watson and Crick's paper. Though the A-form structure is a relatively minor form of DNA and resembles

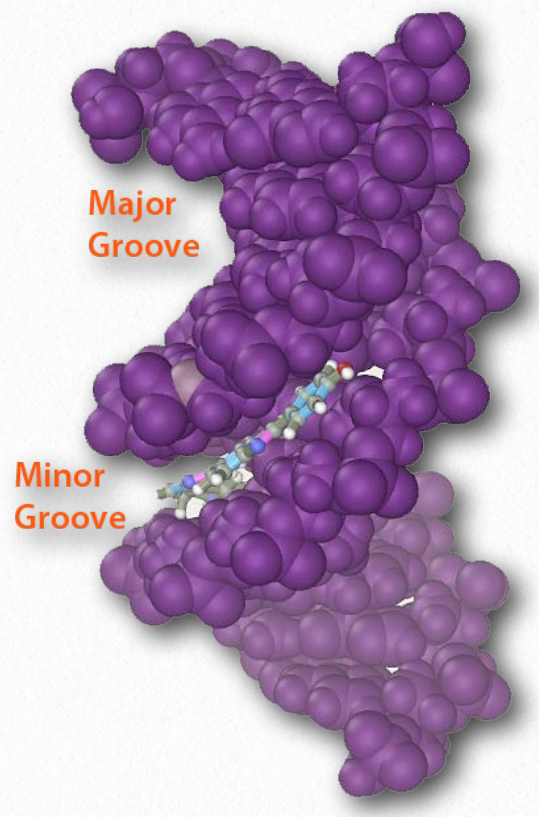

Figure 2.132 - Major and minor grooves of DNA. The minor groove has been bound by a dye

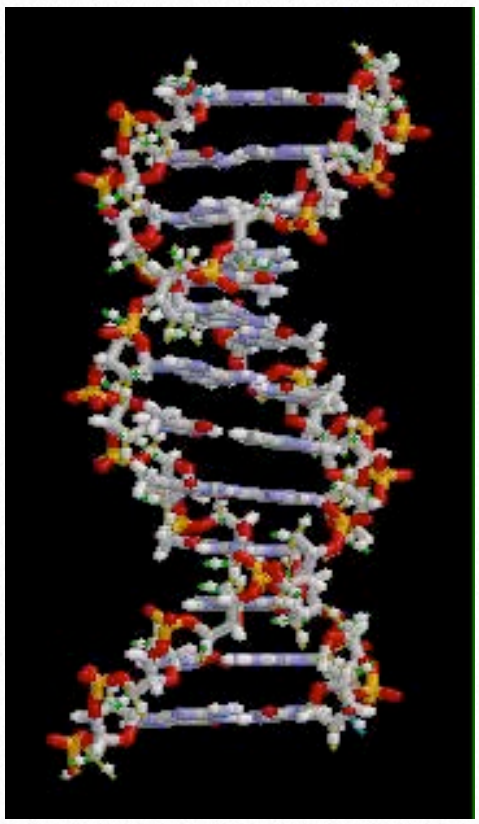
Wikipedia



Movie 2.5 - B-form DNA duplex rotating in space

Wikipedia

the B-form, it turns out to be important in the duplex form of RNA and in RNA-DNA hybrids. Both the A form and the B-form of DNA have the helix oriented in what is termed the right-handed form.

Z-DNA

The A-form and the B-form stand in contrast to another form of DNA, known as the Z-form. Z-DNA, as it is known, has the same base-pairing rules as the B and A forms, but instead has the helices twisted in the opposite direction, making a left-handed helix (Figure 2.133). The Z-form has a sort of zig-zag shape, giving rise to the name Z-DNA.

In addition, the helix is rather stretched out compared to the A- and B-forms. Why are there different topological forms of DNA? The answer relates to both superhelical tension and sequence bias. Sequence bias means that certain sequences tend to favor the "flipping" of B-form DNA into other forms. Z-DNA forms are favored by long stretches of alternating Gs and Cs. Superhelical tension is discussed below.

Superhelicity

Short stretches of linear DNA duplexes exist in the B-form and have 10.5 base pairs per turn. Double helices of DNA in the cell can vary in the number of base pairs per turn they

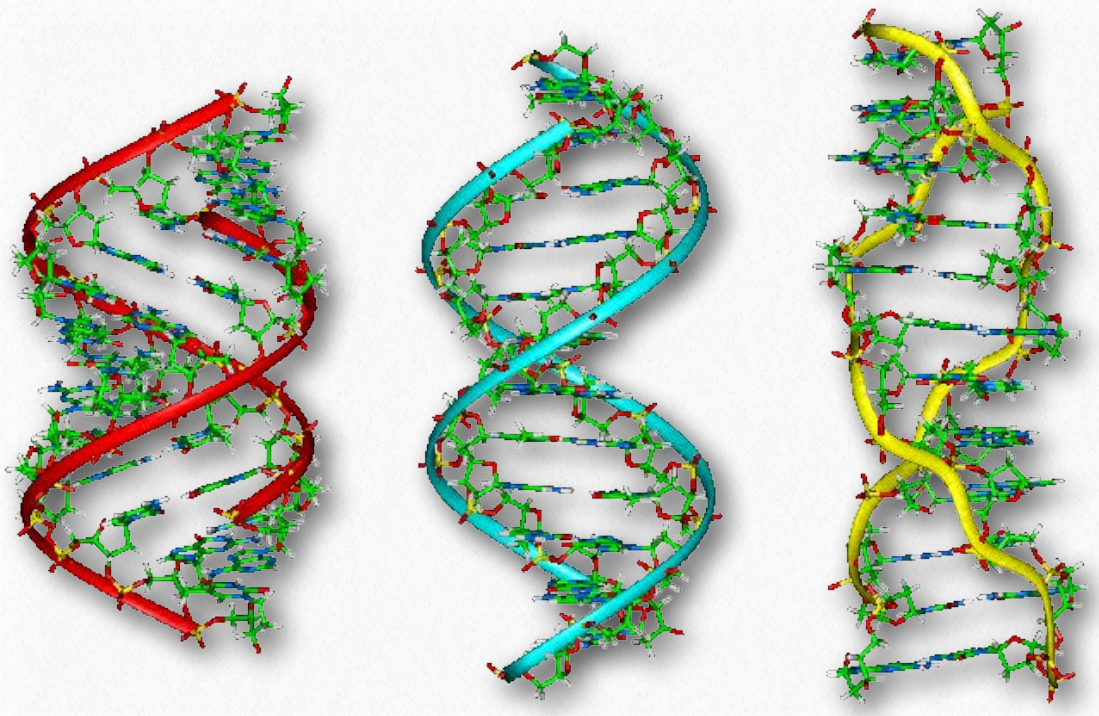


Figure 2.133 - From left to right, the A-, B-, and Z-forms of DNA

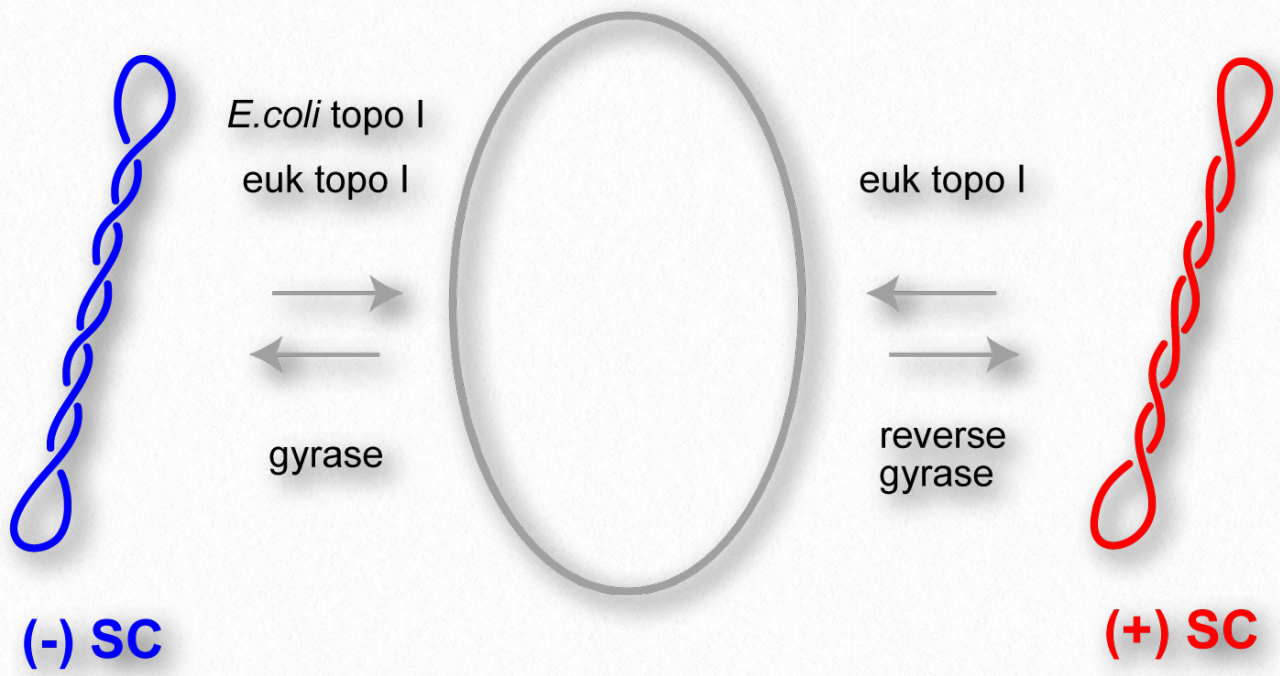

Figure 2.134 - Negatively supercoiled, relaxed circular, and positively supercoiled DNA interconverted by topoisomerase enzymes

Wikipedia

contain. There are several reasons for this. For example, during DNA replication, strands of DNA at the site of replication get unwound at the rate of 6000 rpm by an enzyme called helicase. The effect of such local unwinding at one place in a DNA has the effect increasing the winding ahead of it. Unrelieved, such 'tension' in a DNA duplex can result in structural obstacles to replication.

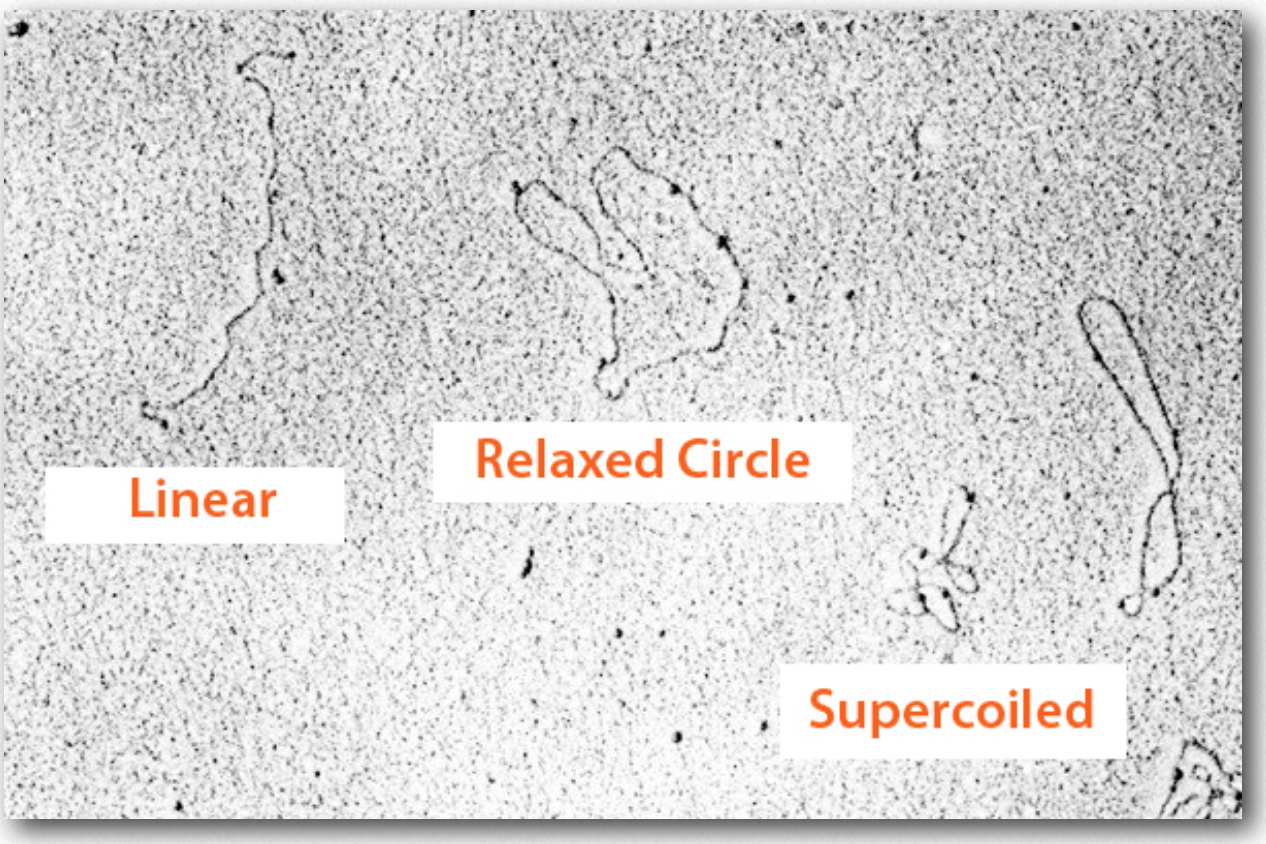

Figure 2.135 - Three topological forms of DNA

Wikipedia

Such adjustments can occur in three ways. First, tension can provide the energy for 'flipping' DNA structure. Z-DNA can arise as a means of relieving the tension. Second, DNA can 'supercoil' to relieve the tension (Figures 2.134 & 2.135). In this method, the duplex crosses over itself repeatedly, much like a rubber band will coil up if one holds one section in place and twists another part of it. Third, enzymes called topoisomerases can act to relieve or, in some cases, increase

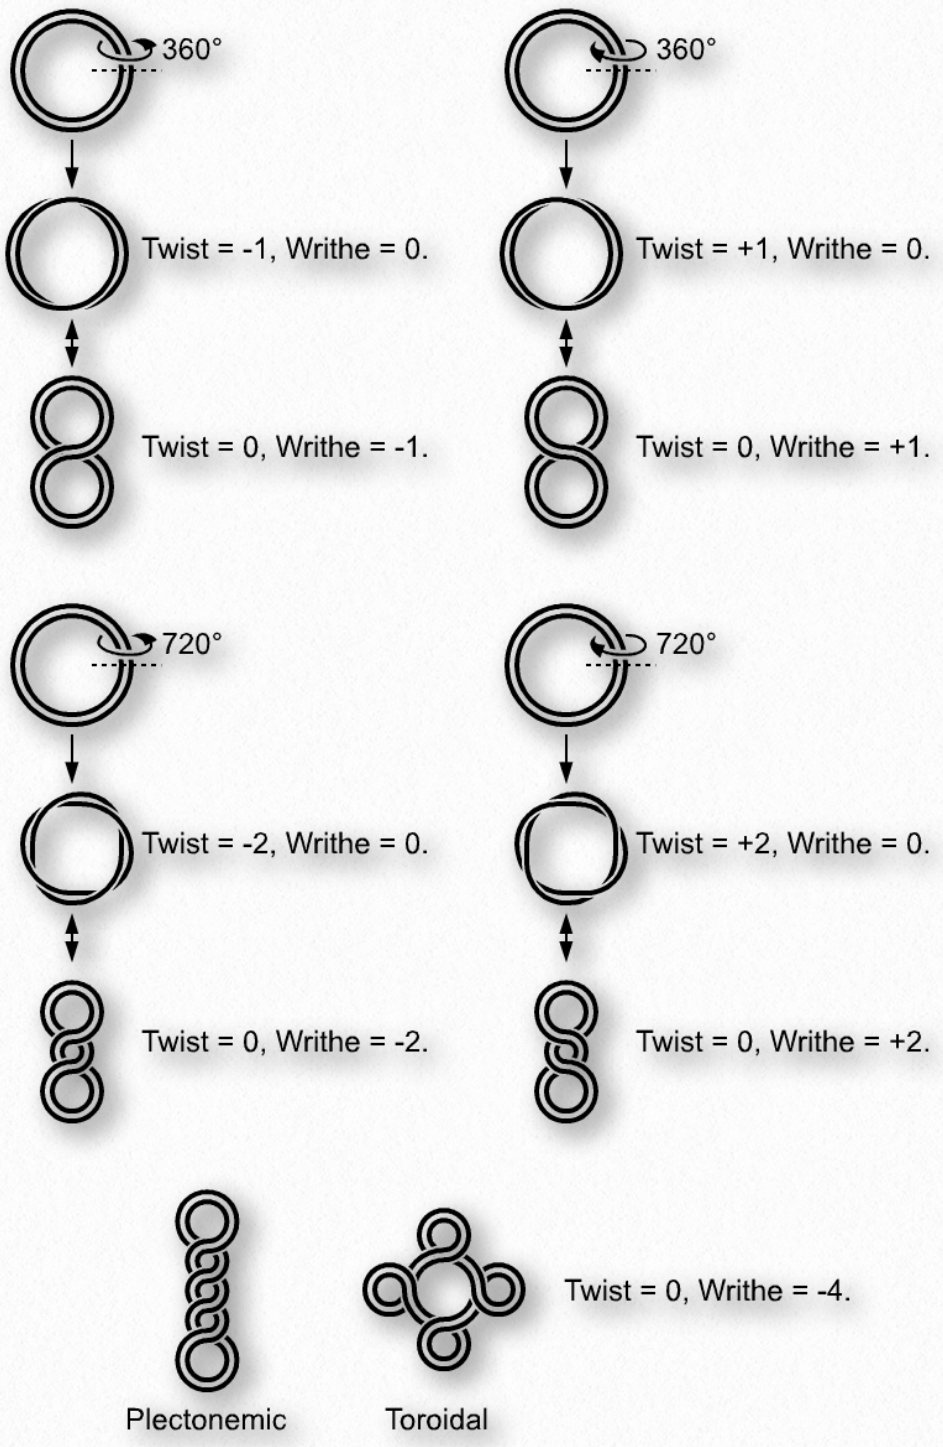

Figure 2.136 - Twists and writhes - DNA duplex coiling omitted for simplicity

Wikipedia

the tension by adding or removing twists in the DNA.

Topological isomers

As noted, so-called "relaxed" DNA has 10.5 base pairs per turn. Each turn corresponds to one twist of the DNA. Using enzymes, it is possible to change the number of base pairs per turn. In either the case of increasing or decreasing the twists per turn, tension is introduced into the DNA structure. If the tension cannot be relieved, the DNA duplex will act to relieve the strain, as noted. This is most easily visualized for circular DNA, though long linear DNA (such as found in eukaryotic chromosomes) or DNAs constrained in other ways will exhibit the same behavior.

YouTube Lectures by Kevin HERE & HERE

Parameters

To understand topologies, we introduce the concepts of 'writhe' and 'linking number'. First, imagine either opening a closed circle of DNA and either removing one twist or adding one twist and then re-forming the circle. Since the strands have no free ends, they cannot relieve the induced tension by re-adding or removing the twists at their ends, respectively. Instead, the tension is relieved by "superhelices" that form with crossing of the double strands over each other (figure 8 structures in Figure 2.136). Though it is not apparent to visualize, each crossing of the double strands in this way allows twists to be increased or decreased correspondingly. Thus, superhelicity allows the double helix to re-assume 10.5 base pairs per turn by adding or subtracting twists as necessary and replacing them with writhes.

We write the equation L = T + W where T is the number of twists in a DNA, W is the number of writhes, and L is the linking number. The linking number is therefore the sum of the twists and writhes. Interestingly, inside of cells, DNAs typically are in a supercoiled form. Supercoiling affects the size of the DNA (compacts it) and also the expression of genes within the DNA, some having enhanced expression and some having reduced expression when supercoiling is present. Enzymes called topoisomerases alter the superhelical density of DNAs and play roles in DNA replication, transcription, and control of gene expression. They work by making cuts in one strand (Type I topoisomerases) or both strands (Type II topoisomerases) and then add or subtract twists as appropriate to the target DNA. After that process is complete, the topoisomerase re-ligates the nick/cut it had made in the DNA in the first step.

Topoisomerases may be the targets of antibiotics. The family of antibiotics known as fluoroquinolones work by interfering with the action of bacterial type II topoisomerases. Ciprofloxacin also preferentially targets bacterial type II topoisomerases. Other topoisomerase inhibitors target eukaryotic topoisomerases and are used in anti-cancer treatments.

RNA

The structure of RNA (Figure 2.137) is very similar to that of a single strand of DNA. Built of ribonucleotides, joined together by the same sort of phosphodiester bonds as in DNA, RNA uses uracil in place of thymine. In cells, RNA is assembled by RNA polymerases, which copy a DNA template in the much same way that DNA polymerases replicate a parental strand. During the synthesis of RNA, uracil is used across from an adenine in the DNA template. The building of messenger RNAs by copying a DNA template is a crucial step in the transfer of the information in DNA to a form that directs the synthesis of protein. Additionally, ribosomal and transfer RNAs serve important roles in "reading" the information in the

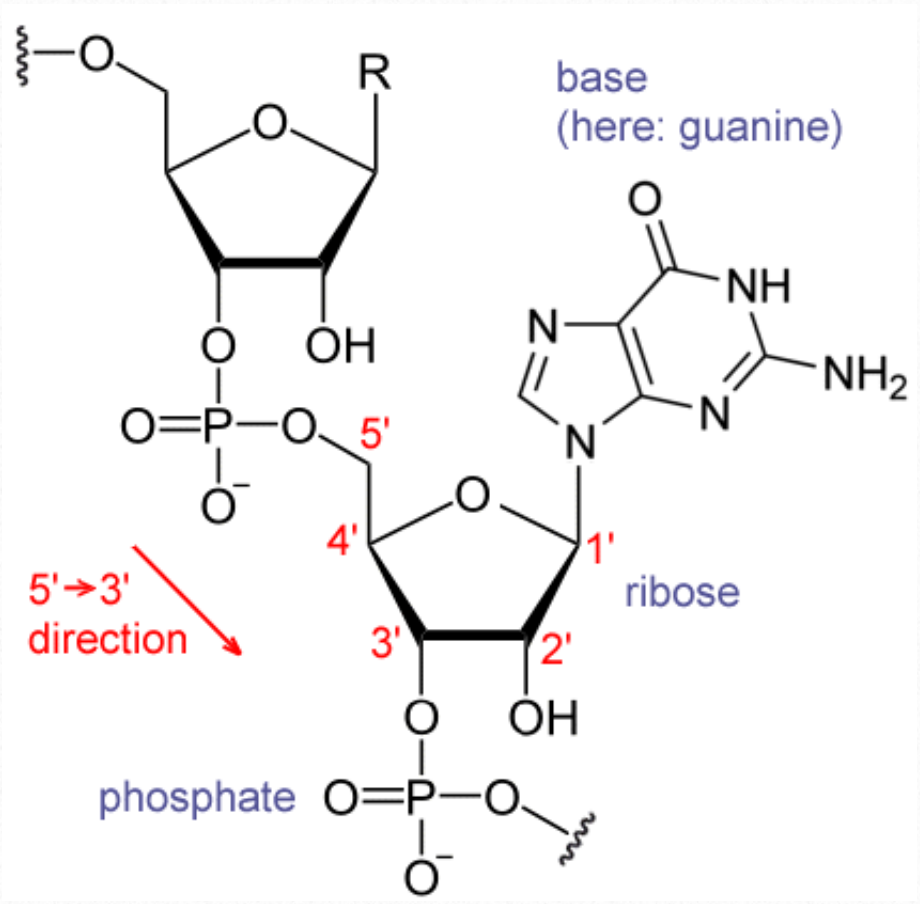

Figure 2.137 A section of an RNA molecule
Wikipedia

mRNA codons and in polypeptide synthesis. RNAs are also known to play important roles in the regulation of gene expression.

RNA world

The discovery, in 1990, that RNAs could play a role in catalysis, a function once thought to be solely the domain of proteins, was followed by the discovery of many more so-called ribozymes- RNAs that functioned as enzymes. This suggested the answer to a long-standing chicken or egg puzzle - if DNA encodes proteins, but the replication of DNA requires proteins, how did a replicating system come into being? This problem could be solved if the first replicator was RNA, a molecule that can both encode information and carry out catalysis. This idea, called the "RNA world" hypothesis, suggests that DNA as genetic material and proteins as catalysts arose later, and eventually prevailed because of the advantages they offer. The lack of a 2'OH on deoxyribose makes DNA more stable than RNA. The double-stranded structure of DNA also provides an elegant way to easily replicate it. RNA catalysts, however, remain, as remnants of that early world. In fact, the formation of peptide bonds, essential for the synthesis of proteins, is catalyzed by RNA.

Secondary structure

With respect to structure, RNAs are more varied than their DNA cousin. Created by copying regions of DNA, cellular RNAs are synthesized as single strands, but they often have self-complementary regions leading to "foldbacks" containing duplex regions. These are most easily visualized in the ribosomal RNAs (rRNAs) and transfer RNAs (tRNAs) (Figure 2.138), though other RNAs, including

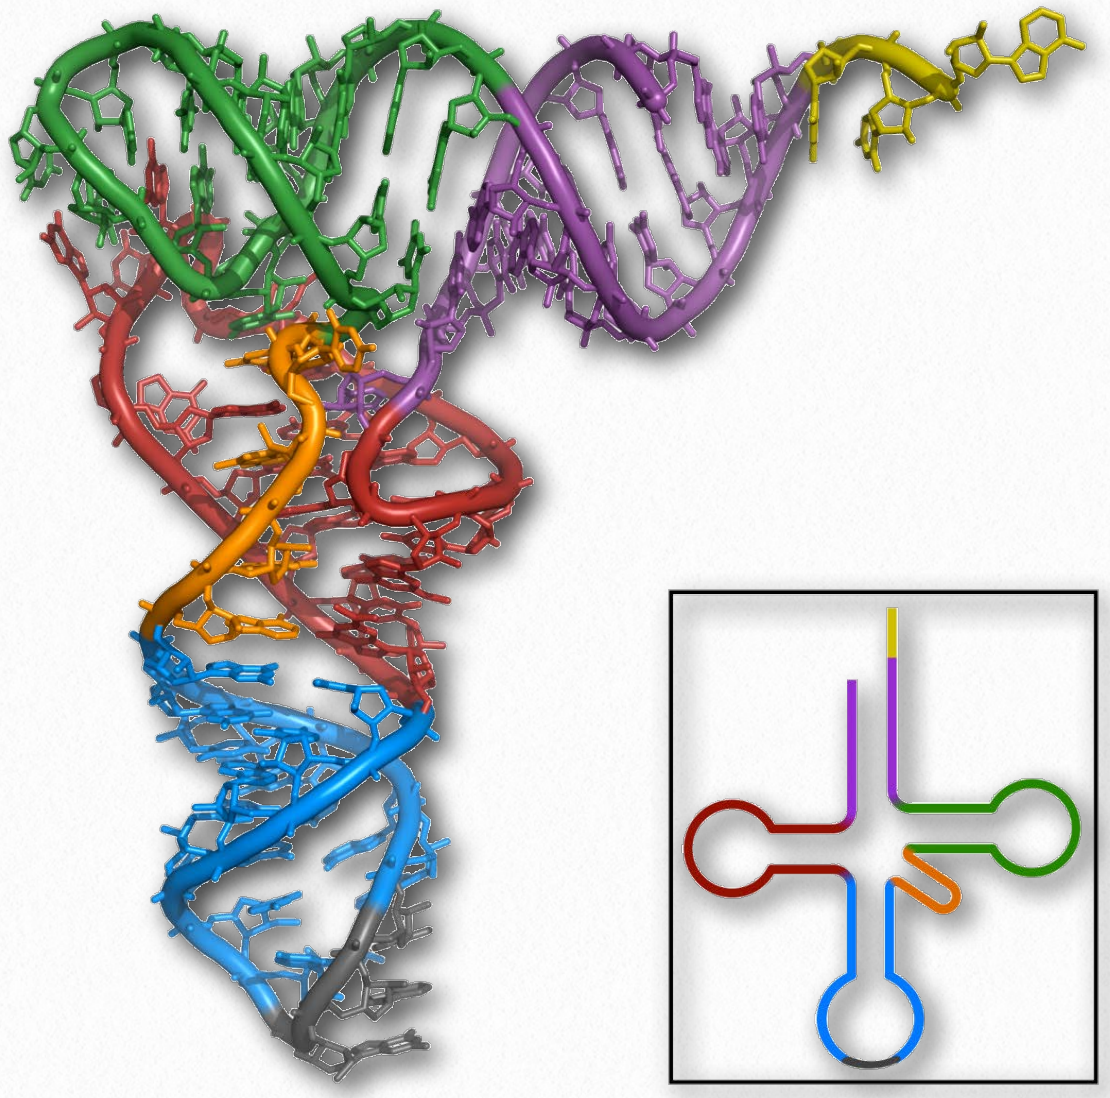

Figure 2.138 - tRNA Images - 3D projection (left) and 2D projection (inset)

Wikipedia

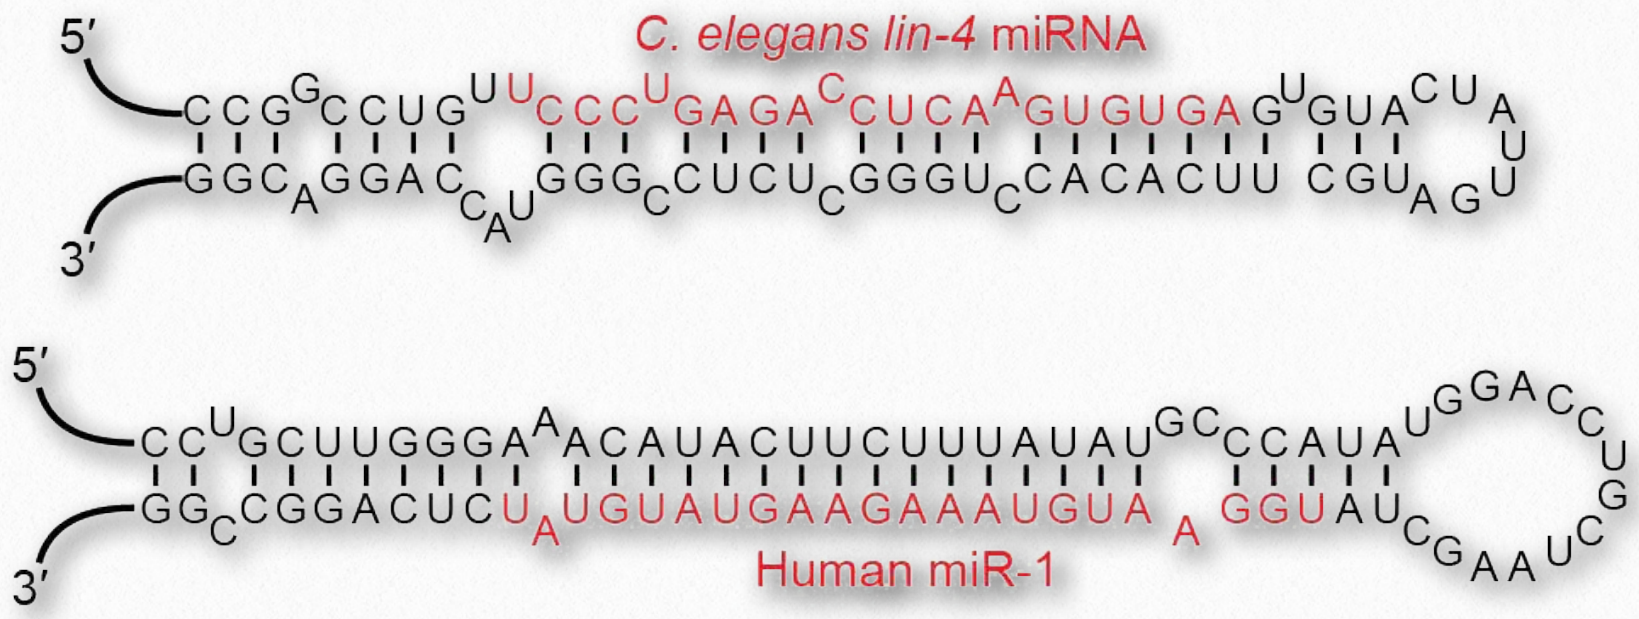

Figure 2.139 - MicroRNA stem loops.

Wikipedia

messenger RNAs (mRNAs), small nuclear RNAs (snRNAs), microRNAs (Figure 2.139), and small interfering RNAs (siRNAs) may each have double helical regions as well.

YouTube Lectures by Kevin HERE & HERE

Base pairing

Base pairing in RNA is slightly different than DNA. This is due to the presence of the base uracil in RNA in place of thymine in DNA. Like thymine, uracil forms base pairs with adenine, but unlike thymine, uracil can, to a limited extent, also base pair with guanine, giving rise to many more possibilities for pairing within a single strand of RNA.

These additional base pairing possibilities mean that RNA has many ways it can fold upon itself that single-stranded DNA cannot. Folding, of course, is critical for protein function, and we now know that, like proteins, some RNAs in their folded form can catalyze reactions just like enzymes. Such RNAs are referred to as ribozymes. It is for this reason scientists think that RNA was the first genetic material, because it could not only carry information, but also catalyze reactions. Such a scheme might allow certain RNAs to make copies of themselves, which would, in turn, make more copies of themselves, providing a positive selection.

Stability

RNA is less chemically stable than DNA. The presence of the 2' hydroxyl on ribose makes RNA much more prone to hydrolysis than DNA, which has a hydrogen instead of a hydroxyl. Further, RNA has uracil instead of thymine. It turns out that cytosine is the

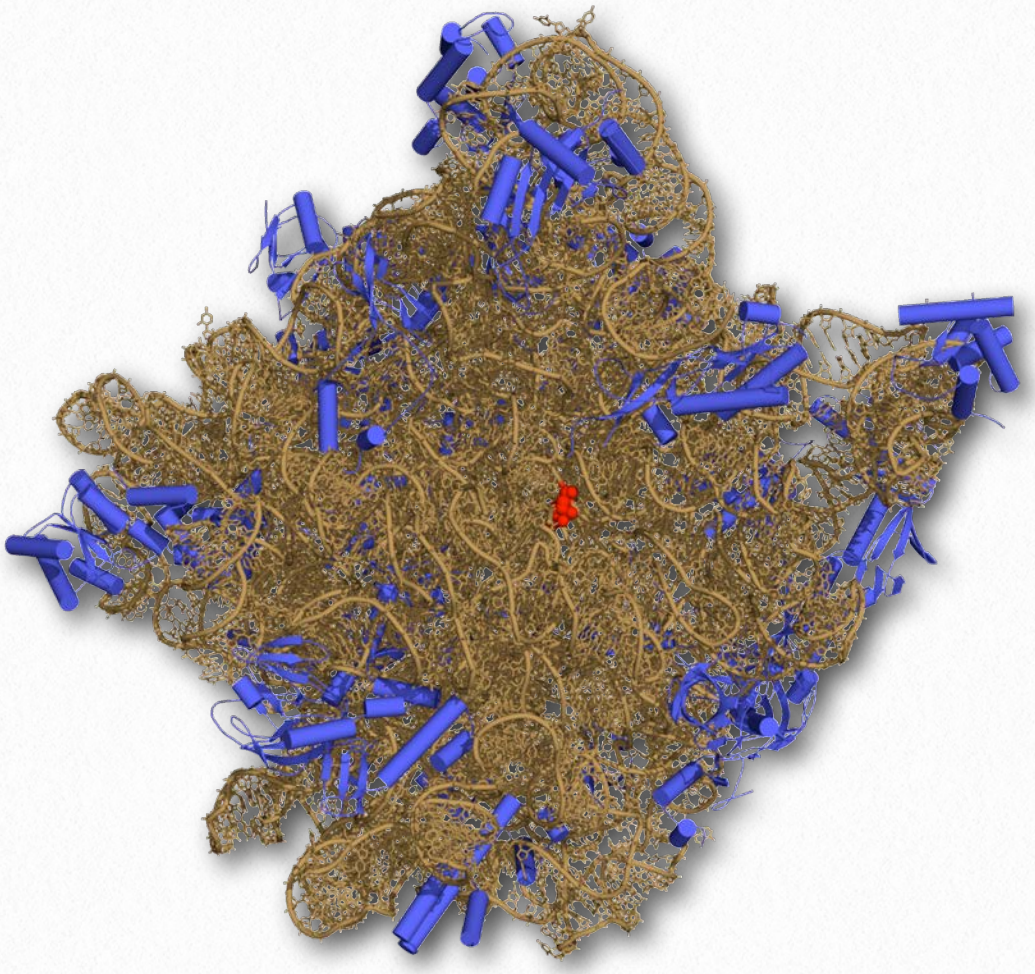

Figure 2.140 - Structure of the 50S ribosomal subunit. rRNA shown in brown. Active site in red
Wikipedia

least chemically stable base in nucleic acids. It can spontaneously deaminate and in turn is converted to a uracil. This reaction occurs in both DNA and RNA, but since DNA normally has thymine instead of uracil, the presence of uracil in DNA indicates that deamination of cytosine has occurred and that the uracil needs to be replaced with a cytosine. Such an event occurring in RNA would be essentially undetectable, since uracil is a normal component of RNA. Mutations in RNA have much fewer consequences than mutations in DNA because they are not passed between cells in division.

Catalysis

RNA structure, like protein structure, has importance, in some cases, for catalytic function. Like random coils in proteins that give rise to tertiary structure, single-stranded regions of RNA that link duplex regions give these molecules a tertiary structure, as well. Catalytic RNAs, called ribozymes, catalyze important cellular reactions, including the formation of peptide bonds in ribosomes (Figure 2.114). DNA, which is usually present in cells in strictly duplex forms (no tertiary structure, per se), is not known to be involved in catalysis.

RNA structures are important for reasons other than catalysis. The 3D arrangement of tRNAs is necessary for enzymes that attach amino acids to them to do so properly. Further, small RNAs called siRNAs found in the nucleus of cells appear to play roles in both gene regulation and in cellular defenses against viruses. The key to the mechanisms of these actions is the formation of short fold-back RNA structures that are recognized by cellular proteins and then chopped into smaller units. One strand is copied and used to base pair with specific mRNAs to prevent the synthesis of proteins from them.

Denaturing nucleic acids

Like proteins, nucleic acids can be denatured. Forces holding duplexes together include hydrogen bonds between the bases of each strand that, like the hydrogen bonds in proteins, can be broken with heat or urea. (Another important stabilizing force for DNA arises from the stacking interactions between the bases in a strand.) Single strands absorb light at 260 nm more strongly than double strands. This is known as the hyperchromic effect (Figure 2.141)and is a consequence of the disruption of interactions among the stacked bases. The changes in absorbance allow one to easily follow the course of DNA denaturation. Denatured duplexes can readily renature when the temperature is lowered below the "melting temperature" or T_m, the temperature at which half of the DNA strands are in duplex form. Under such conditions, the two strands can re-form hydrogen bonds between the complementary sequences, returning the duplex to its original state. For DNA, strand separation and re-hybridization are important for the technique known as the polymerase chain reaction (PCR). Strand separation of DNA duplexes is accomplished in the method by heating them to boiling. Hybridization is an important aspect of the method that requires single stranded primers to "find" matching sequences on the template DNA and form a duplex. Considerations for efficient hybridization (also called annealing) include temperature, salt concentration, strand concentration, and magnesium ion levels (for more on PCR, see HERE).

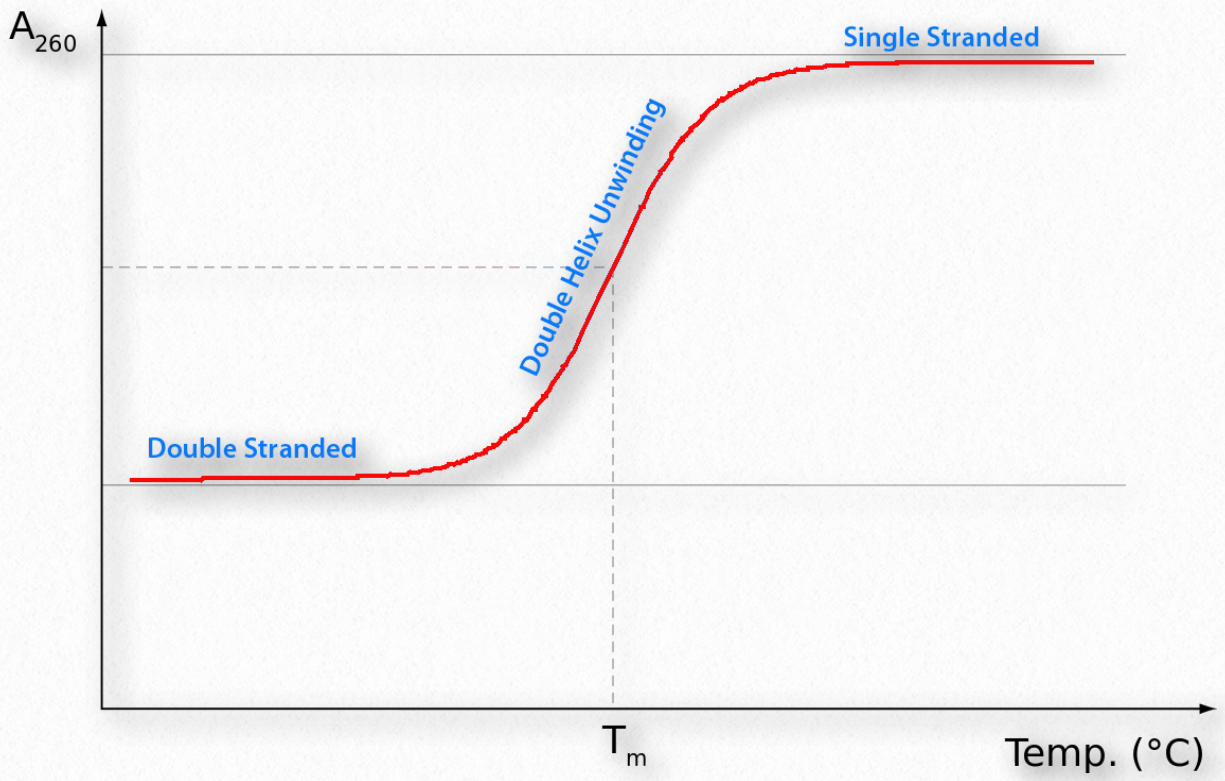

Figure 2.141 - The hyperchromic effect

Wikipedia

DNA packaging

DNA is easily the largest macromolecule in a cell. The single chromosome in small bacterial cells, for example, can have a molecular weight of over 1 billion Daltons. If one were to take all of the DNA of human chromosomes from a single cell and lay them end to end, they would be over 7 feet

long. Such an enormous molecule demands careful packaging to fit within the confines of a nucleus (eukaryotes) or a tiny cell (bacteria). The chromatin system of eukaryotes is the best known, but bacteria, too, have a system for compacting DNA.

Bacteria

In bacteria, there is no nucleus for the DNA. Instead, DNA is contained in a structure

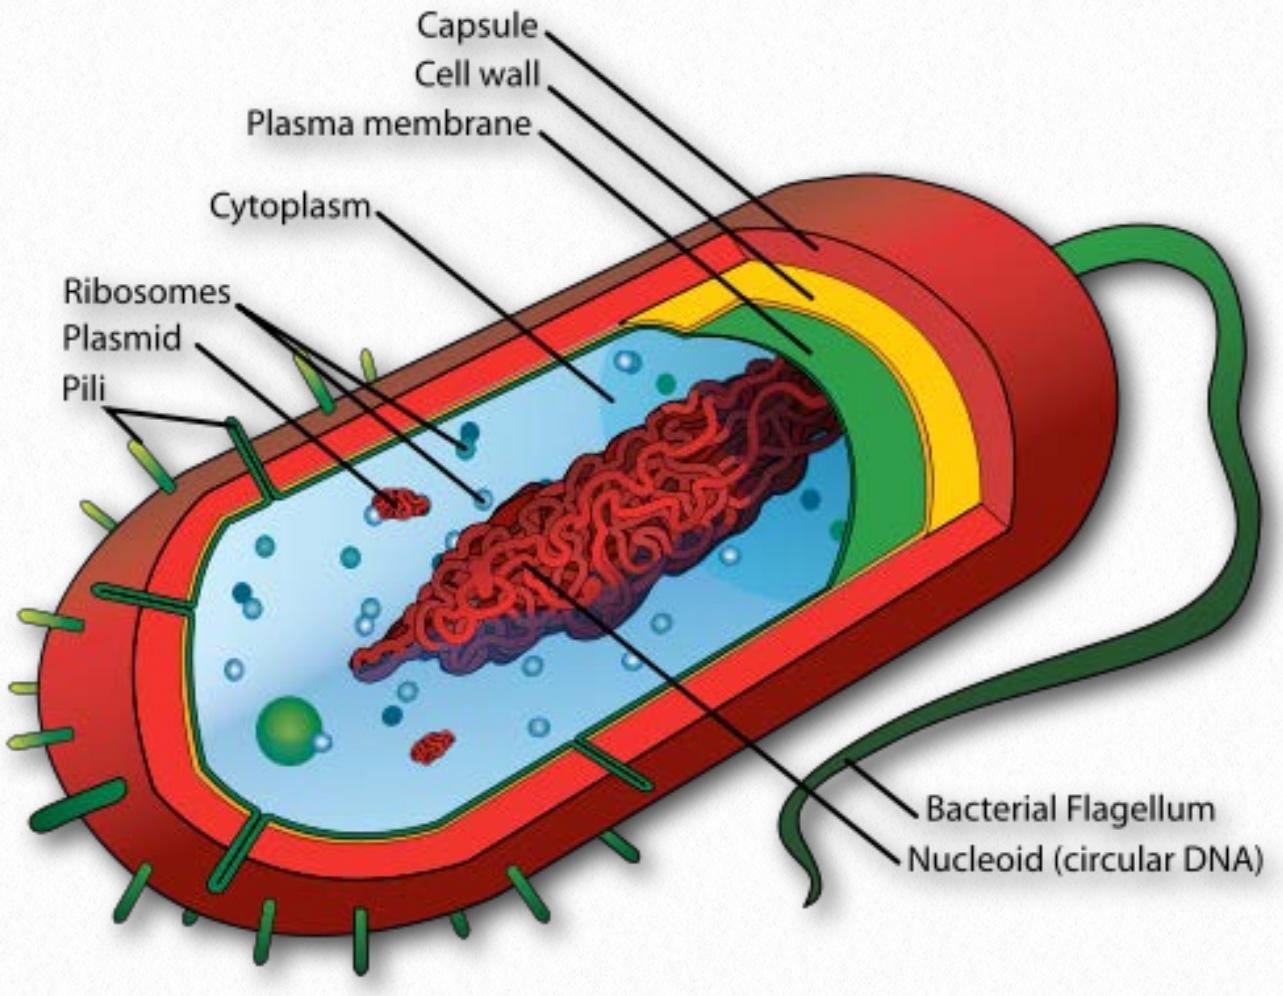

Figure 2.142 - Anatomy of a bacterial cell.

called a nucleoid (Figure 2.142). It contains about 60% DNA with much of the remainder comprised of RNAs and transcription factors. Bacteria do not have histone proteins that DNA wrap around, but they do have proteins that help organize the DNA in the cell - mostly by making looping structures.

These proteins are known as Nucleoid Associated Proteins and include ones named HU, H-NS, Fis, CbpA, and Dps. Of these, HU most resembles eukaryotic histone H2B and binds to DNA non-specifically. The proteins associate with the DNA and can also cluster, which may be the origin of the loops. It is likely these proteins play a role in helping to regulate transcription and respond to DNA damage. They may also be involved in recombination.

Eukaryotes

The method eukaryotes use for compacting DNA in the nucleus is considerably different, and with good reason - eukaryotic DNAs are typically much larger than prokaryotic DNAs, but must fit into a nucleus that is not much bigger than a prokaryotic cell. Human DNA, for example, is about 1000 times longer than *c* DNA.

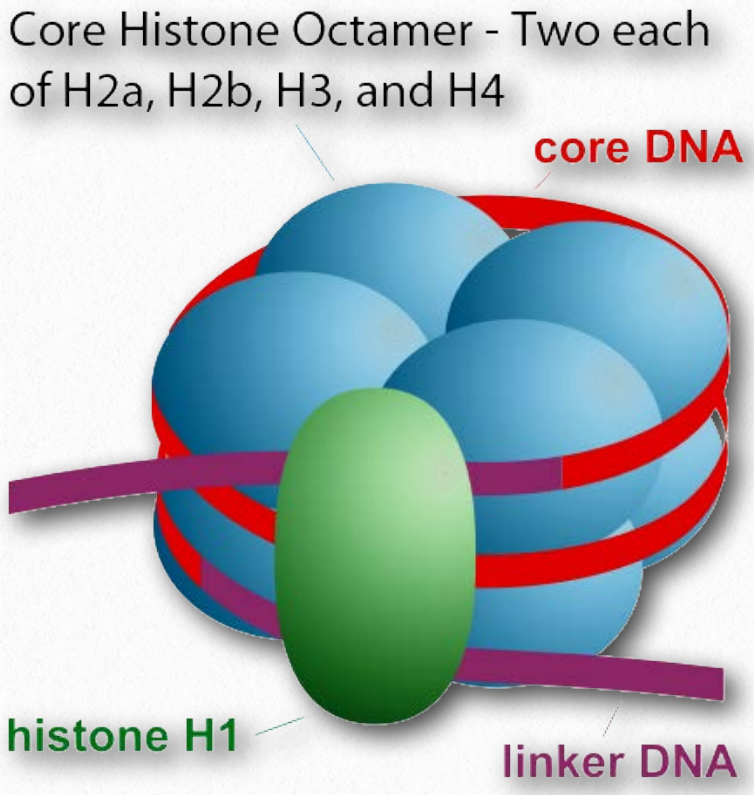

Figure 2.143 - Structure of a nucleosome

Wikipedia

Octamer

The core of 8 proteins is called an octamer. The stretch of DNA wrapped around the octamer totals about 147 base pairs and makes 1 2/3 turns around it. This complex is referred to as a core particle (Figure 2.144). A linker region of about 50-80 base pairs separate core particles. The term nucleosome then refers to a a core particle plus a linker region (Figure 2.143). Histone H1 sits near the junction of the incoming DNA and the histone core. It is often referred to as the linker histone. In the absence of H1, non-condensed nucleosomes resemble "beads on a string" when viewed in an electron microscope.

The strategy employed in eukaryotic cells is that of spooling - DNA is coiled around positively charged proteins called histones. These proteins, whose sequence is very similar in cells as diverse as yeast and humans, come in four types, dubbed H1, H2a, H2b, H3, and H4. A sixth type, referred to as H5 is actually an isoform of H1 and is rare. Two each of H2a, H2b, H3, and H4 are found in the core structure of what is called the fundamental unit of chromatin - the nucleosome (Figure 2.143).

Figure 2.145 - Amino acid sequence (1-letter code) of histone H3 of *S. cerevisiae*. Arginines (R) and lysines (K) shown in red.

Histones

Histone proteins are similar in structure and are rich in basic amino acids, such as lysine and arginine (Figure 2.145). These amino acids are positively charged at physiological pH, with enables them to form tight ionic bonds with the negatively charged phosphate backbone of DNA.

YouTube Lectures by Kevin HERE & HERE

For DNA, compression comes at different levels (Figure 2.146). The first level is at the nucleosomal level. Nucleosomes are stacked and coiled into higher order structures. 10 nm fibers are the simplest higher order structure (beads on a string) and they grow in complexity. 30 nm fibers consist of stacked nucleosomes and they are packed tightly. Higher level packing produces the metaphase chromosome found in meiosis and mitosis.

The chromatin complex is a logistical concern for the processes of DNA replication and (particularly) gene expression where specific regions of DNA must be transcribed. Altering chromatin structure is therefore an essential function for transcriptional activation in eukaryotes. One strategy involves adding acetyl groups to the positively charged lysine side chains to "loosen their grip" on the negatively charged DNA, thus allowing greater access of proteins involved in activating transcription to gain access to the DNA. The mechanisms involved in eukaryotic gene expression are

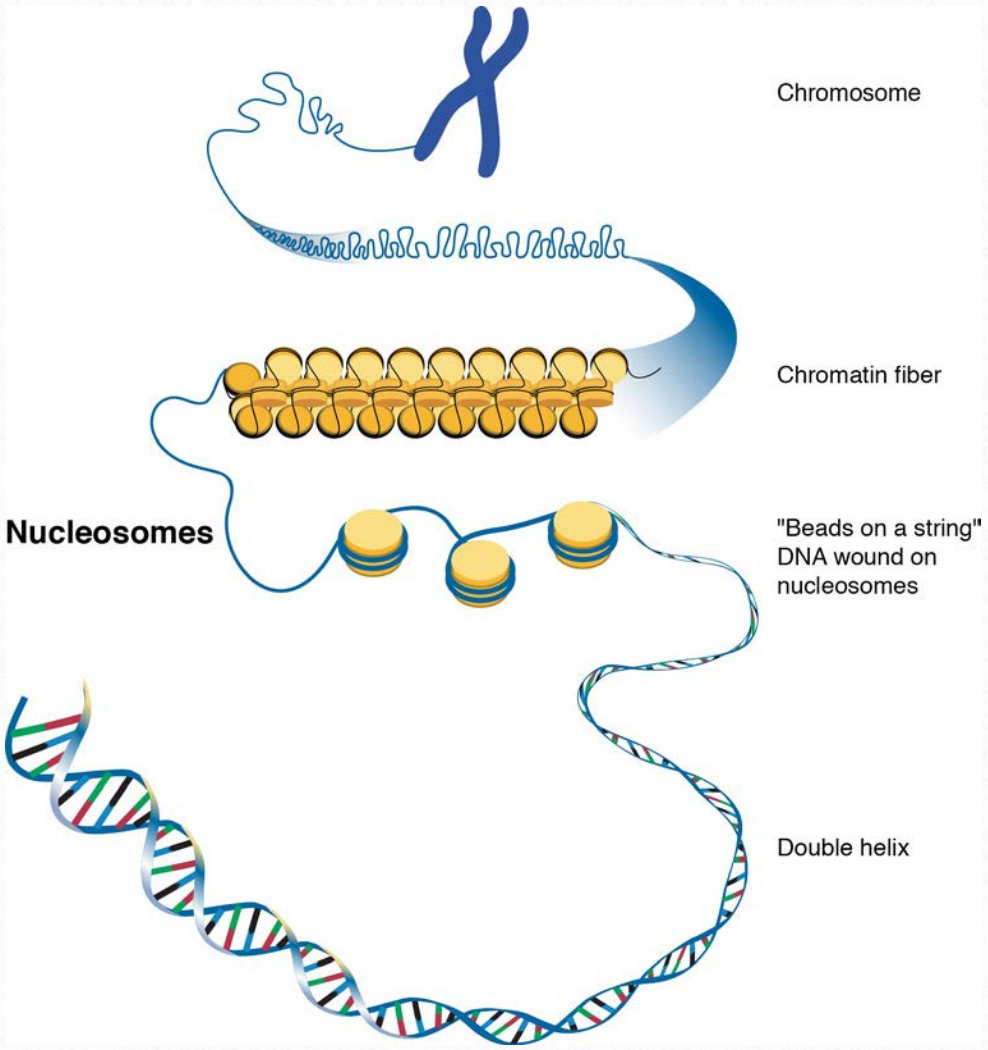

Figure 2.146 Packaging of DNA into a chromosome

discussed in more detail HERE.

Ames test

The Ames test (Figure 2.147) is an analytical method that allows one to determine whether a compound causes mutations in DNA (is mutagenic) or not. The test is named for Dr. Bruce Ames, a UC Berkeley emeritus professor who was instrumental in creating it. In the procedure, a single base pair of a selectable marker of an organism is mutated in a plasmid to render it non-functional. In the example, a strain of *Salmonella* is created that lacks the ability to grow in the absence of histidine. Without histidine, the organism will not grow, but if that one base in the plasmid's histidine gene gets changed back to its original base, a functional gene will be made and the organism will be able to grow without histidine.

A culture of the bacterium lacking the functional gene is grown with the supply of histidine it requires. It is split into two vials. To one of the vials, a compound that one wants to test the mutagenicity of is added. To the other vial, nothing is added. The bacteria in each vial are spread onto plates lacking histidine. In the absence of mutation, no bacteria will grow. The more colonies of bacteria that grow, the more mutation happened. Note that even the vial without the possible mutagenic compound will have a few colonies grow, as a result of mutations unlinked to the potential mutagen.

Mutation happens in all cells at a low level. If the plate with the cells from the vial with the compound has more colonies than the cells from the control vial (no compound), then that would be evidence that the compound causes more mutations than would normally occur and it is therefore a mutagen. On the

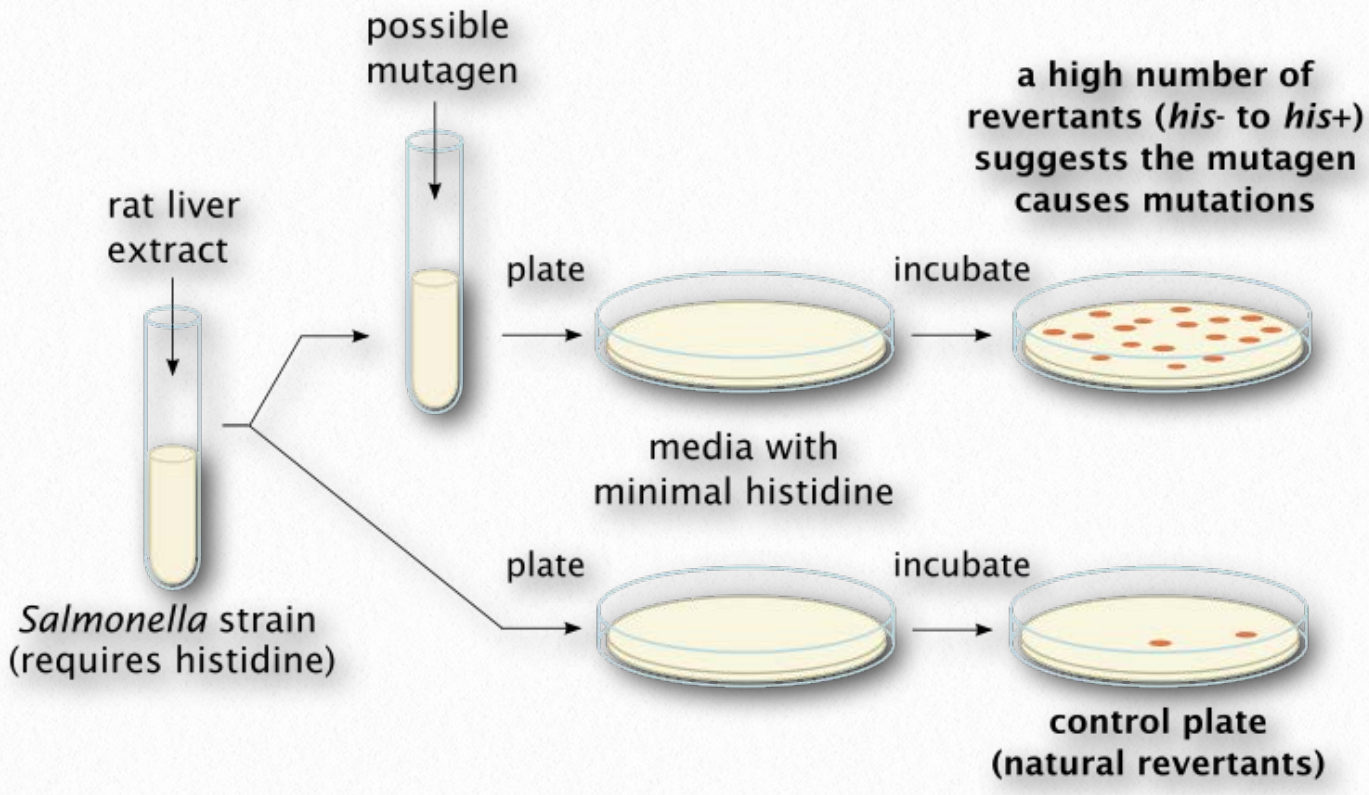

Figure 2.147 - The Ames test

Wikipedia

other hand, if there was no significant difference in the number of colonies on each plate, then that would suggest it is not mutagenic. The test is not perfect - it identifies about 90% of known mutagens - but its simplicity and inexpensive design make it an excellent choice for an initial screen of a compound.

Lyrics by Kevin Ahern

Structure & Function: Carbohydrates

Introduction

Carbohydrates are a third major group of biomolecules. This diverse group is commonly described as sugars, or saccharides, from the Greek word for sugar. The simplest carbohydrates are called monosaccharides, or simple sugars. An example is glucose. Monosaccharides can be joined to make larger molecules. Disaccharides contain two monosaccharides. Sucrose is a disaccharide, containing both fructose and glucose. Polysaccharides are chains of many sugar subunits. Examples include glycogen and cellulose, both of which are polymers of glucose (but with different configurations).

YouTube Lectures by Kevin HERE & HERE

Carbohydrates are literally “hydrates of carbon.” This designation derives from the generalized formula of simple monosaccharides, which can be written in the form of $C_x(H_2O)_x$, where x is a digit typically between 3 and 8. Not all sugars have this formula, however. Deoxyribose, the sugar found in every nucleo-

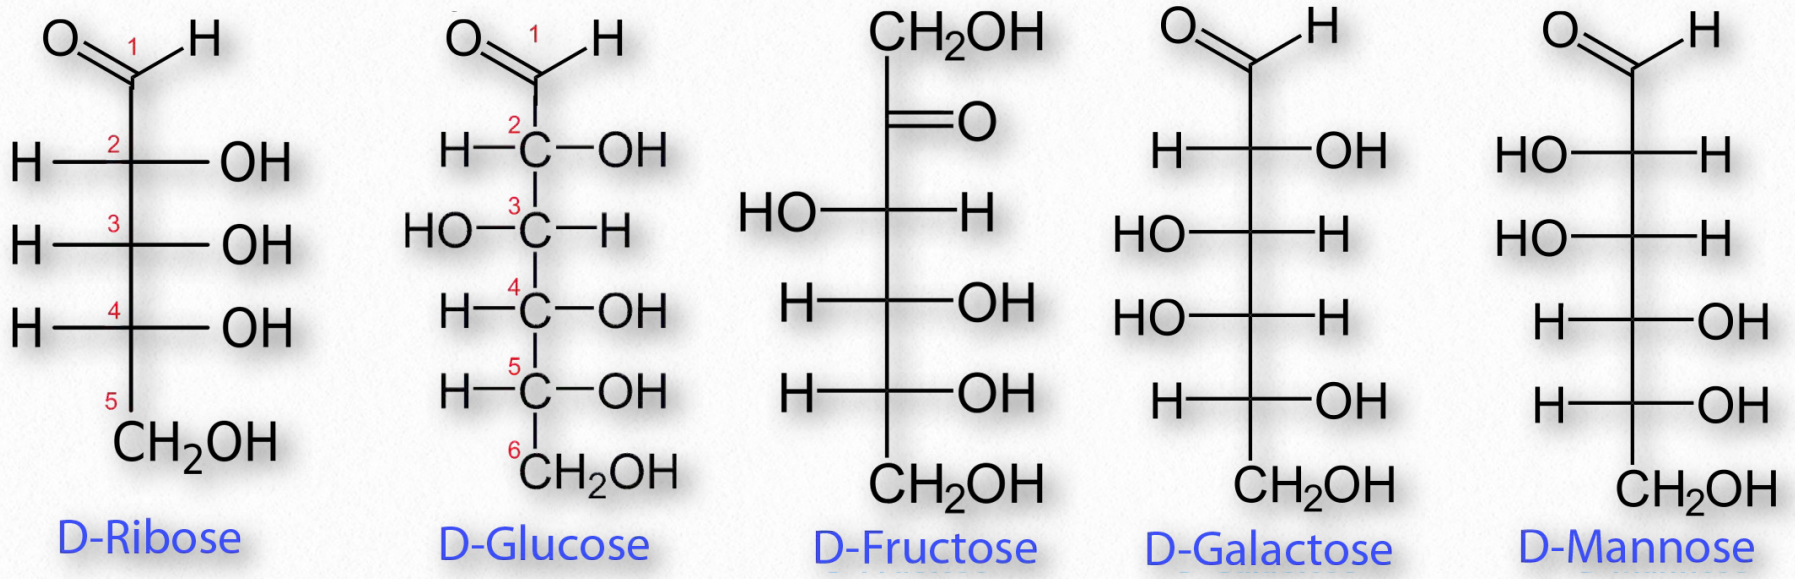

Figure 2.148 - Common sugar structures

tide in a DNA molecule lacks one oxygen and thus has the formula $C_5H_{10}O_4$.

Carbohydrates are important in cells as energy sources (glucose, glycogen, amylose), as markers of cellular identity (oligosaccharides on the surface of cells of multicellular organisms), as structural components (cellulose in plants), and as constituents of nucleotides (ribose in RNA, deoxyribose in DNA).

The building blocks of carbohydrates are simple sugars and it is here we begin our description.

Monosaccharides

The most common monosaccharides include glucose, fructose, galactose, ribose, and mannose. Of these sugars, all but one (fructose) exists as an aldehyde. Fructose and other less well known sugars are ketones. Figure 2.148 shows the structure of these sugars. Some discussion of nomenclature is appropriate.

By convention, the letters 'ose' at the end of a biochemical name flags a molecule as a sugar. Thus, there are glucose, galactose, sucrose, and many other '-oses'. Other descriptive nomenclature involves use of a prefix that tells how many carbons the sugar contains. For example, glucose, which contains six carbons, is described as a hexose. The following list shows the prefixes for numbers of carbons in a sugar:

- **Tri- = 3**
- **Tetr- = 4**
- **Pent- = 5**
- **Hex- =6**
- **Hept- = 7**
- **Oct- = 8**

Other prefixes identify whether the sugar contains an aldehyde group (aldo-) or a ketone (keto-) group. Prefixes may be combined. Glucose, which is a 6-carbon sugar with an aldehyde group, can be described as an aldo-

hexose. The list that follows gives the common sugars and their descriptors.

- **Ribose = aldo-pentose**
- **Glucose = aldo-hexose**
- **Galactose = aldo-hexose**
- **Mannose = aldo-hexose**
- **Fructose = keto-hexose**

Diastereomers

Sugars may have multiple asymmetric carbons and thus differ from each other in the configuration of hydroxyl groups on asymmetric carbons. Two sugars having the same chemical form (aldoses, for example) and the same number of carbons, but that differ only in the stereochemical orientations of their carbons are referred to as diastereomers (Figure 2.149). For example, glucose, galactose, and mannose all have the formula of $C_6H_{12}O_6$, but are chemically distinct from each other in the orientation of hydroxyl groups around the carbons within them.

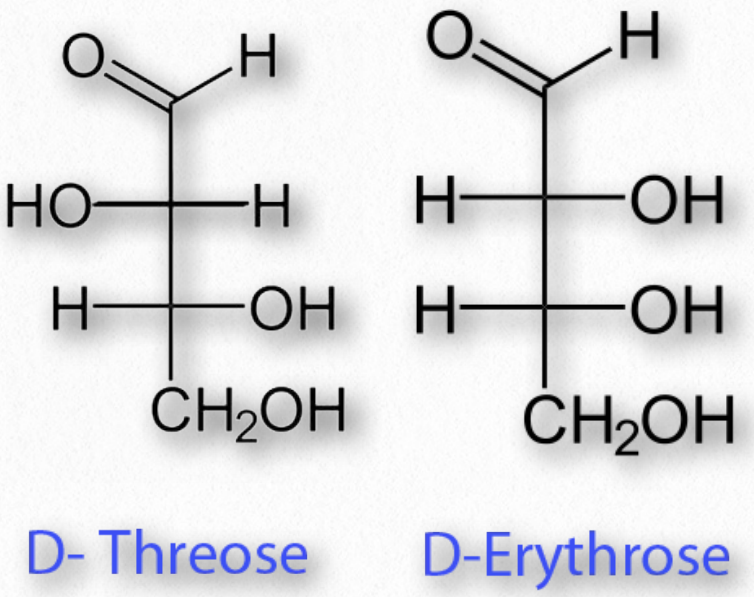

Figure 2.149 - Diastereomers

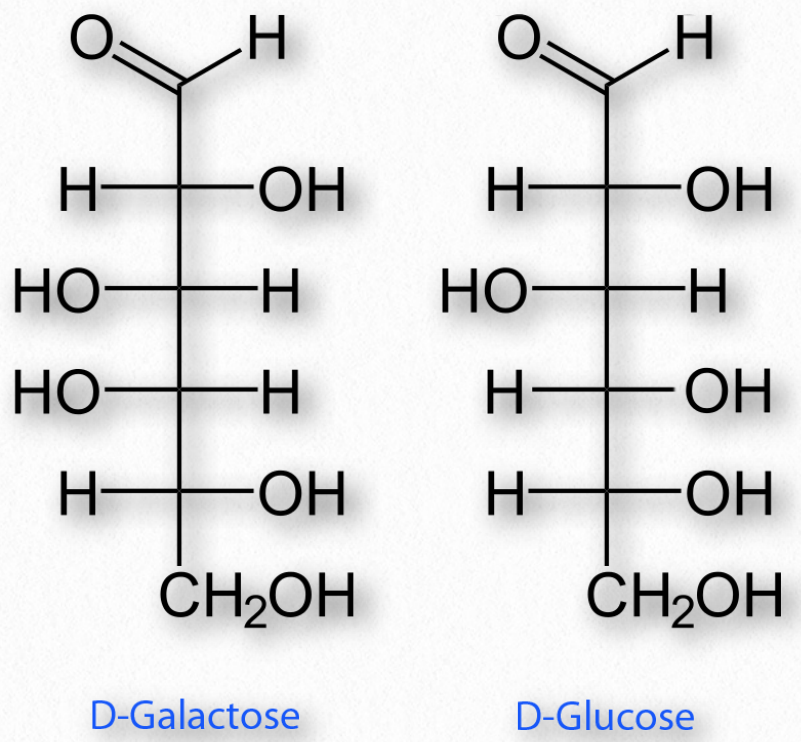

Figure 2.150 - Epimers - D-Galactose and D-Glucose differ only in the configuration of carbon #4

Enantiomers and epimers

If two sugars are identical except for having one hydroxyl configured differently (such as

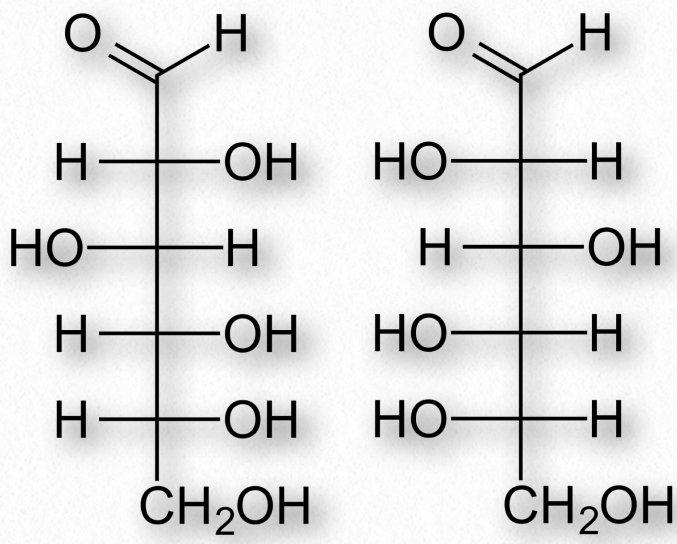

Figure 2.151 - Enantiomers - D-Glucose (left) and L-Glucose (right) are mirror images

ror
im-

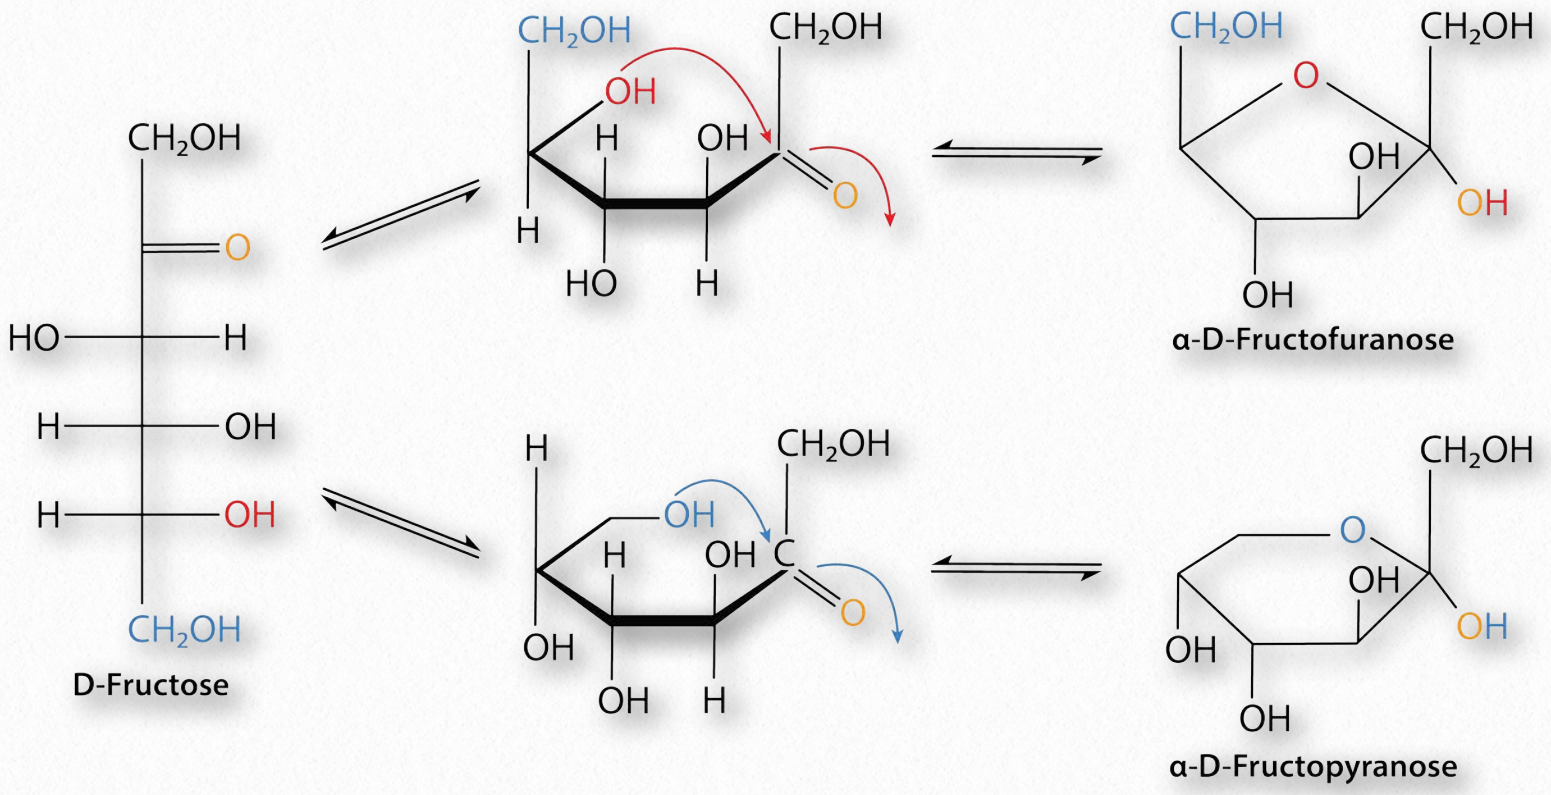

Figure 2.152 - Conversion of D-fructose between furanose (top right), linear (left), and pyranose (bottom right) forms

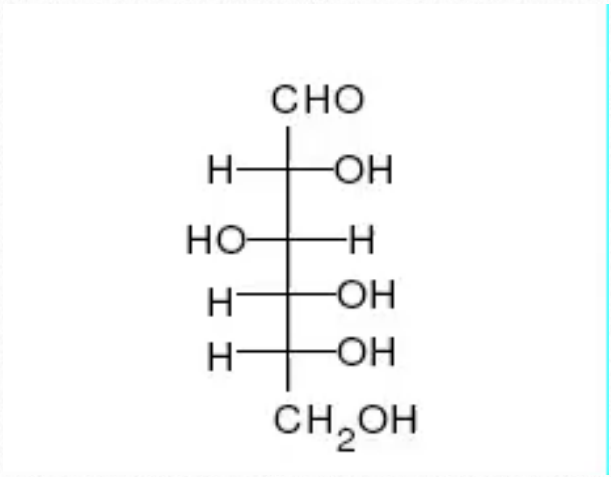
Image by Pehr Jacobson

glucose and galactose - Figure 2.150), they are diastereomers known as epimers. If the configuration of all of the hydroxyls of one sugar is exactly the opposite of their configuration in another sugar, the two sugars are mirror images of each other (Figure 2.151). Mirages of sugars are known as enantiomers. Please note that due to the way sugars are named, L-glucose is the mirror image of D-glucose.



Movie 2.6 - Conversion of glucose from a straight chain form to a ring form

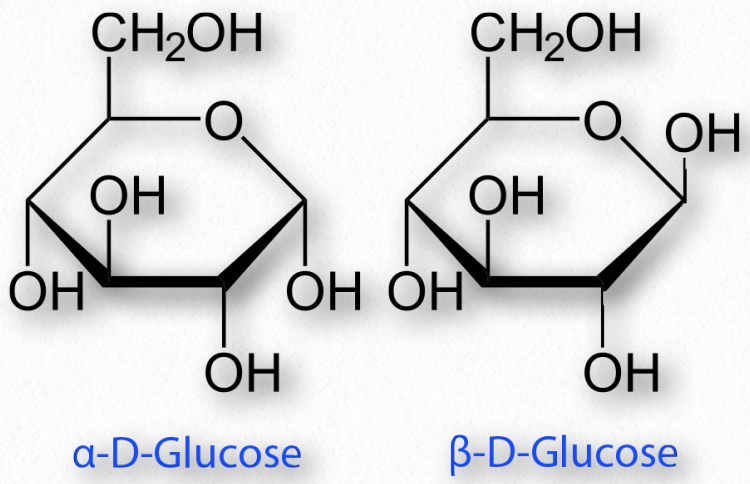


Figure 2.153 - Anomers - α-D-Glucose and β-D-Glucose differ only in the configuration of the anomeric carbon #1

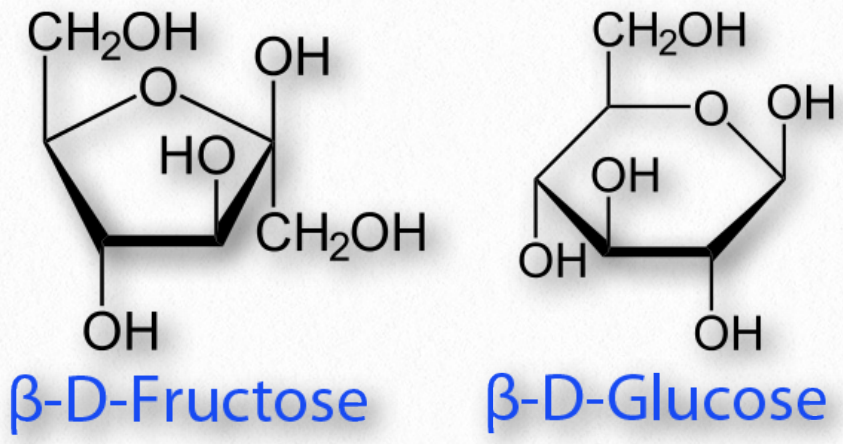

Figure 2.154 - A furanose (left) and a pyranose (right)

Sugars with five and six carbons can readily cyclize (Figure 2.152, Movie 2.6) and when they do, a new asymmetric carbon is created that didn't exist in the same sugars when they were in the straight chain form. This carbon has a special name - it is called the anomeric carbon and (like the other asymmetric carbons in sugars) it can have the hydroxyl in two different positions. These positions are referred to as α and β . Sugars, such as α-D-glucose and β-D-glucose that differ only in the configuration of the anomeric carbon are referred to as anomers (Figure 2.153).

Sugars cyclizing to form rings with five atoms in them (see fructose in Figure 2.128) are referred to as furanoses (named for furan) and those forming rings with six atoms, such as glucose in the same figure, are called pyranoses (named for pyran). The carbonyl carbon beomces the anomeric carbon in the ring by binding to the oxygen of a hydroxyl elsewhere in the chain. α- and β- forms of a given sugar can readily "flip" between each form in solution, so long as the anomeric hydroxyl is free. Most pentoses and hexoses can form both furanose and pyranose structures (Figure 2.152).

Linking the anomeric hydroxyl to another group will create a glycoside and glycosides will remain locked in whichever α- or β- configuration they were in when the anomeric hydroxyl was altered.

YouTube Lectures by Kevin HERE & HERE

Boat/chair conformations

Orbitals of carbon prefer to be in tetrahedral conformations and this means that the bonds between carbons in a ring do not lie flat. Indeed, rings "pucker" to try to accommodate this tendency, giving rise to different 3D forms for any given sugar. Some of these

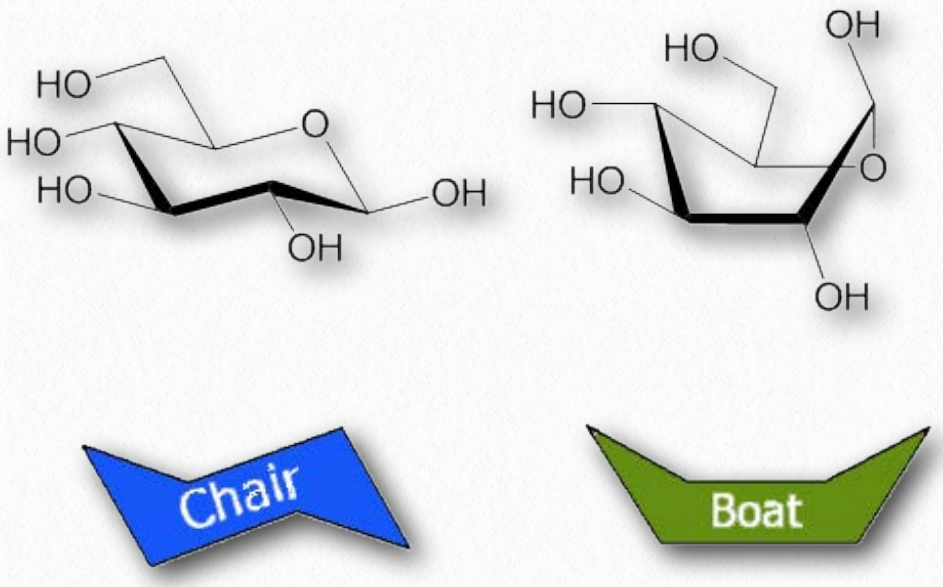

Figure 2.155 - Chair and boat forms of glucose

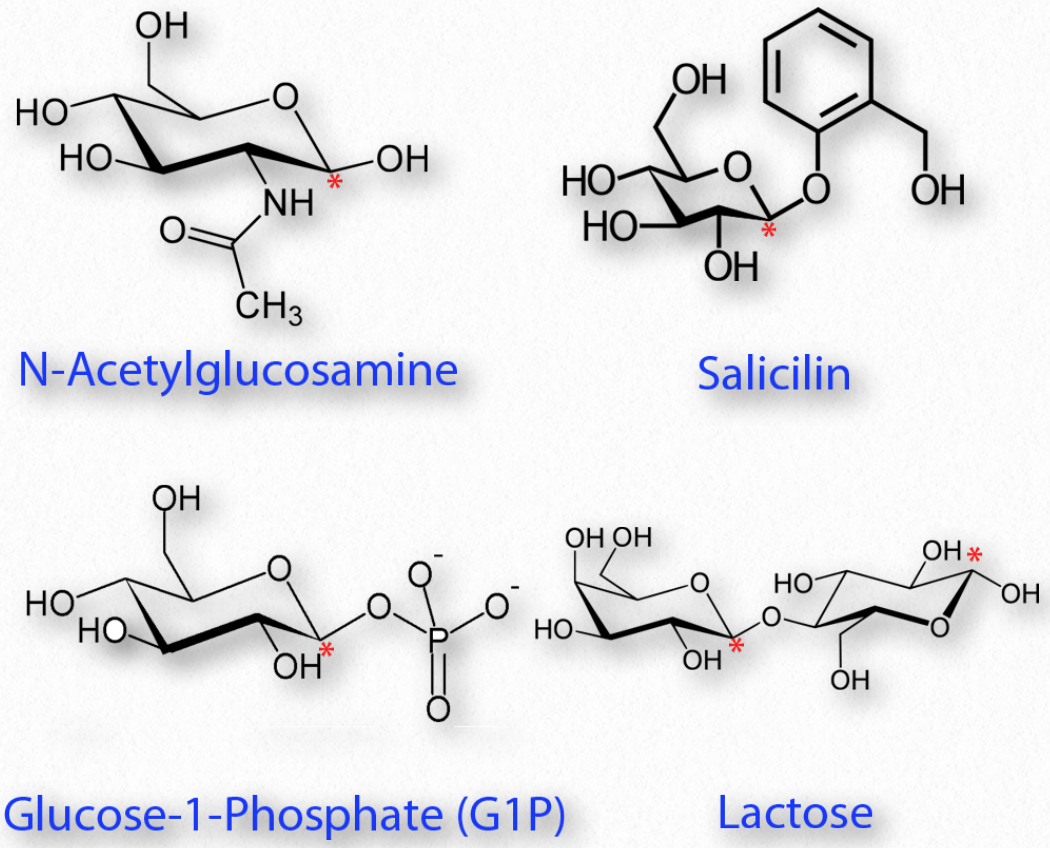

Figure 2.156 - Modified sugars. Locations of glycosidic carbon indicated with red asterisks. All are glycosides except N-acetylglucosamine

forms resemble boat structures, which others resemble chairs or envelopes (Figure 2.155). The stablest (and thus most abundant) of these forms have all of the hydoxyls in the equatorial positions, resulting in less steric hindrance.

Modified monosaccharides

Many modifications can occur on sugar residues (Figure 2.156). Common ones include oxidation, reduction, phosphorylation, and substitution of an amine or an acetylamine for a hydroxyl. The ones that affect the anomeric hydroxyl group make glycosides (Figure 2.157), whereas modifications that don't affect the anomeric hydroxyl, (glucose-6-phosphate, for example), do not.

Oxidation/reduction

The last considerations for simple sugars relative to their structure are their chemical reactivity and modification. Sugars that are readily oxidized are called 'reducing sugars' because their oxidation causes other reacting molecules to be reduced. A test for reducing sugars is known as Benedict's test. In it, sugars are mixed and heated with an alkaline solution containing Cu^{++}. Reducing sugars will donate an elec-

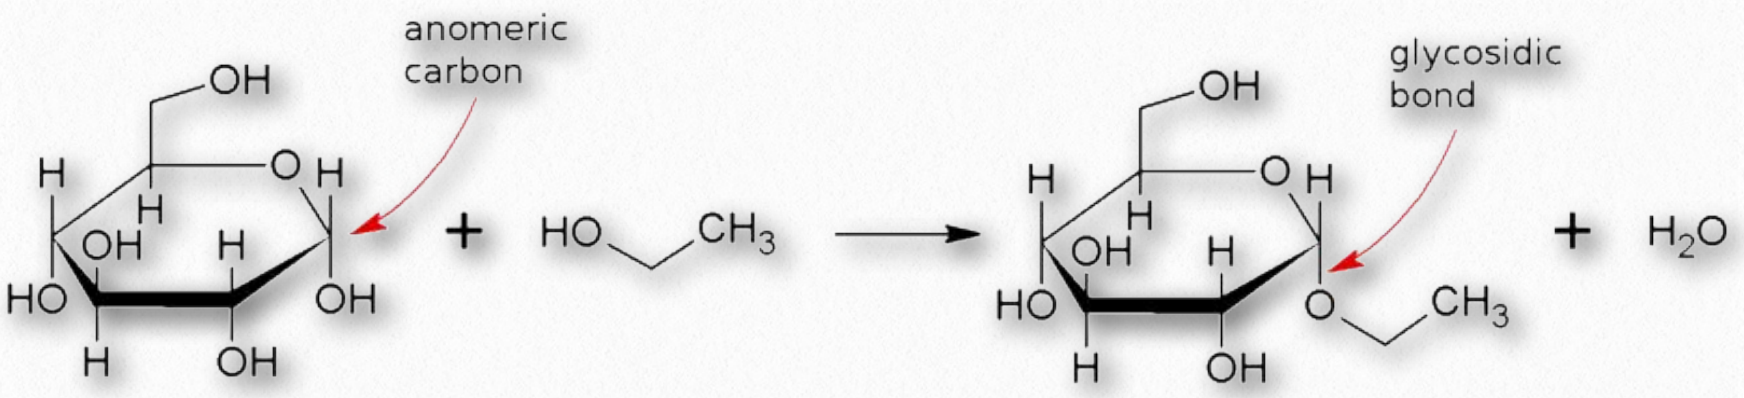

Figure 2.157 - Formation of a glycosidic bond

Figure 2.158 - A positive Benedict's test starting at left and moving right

Wikipedia

tron to Cu^{++}, converting it to Cu^{+}, which will produce cuprous oxide Cu_2O, as an orange precipitate (Figure 2.158). Since Cu^{++} solution is blue, the change of color provides an easy visual indication of a reducing sugar.

The aldehyde group of aldoses is very susceptible to oxidation, whereas ketoses are less so, but can easily be oxidized if, like fructose, they contain an α-hydroxyl and can tautomerize to an aldose. Most monosaccharides are reducing sugars. This includes all of the common ones galactose, glucose, fructose, ribose, xylose, and mannose. Some disaccharides, such as lactose and maltose are reducing sugars since they have at least one anomeric carbon free, allowing that part of the sugar to linearize and yield

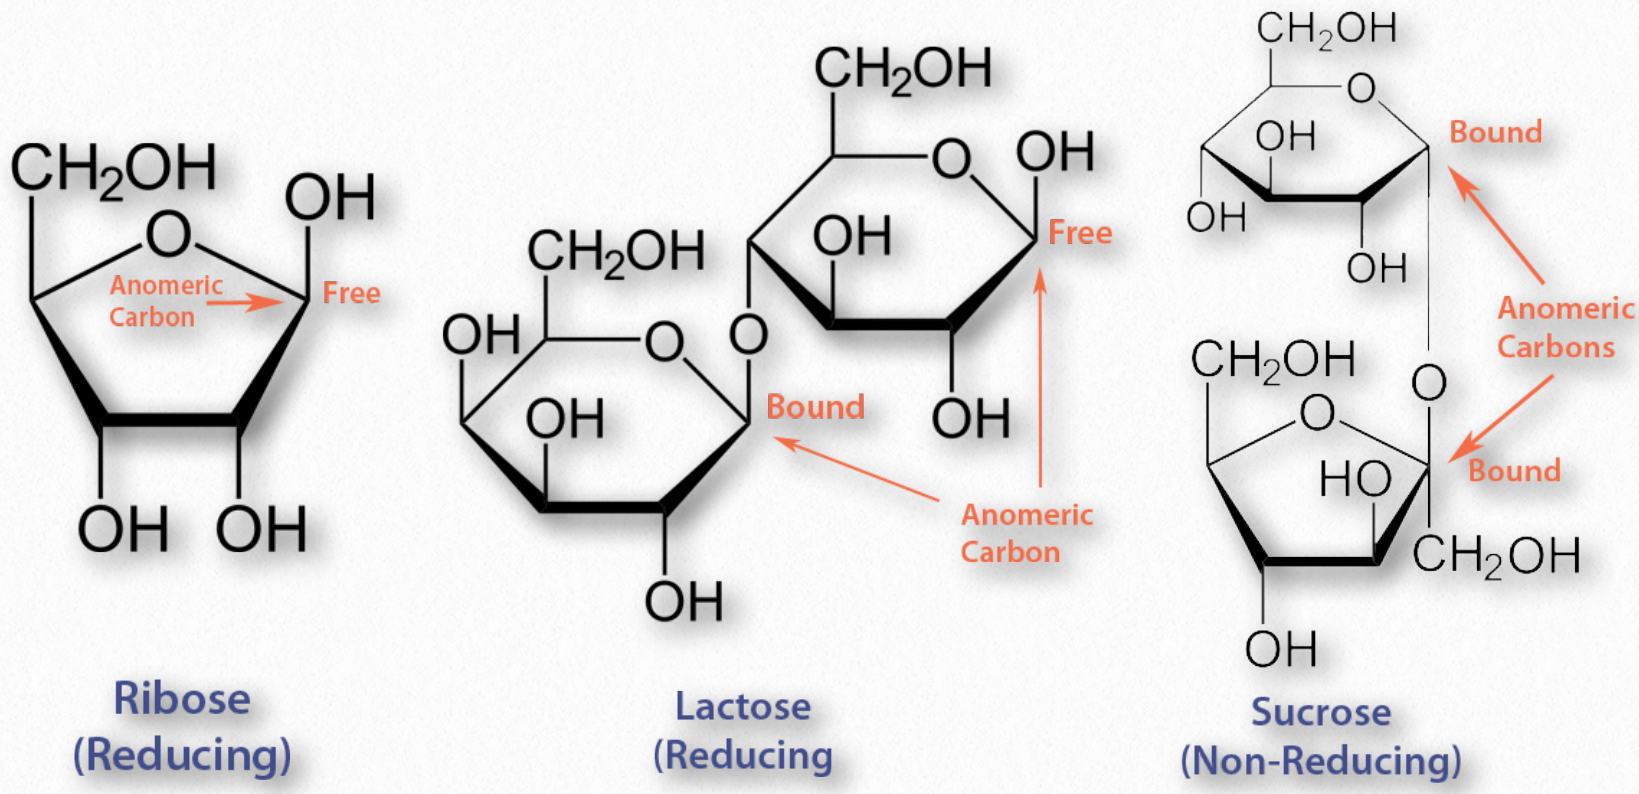

Figure 2.159 - Reducing and non-reducing sugars

an aldose. Sucrose, on the other hand has no anomeric carbons free - both are involved in a glycosidic linkage, so they cannot linearize and thus it is not a reducing sugar.

Oxidation and reduction of sugars can occur in cells. As we will see, phosphorylation of sugars occurs routinely during metabolism.

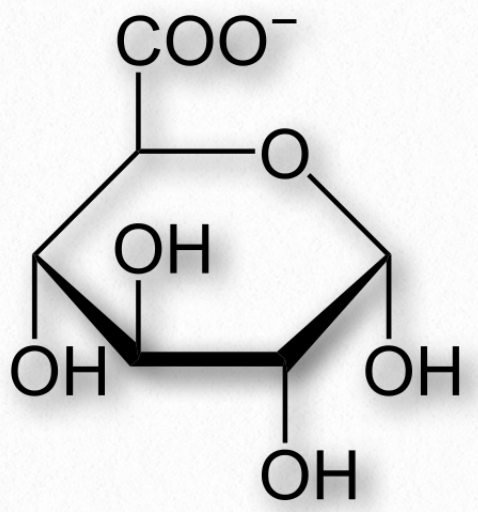

Figure 2.160 - Glucuronic acid

Glucuronic acid

One oxidation product of glucose is glucuronic acid, a six carbon molecule where the CH_2OH on carbon six is oxidized to a carboxylic acid (Figure 2.160). Related oxidized sugars include galacturonic acid and mannuronic acid. Glucuronic acid is commonly conjugated to other molecules in the liver/bile by UDP-glucuronyltransferase enzymes to make the molecules more water soluble for excretion, since the carboxyl group of glucoronic acid ionizes readily at physiological pH. The reactions are usually done starting with glucuronic acid linked to UDP (UDP-Glucuronic Acid). In addition, glucuronic acid is made from a UDP-glucose precursor. Glucuronic acid is a common constituent of glycosaminoglycans, proteoglycans, and glycoglycerolipids. Glucuronic acid is found in heparin, dermatan sulfate, chondroitin sulfate, hyaluronic acid, and keratan sulfate. Glucuronic acid is also a precursor of ascorbic acid (Vitamin C) in organisms that synthesize this compound.

Sugar alcohols

Reduction of aldoses or ketoses by hydrogenation produces the corresponding sugar alcohols. The compounds are widely used as thickeners of food or as artificial sweeteners, due to their ability to stimulate sweet receptors on the tongue. Common sugar alcohols (sugar progenitor in parentheses) include glycerol (glyceraldehyde), xylitol (xylose), sorbitol (Figure 2.161 - from glucose), galactitol (galactose), arabitol (arabinose), and ribitol (ribose). Most of these compounds have a sweetness of between 0.4 and 1.0 times as sweet as sucrose, but provide considerably fewer calories per weight. Xylitol is the sweetest of them with a sweetness equal to

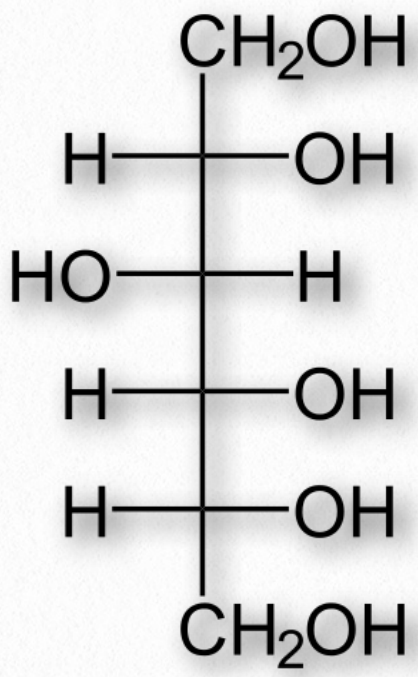

Figure 2.161 - Sorbitol (also called glucitol)

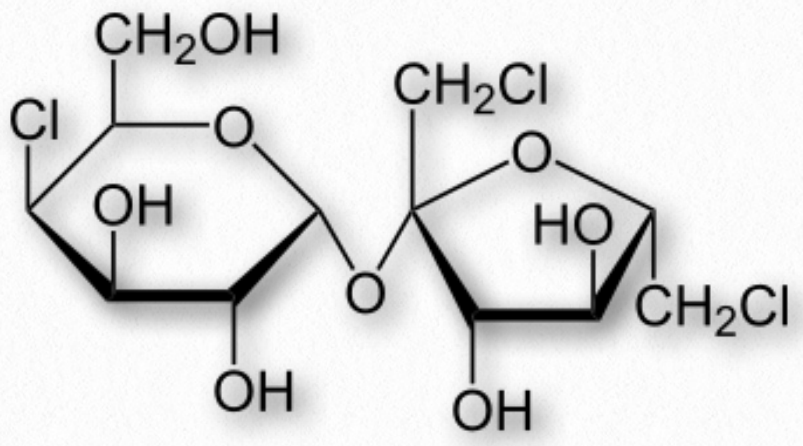

Figure 2.162 - Structure of sucralose

that of sucrose. Sugar alcohols are used sometimes to mask the aftertaste of other artificial sweeteners. Many of them also produce a cooling sensation upon dissolving, due to that being an endothermic process for them, resulting in a pleasant mouth sensation. Last, they are poorly absorbed by intestines, and so have a low glycemic index.

YouTube Lectures by Kevin HERE & HERE

Artificial sweeteners

Artificial sweeteners are compounds that stimulate taste receptors for sweetness, but are metabolized for energy inefficiently at best. Such compounds frequently are many times sweeter than table sugar (sucrose) on a weight/weight basis and are referred to as "intensely sweet." Most of the artificial sweeteners are not carbohydrates, but rather are able to stimulate the same sweet receptors that sugar does. Seven such compounds are approved for use in the U.S. - stevia, aspartame, sucralose, neotame, acesulfame potassium, saccharin,

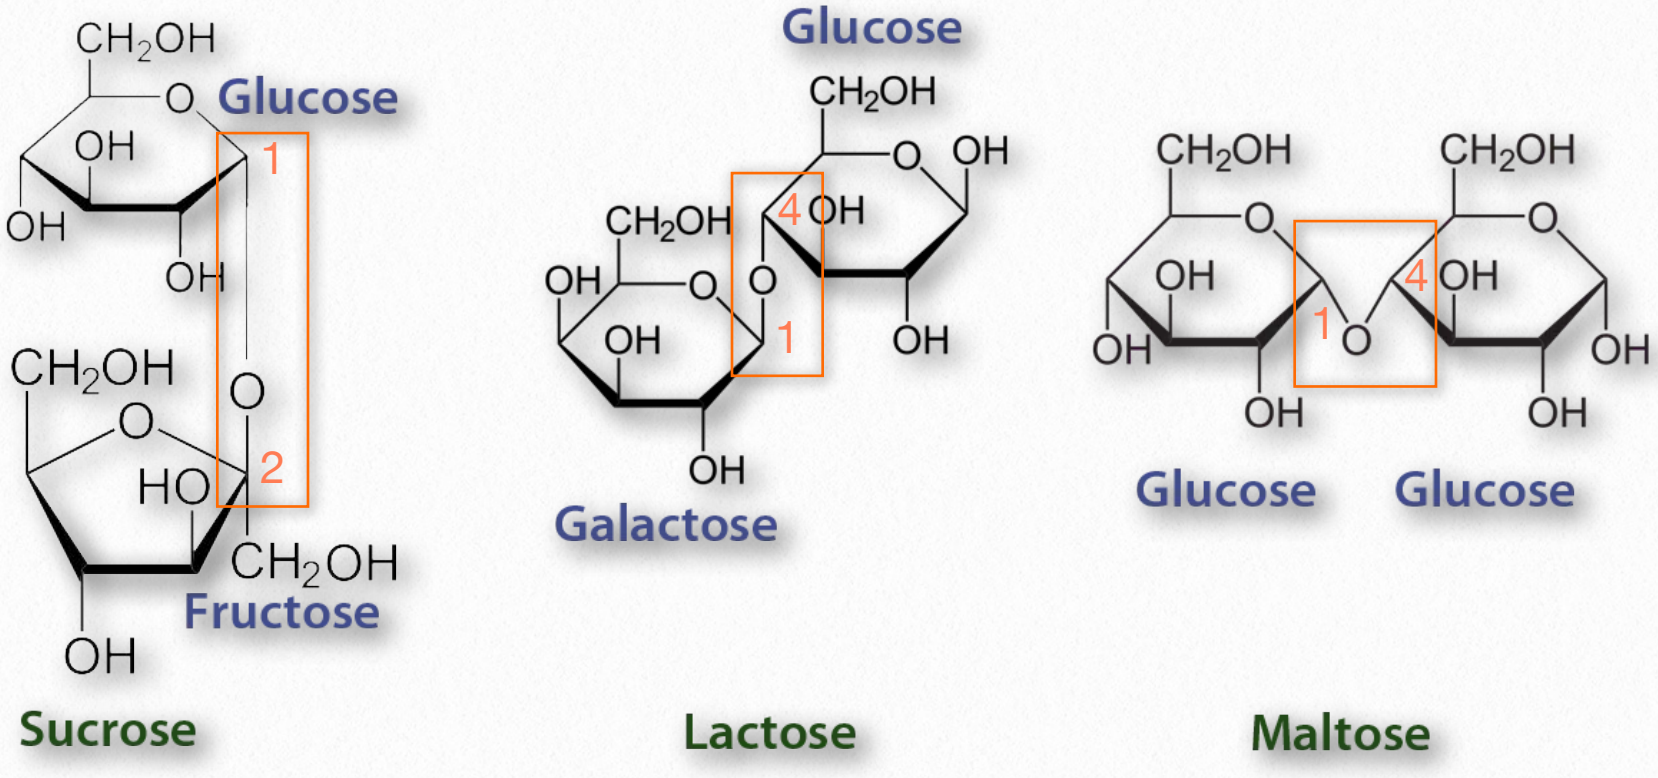

Figure 2.163 - Common disaccharides - glycosidic bonds in rectangles

and advantame. The sugar alcohol known as sorbitol is also sometimes used as an artificial sweetener.

Disaccharides

Disaccharides (Figure 2.163) are made up of two monosaccharides. The most common ones include sucrose (glucose and fructose), lactose (galactose and glucose), and maltose (glucose and glucose). All of the common disaccharides contain at least one glycosidic bond (see HERE). We name the disaccharides according to which carbons are linked to each other and the how the anomeric carbon of the glycosidic bond is configured. Lactose, for example, is described as β-D-galactopyranosyl-(1→4)-D-glucose, or more succinctly as having an α-1,4 glycosidic bond.

Oligosaccharides

As their name implies, oligosaccharides (Figure 2.164) are comprised of a few (typically 3 to 9) sugar residues. These often, but not always contain modified sugars. Unlike all of the other saccharides, oligosaccharides are not typically found unattached to other cellular structures. Instead, oligosaccharides are found bound, for example, to sphingolipids (making cerebrosides or gangliosides) or proteins (making glycoproteins).

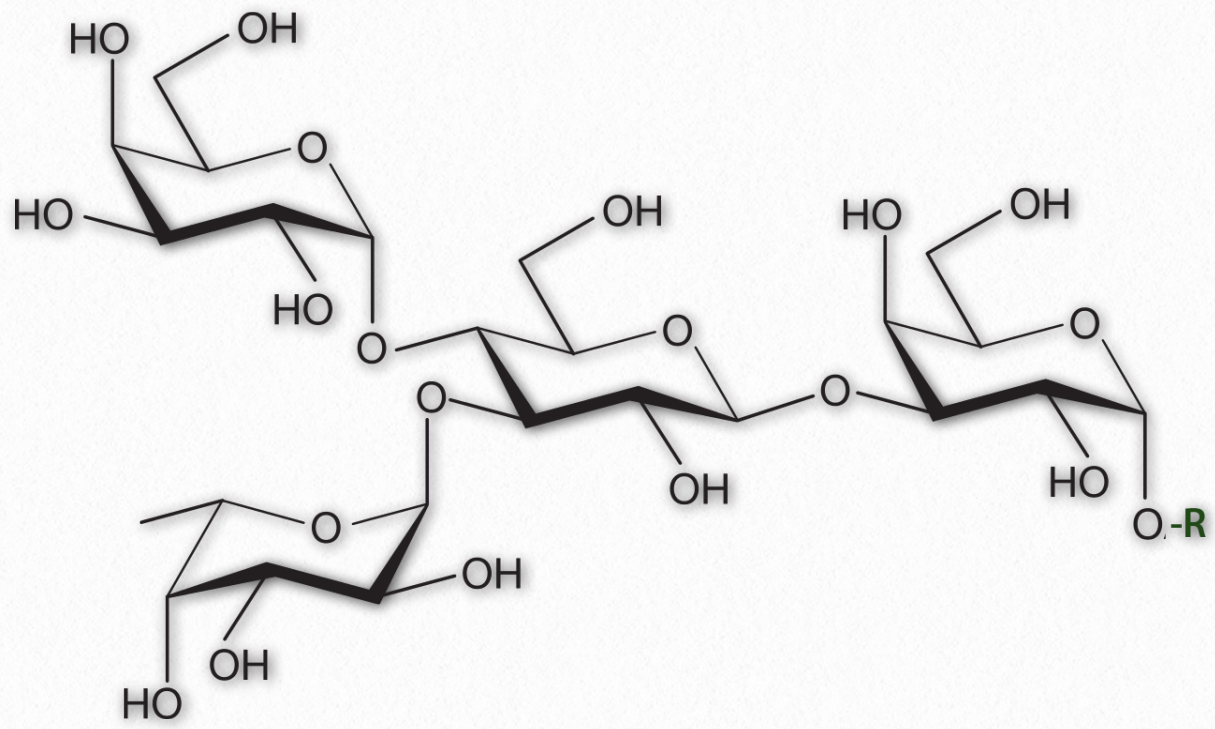

Figure 2.164 - A Branched oligosaccharide attached to an R-Group

Oligosaccharides in membrane glycoproteins play important roles in cellular identity/recognition. The patterns of oligosaccharides displayed on the extracellular face of the plasma membrane acts as a sort of barcode that identifies specific cell types. The immune system recognizes these identity tags in the body. “Foreign” oligosaccharide structures trigger the immune system to attack them. While this provides a very good defense against invading cells of an organism, it

also can pose significant problems when organs are transplanted from one individual into another, with rejection of donated organs, in some cases.

Organelle targeting

The oligosaccharides that are attached to proteins may also determine their cellular destinations. Improper glycosylation or errors in subsequent sugar modification patterns can result in the failure of proteins to reach the correct cellular compartment.

For example, inclusion cell disease (also called I-cell disease) arises from a defective phosphotransferase in the Golgi apparatus. This enzyme normally catalyzes the addition of a phosphate to a mannose sugar attached to a protein destined for the lysosome. In the absence of a functioning enzyme, the unphosphorylated glycoprotein never makes it to the lysosome and is instead exported out of the cell where it accumulates in the blood and

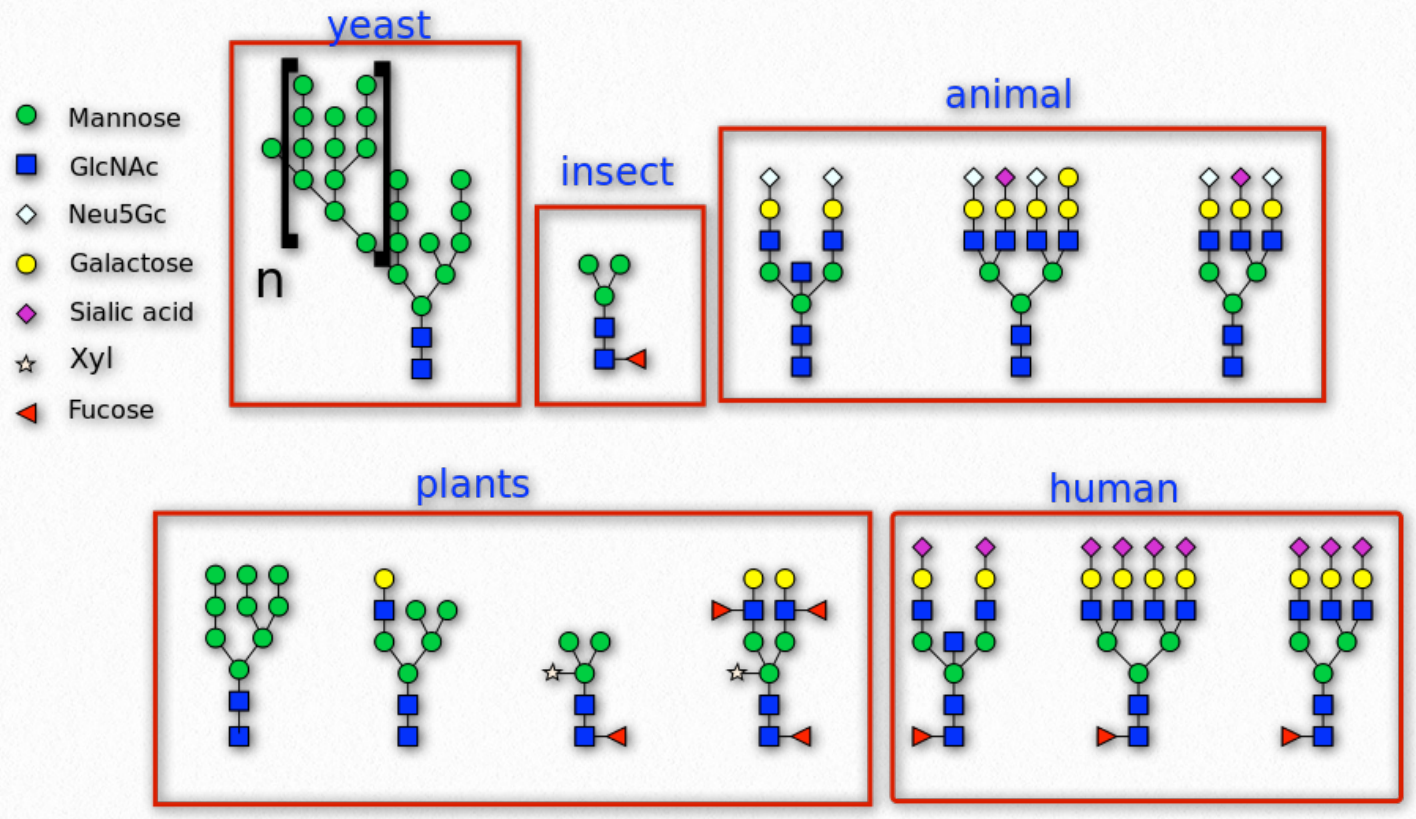

Figure 2.165 - N-linked glycosylation in various organisms

Wikipedia

is excreted in the urine. Individuals with I-cell disease suffer developmental delays, abnormal skeletal development, and restricted joint movement.

Glycosylation

Sugars are commonly attached to proteins in a process called glycosylation. Typically the attachment is to a hydroxyl or other functional group. The majority of proteins synthesized in the endoplasmic reticulum are glycosylated. Five classes of glycosylated products (called glycans if multiple carbohydrates are attached via glycosidic bonds) are known. They include:

• N-linked glycans (Figure 2.165) - carbohydrate attached to N group of asparagine or arginine side chain

• O-linked glycans - carbohydrate attached to OH of serine, threonine, tyrosine, hydroxyproline, hydroxylysine, or lipids.

• Phosphoglycans - attachment to a phosphoserine

• Glypiation - linkage of a phosphatidyl inositol to link proteins to lipids via glycan linkages

• C-linked glycans - sugar attached to a carbon on a tryptophan side chain.

YouTube Lectures by Kevin HERE & HERE

Glycosylation has several molecular/cellular functions. Some proteins require glycosylation to fold properly or to be stable. Glycosylated proteins on the plasma membrane serve as cellular identifiers. Blood types, for example, arise from differential glycosylation of a blood cell membrane protein. Glycosylation can also play an important role in cell-cell adhesion - important in the immune system.

N-linked glycosylation

N-linked protein glycosylation is one of five different types of protein glycosylation and it is the most common type of such alteration. The process 1) occurs in the endoplasmic reticulum, 2) involves "building" a part of the glycosyl chain on a molecule called dolichol pyrophosphate before transfer to the amide nitrogen of a target protein's asparagine, and 3) has a common "core" structure of carbohydrate residues linked to the proteins.

The process occurs commonly in eukaryotic cells, in some archaean cells, and rarely in bacteria. The structure of glycans varies a bit by protein and it also varies by the cell and by the organism. Bonds between the sugars of the glycan are glycosidic (involve anomeric carbon) and usually occur between carbons one and four. The consensus sequence of the protein attachment site is the asparagine in the sequence Asn-X-Ser/Thr where X is any amino acid except proline.

Steps

The process of making an N-linked protein occurs in three steps. It begins with synthesis of a pre-oligosaccharide on the terminal phosphate of dolichol pyrophosphate. Dolichol is a lipid molecule comprised of multiple isoprene units. The pre-oligosaccharide is assembled as follows:

a. Two molecules of UDP-N-acetylglucosamine donate N-acetylglucosamines to the pyrophosphate.

b. Five molecules of GDP-mannose donate mannose to the N-acetylglucosamines

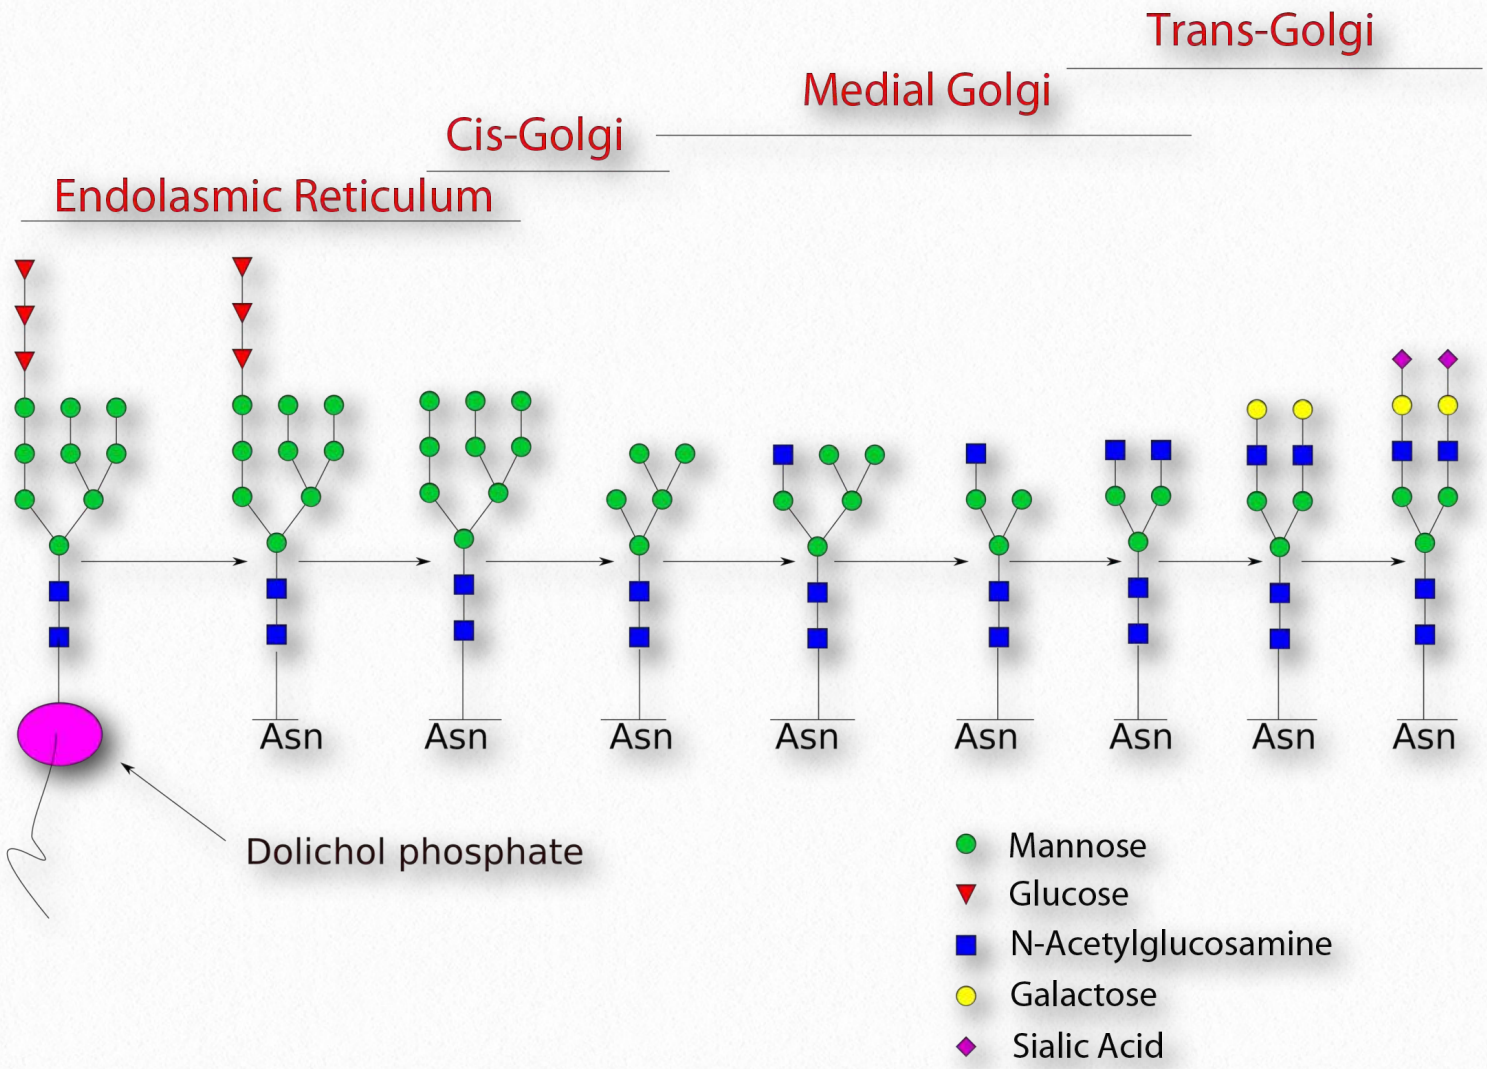

Figure 2.166 - Processing path for N-linked glycosylation

Wikipedia

At this point, the dolichol-sugar complex flips with respect to the endoplasmic reticulum membrane (catalyzed by an enzyme known as flippase), moving the sugar from facing the cytoplasm to facing the inside of the ER lumen. This completes Phase I of the modification. In Phase II, four more mannoses and three glucoses are added to the sugars on the end of the dolichol complex, creating the finished intermediate (Dolichol - GlcNAc2 – Man9-Glc3), which is then transferred to the amide nitrogen on asparagine of the target protein.

Last alterations

The remaining alterations occur to the glycan unit on the protein. First, the protein folds and then the three glucoses are removed. If the protein cannot fold properly, it cannot leave the ER and the glucoses remain intact. A properly folded protein is transferred to the cis-Golgi where various glycan modifications can occur, giving rise to three

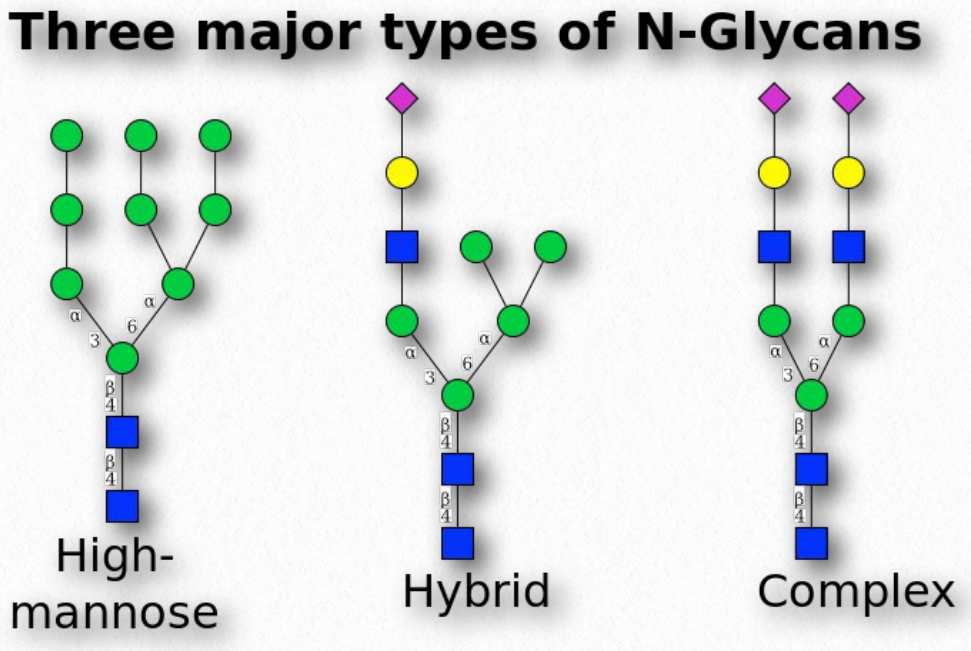

Figure 2.167 - Major N-glycan types - green = mannose, blue = N-acetylglucosamine, red = glucose
Wikipedia

major glycan types (Figure 2.167) - 1) high mannose, 2) hybrid glycans, and 3) complex glycans.

N-glycans on cell surfaces play roles in the immune system. The immunoglobulin types (IgG, IgA, IgE, IgD, and IgM) have distinct glycosylation patterns that confer unique functions by affecting their affinities for immune receptors. Glycans also are important in self/non-self identity is tissue rejection and autoimmune diseases.

O-Linked protein glycosylation

O-linked glycosylation is one of five types of glycosylation that occurs to proteins in all kingdoms of biology. The process is initiated primarily in the Golgi apparatus of eukaryotic cells, though a few such linkages start in the endoplasmic reticulum. The modification occurs on the oxygen of the hydroxyl group of serine, threonine, or tyrosine residues, but there is no clear sequence pattern directing the process. Amino acids that become hydroxylated through post-translational modification can also be involved in O-linkages (see below).

O-linked glycosylation commonly starts with attachment of a sugar, such as N-acetylgalactosamine to a serine or threonine side chain. Other sugars are then attached to this initial one. These include sialic acid, galactose, and others. The synthesis of proteoglycans occurs via this route

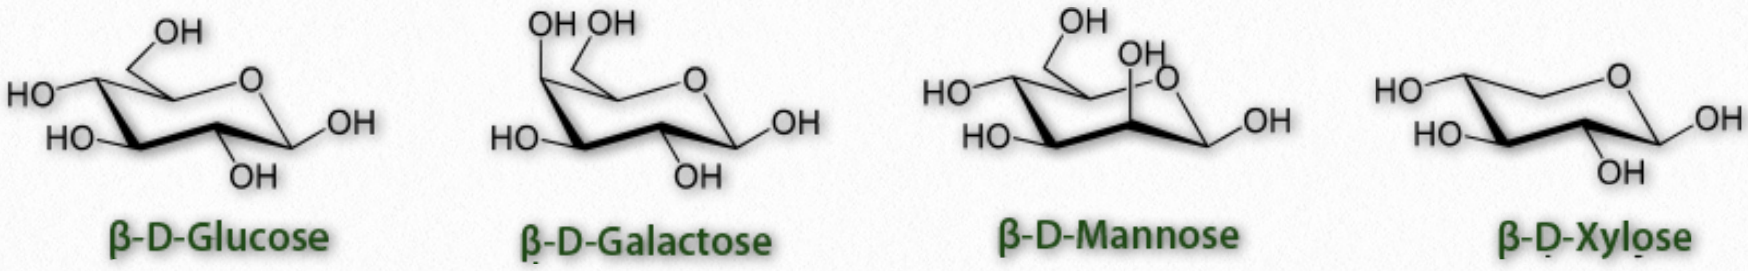

Figure 2.168 - Simple sugars common in glycosylation

when a xylose residue of a glycosaminoglycan is attached to a serine via an O-linkage. Mucins are membrane or secreted glycoproteins that have many O-linked oligosaccharide chains and are present in most bodily secretions.

Other sugars

Other sugars attached to proteins via O-linkages include fucose, glucose, N-acetylglucosamine, and mannose. Collagen is an important fibrous protein whose lysine residues are commonly hydroxylated in post-translational modification. Hydroxyls can be linked via their O-groups to galactose followed by attachment of glucose residues to the galactose. Such modifications are essential for proper functioning of collagen. Interestingly, hydroxyproline is also formed in collagen, but it is not a target for glycosylation.

C-linked glycosylation

C-linked glycosylation is the rarest and least understood protein glycosylation. It commonly occurs as a link between a mannose residue and a tryptophan side chain. The protein amino acid sequence where this occurs is typically Trp-X-X-Trp, where X is any amino acid and the first Trp is the location of the mannosylation. Thrombospondin proteins are the most commonly C-linked proteins.

Phospho-linked glycosylation

Attachment of a sugar residue to a phosphoserine occurs in phospho-linked glycosylation of proteins. Linkages to fucose, mannose, N-acetylglucosamine, and xylose are known.

Glypiation

In glypiation, a protein becomes linked to glycosylphosphatidylinositol (GPI) as a means of anchoring it to a cell membrane. The linkage occurs at the carboxyl terminus of the protein through one or more phosphoethanolamine linkers, which are, in turn, linked to mannose residues that are attached to GPI embedded in the membrane.

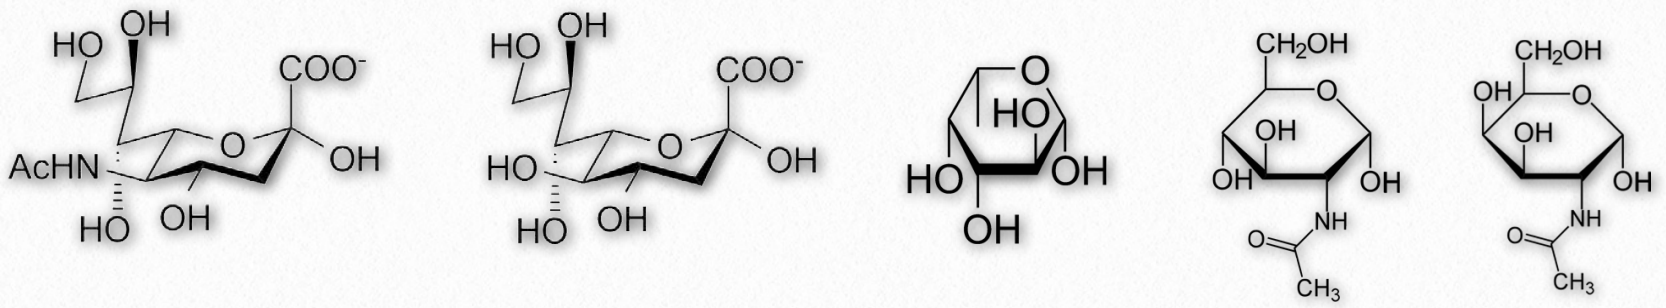

Figure 2.169 - Common modified sugars in glycosylated proteins - from left - two sialic acids (N-acetylneuraminic acid and 2-keto-3-deoxynonic acid), α-L-fucose, N-acetylglucosamine, and N-acetylgalactosamine

Glycoproteins

Glycoproteins are a very diverse collection of saccharide-containing proteins with many functions. Attachment of the saccharide to the protein is known as glycosylation. Secreted extracellular proteins and membrane proteins with exposed extracellular regions are often glycosylated. Saccharides attached to these may be short (oligosaccharides) or very large (polysaccharides). Glycoproteins play important roles in the immune system in antibodies and as components of the major histocompatibility complex (MHC). They are important for interactions between sperms and eggs, in connective tissues and are abundant in egg whites and blood plasma. Two glycoproteins (gp41 and gp120) are part of the HIV viral coat and are important in the infection process. Some hormones, such as erythropoietin, human chorionic gonadotropin, follicle-stimulating hormone and luteinizing hormone are also glycoproteins.

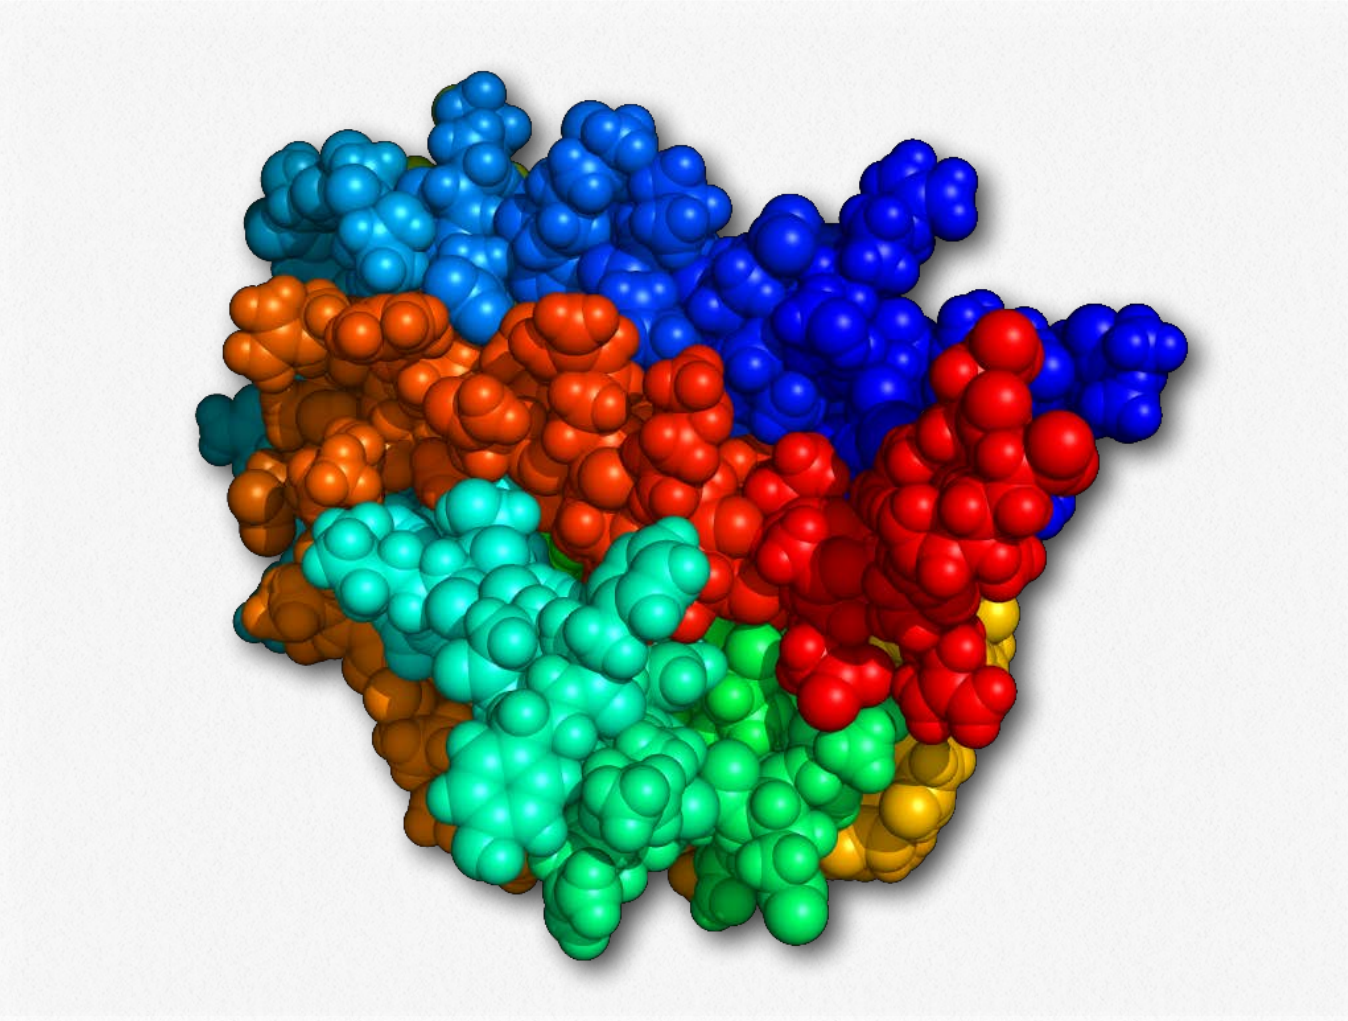

Figure 2.170 - Erythropoietin
Wikipedia

Glycation

Glycation is a chemical process (non-enzymatic) that occurs when a protein or lipid covalently binds to a sugar, such as glucose or fructose. Glycation differs from glycosylation in that the latter process is controlled by enzymes and results in specific attachment of specific sugars to biomolecules. Glycation, by contrast, is driven by two properties of monosaccharides 1) their chemistry and 2) their concentration. Glycations may be endogenous (occurring in an organism) or exogenous (occurring external to an organism).

Exogenous glycation arises most commonly as a result of cooking of food and this results in

attachment of sugars to lipids and/or proteins to form advanced glycation endproducts (AGEs). At temperatures above 120°C, AGE production occurs readily and contributes to the taste and the appearance of the food we eat.

Cooking

Browning of food, for example, is a product of glycation and is enhanced as the sugar content of a food increases. Browning of french fries is often enhanced, for example, by adding sugar to them. The formation of a crust of bread or the toasting of bread are other examples. These glycations are products of the Maillard reaction in which a reactive sugar carbonyl group combines with a nucleophilic amine of an amino acid. The process is favored in an alkaline environment, when amines are less protonated. The formation of the harder shell of a pretzel, for example, results from addition of lye to the exterior. At higher temperatures, though, a carcinogen known as acrylamide can be formed by reactions involving asparagine.

YouTube Lectures by Kevin HERE & HERE

Endogenous glycation, on the other hand, arises with a frequency that is proportional to the concentration of free sugar in the body. These occur most frequently with fructose, galactose, and glucose in that decreasing order and are detected in the bloodstream. Both proteins and lipids can be glycated and the accumulation of endogenous advanced glycation endproducts (AGEs) is associated with Type 2 diabetes, as well as in increases in cardiovascular disease (damage to endothelium, cartilage, and fibrinogen), peripheral neuropathy (attack of myelin sheath), and deafness (loss of myelin sheath).

The formation of AGEs increases oxidative stress, but is also thought to be exacerbated by it. Increased oxidative stress, in turn causes additional harm. Damage to collagen in blood cells causes them to stiffen and weaken and is a factor in hardening of the arteries and formation of aneurysms, respectively. One indicator of diabetes is increased glycation of hemoglobin in red blood cells, since circulating sugar concentration are high in the blood of diabetics. Hemoglobin glycation is measured in testing for blood glucose control in diabetic patients.

Homopolymer	Monomeric Unit
Glycogen	Glucose
Cellulose	Glucose
Amylose	Glucose
Callose	Glucose
Chitin	N-acetylglucosamine
Xylan	Xylose
Mannan	Mannose
Chrysolaminarin	Glucose

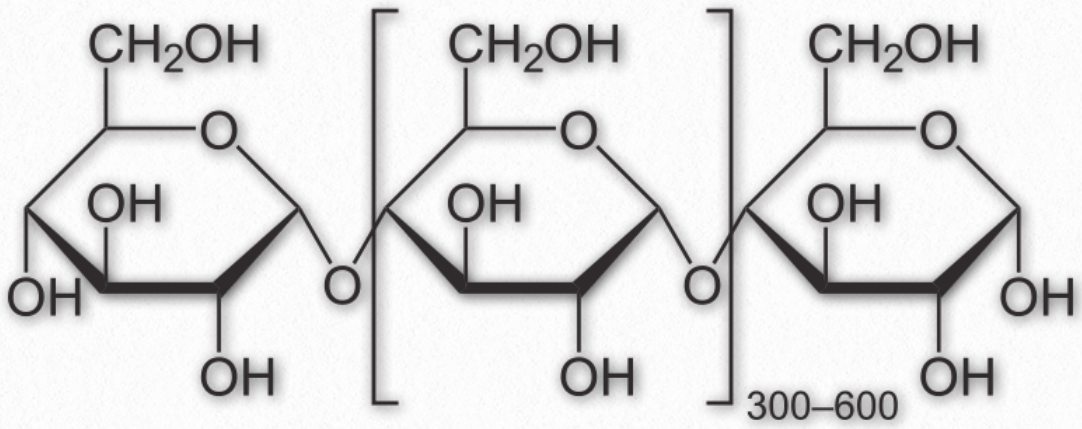

Figure 2.171 - Repeating unit of amylose

Nutritional polysaccharides

This group of polysaccharides is used exclusively for storage of sugar residues. They are easily easily broken down by the organism making them, allowing for rapid release of sugar to meet rapidly changing energy needs.

Polysaccharides

Long polymers of sugar residues are called polysaccharides and can be up to many thousands of units long. Polysaccharides are found free (not attached to other molecules) or bound to other cellular structures such as proteins. Some polysaccharides are homopolymers (contain only one kind of sugar),Others are heteropolymers (glycosaminoglycans, hemicellulose). Polysaccharides function in energy storage (nutritional polysaccharides, such as glycogen, amylose, amylopectin, e.g.), structure enhancement (chitin, cellulose, e.g.), and lubrication (hyaluronic acid, e.g.). These individual categories of polysaccharides are discussed below.

Amylose

Amylose has the simplest structure of any of the nutritional polysaccharides, being made up solely of glucose polymers linked only by α-1,4 bonds (Figures 2.171 & 2.172). (Note that the term 'starch' is actually a mixture of amylose and amylopectin). Amylose is insoluble in water and is harder to digest than amylopectin (see below). The complexing of amylopectin with amylose facilitates its water

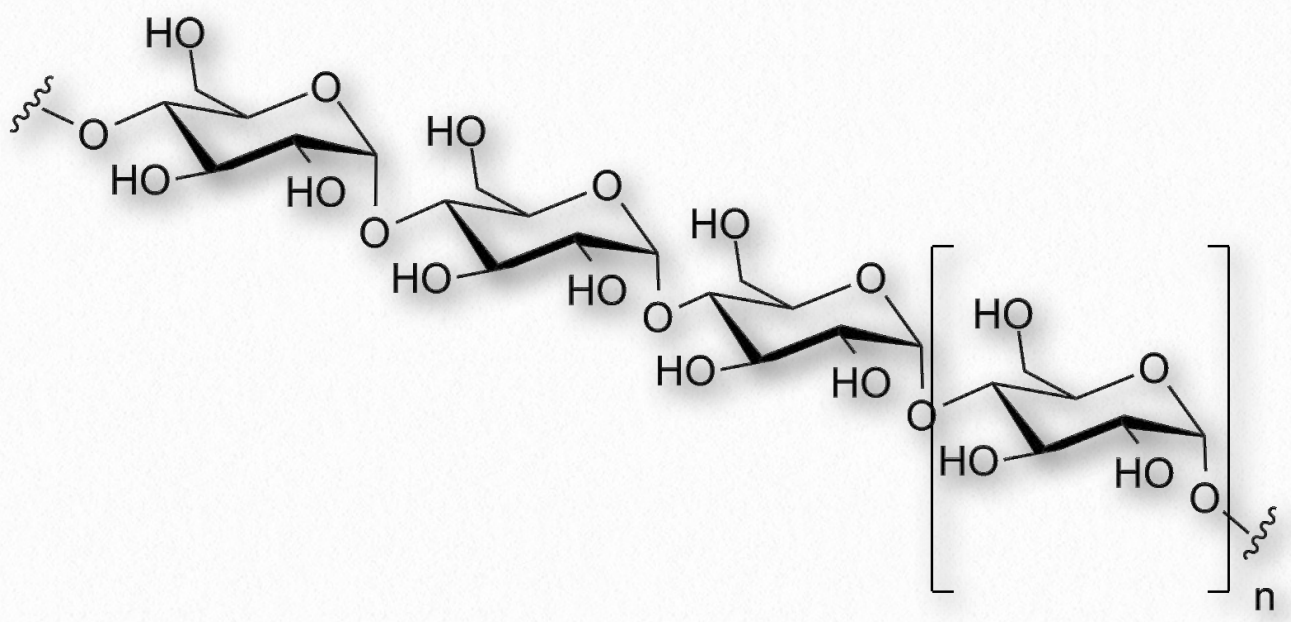

Figure 2.172 - Another view of amylose

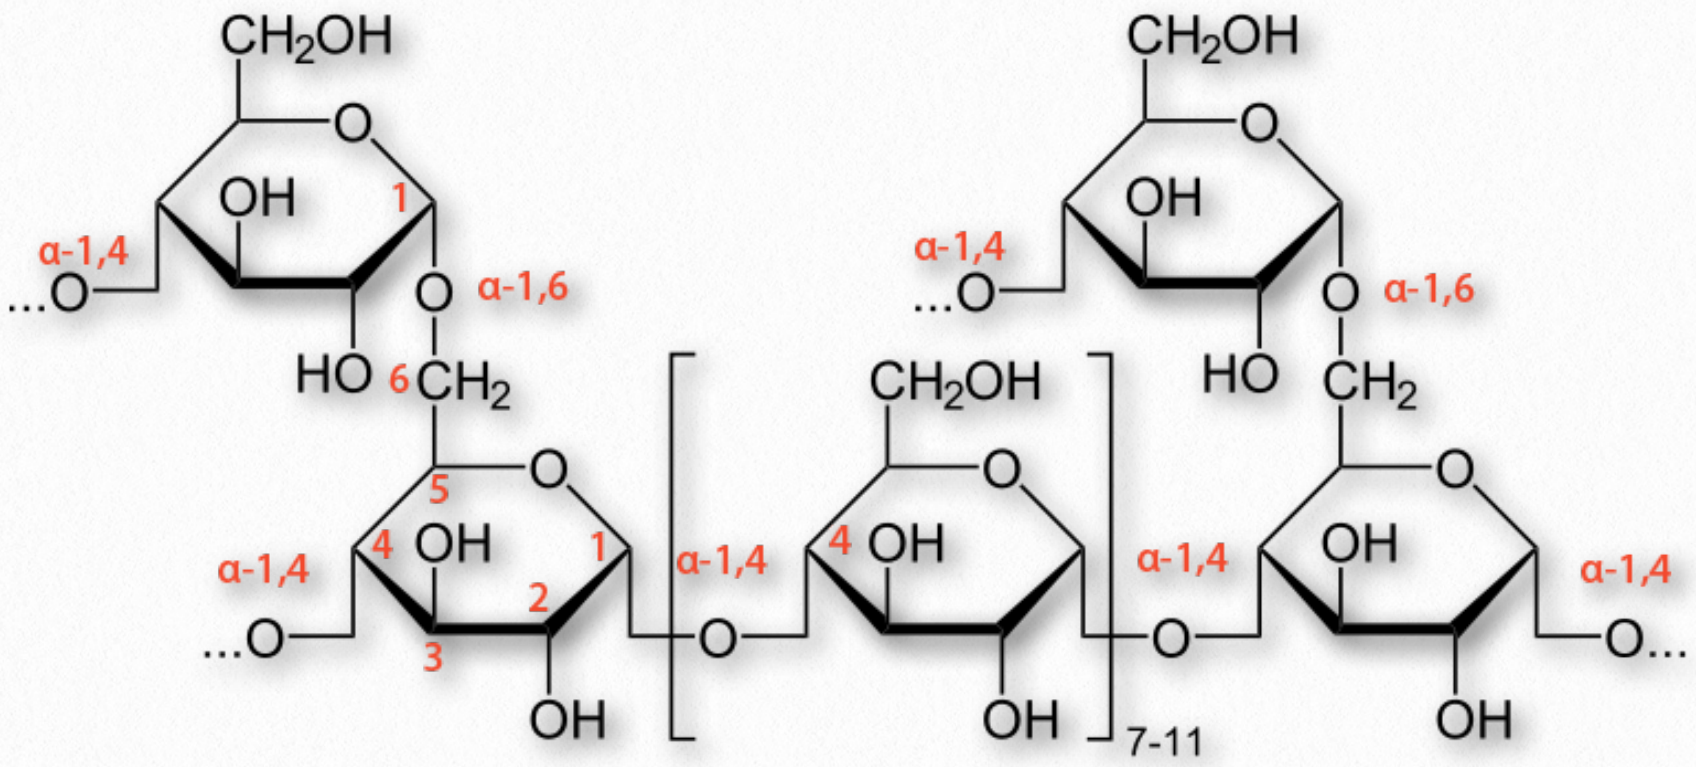

Figure 2.173 - Structure of glycogen

solubility and its digestion. Amylose is produced in plants for energy storage and since plants don't have rapidly changing demands for glucose (no muscular contraction, for example), its compact structure and slow breakdown characteristics are consistent with plants' needs.

Amylopectin and glycogen

More complicated homopolymers of glucose are possessed by amylopectin in plants and glycogen (Figure 2.173) in animals. Both compounds contain long glucose chains with α-1,4 bonds like amylose, but unlike amylose, these long chains have branches of α-1,6 bonds. Amylopectin is the less-branched of the two, having such bonds about every 25-30 residues, whereas glycogen has branches about every 8-12 residues. Branching plays important roles in increasing water solubility and in providing more "ends" to the polymer. In animals, glycogen is broken down starting at the ends, so more ends means more glucose can be released quickly. Again, plants, which have a lower need for quick release of glucose than animals get by with less branching and fewer ends.

Structural polysaccharides

An additional function of polysaccharides in cells relates to structure. Cellulose, which is a polymer of glucose with exclusive β-1,4 linkages between the units (Figure 2.174) is an important structural component of plants and fungi cells. Notably, most non-ruminant animals are unable to digest this polymer, as they lack the enzyme known as cellulase.

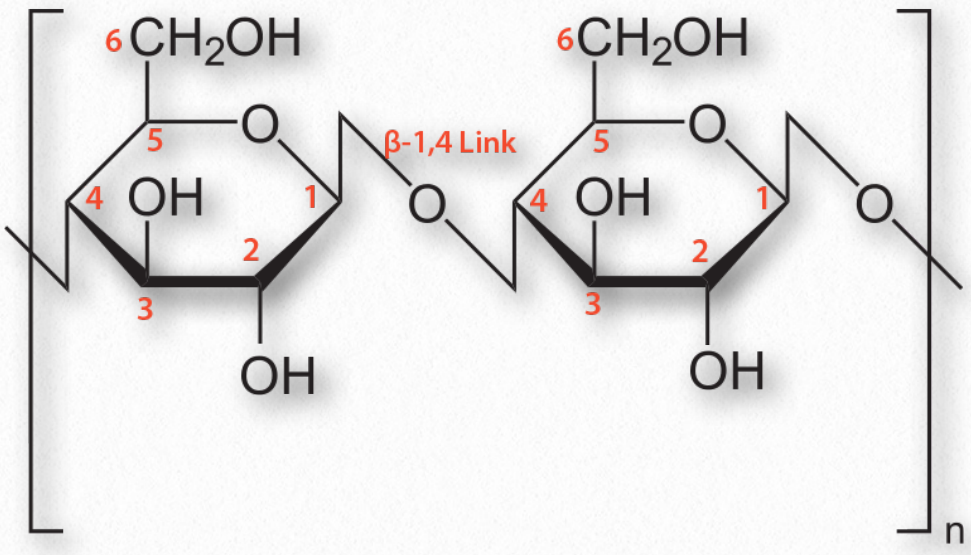

Figure 2.174 - Cellulose with β-1,4 links between glucose sugars

Ruminants, such as cattle, however, contain in their rumen a bacterium that possesses this enzyme and allows them to obtain glucose energy from plants. Another group of polysaccharides found in plant cell walls is the hemicelluloses. This class of molecules encompasses several branched heteropolymers of (mostly) D-pentose sugars along with a few hexoses and L-sugars as well. Hemicelluloses are shorter than cellulose (500-3000 sugars versus 7000-15,000 sugars).

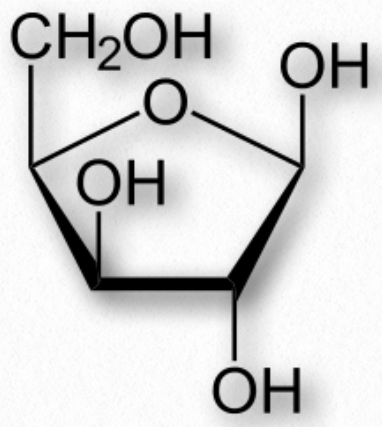

Figure 2.175 Xylose

Monomer sugars of polysaccharides besides glucose include xylose, mannose, galactose, rhamnose, and arabinose. Xylose is usually present in the greatest amount (Figure 2.175).

Chitin

Chitin (Figure 2.176) is another structural polysaccharide, being comprised of N-acetylglucosamine units joined by β-1,4 linkages. It is a primary component of the cell walls of fungi and is also prominent in the exoskeletons of arthropods and insects, as well as the beaks and internal shells of cephalopods (Figure 2.177). Chitin's structure was solved by Albert Hofmann in 1929. It is like cellulose except for the acetylamine group replacing the hydroxyl on position 2. This change allows hydrogen bonding to occur between adjacent polymers, thus providing greater strength.

Pectins

Another group of structural polysaccharides is the pectins (Figure 2.178). These com-

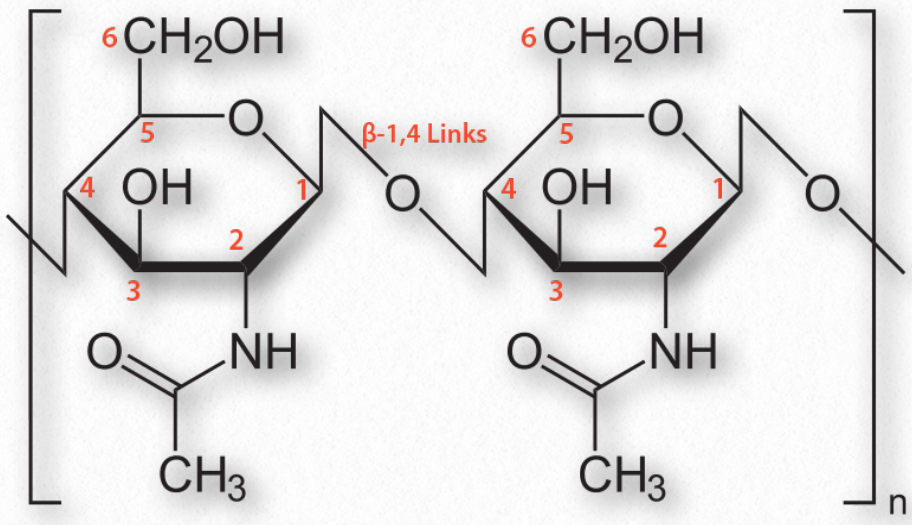

Figure 2.176 - Chitin with β-1,4 links between N-acetylglucosamine sugars

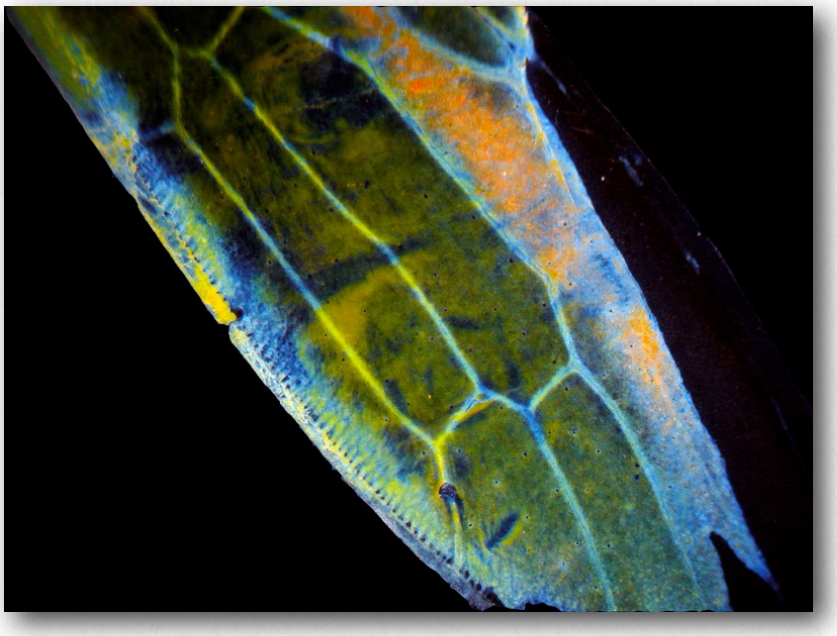

Figure 2.177 - Chitin in the wing of a sap beetle

Wikipedia

pounds are present in most primary plant cell walls and are abundant in non-woody parts of terrestrial plants. They are rich in galacturonic acid (α-1,4 links with no branches - Figure 2.179) and are used commercially as a gelling agent in jams/jellies, as well as a stabilizer in fruit juices and milk drinks. Pectin consumption may result in reduced blood cholesterol levels due to its tendency to 1) bind cholesterol and 2) to increase viscosity in the intestinal tract, thus reducing absorption of cholesterol from food. Pectins also trap carbohydrates in the digestive system and reduce their rate of absorption.

Figure 2.178 - A powdered form of pectin

Lectins

Lectins are not carbohydrates, but proteins that specifically bind to carbohydrate molecules found in animals and plants (where they are known as phytohemagglutinins) and are each highly specific for certain sugars. They function in cellular and molecular recognition, as well as cell adhesion. One lectin recognizes hydrolytic enzymes containing mannose-6-phosphate and targets them to be delivered to lysosomes. In the innate immune system, a mannose binding lectin helps defend against invading microbes. Other lectins have roles in inflammation and autoimmune disorders.

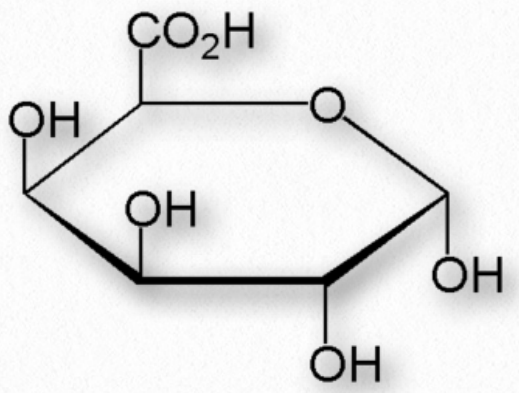

Figure 2.179 - α-D-Galacturonic acid - An important component of pectin polymers

Some viruses and bacteria use lectins to recognize and bind specific carbohydrate residues on the surface of target cells. Flu virus, for example, carries a lectin known as hemagglutinin (Figure 2.180) that binds to sialic acid and is essential for entrance of the virus into the target cell. After binding, the viral particle enters by endocytosis after the hemagglutinin has been cleaved by a protease.

After replication of the virus inside of the cell, hemagglutinin and and a viral enzyme known as neuraminidase cluster in the cell membrane. Viral RNA and associated viral proteins cluster near this membrane site and new viruses bud off in a portion of the cell's membrane after the hemagglutinin-sialic acid link to the infected cell is released by the neuraminidase cutting the bond between the sialic acid and the rest of the cell surface carbohydrate. Drugs, such as tamiflu, that interfere with neuraminidase work by preventing release of the viral particle. Unreleased particles will tend to aggregate and not function.

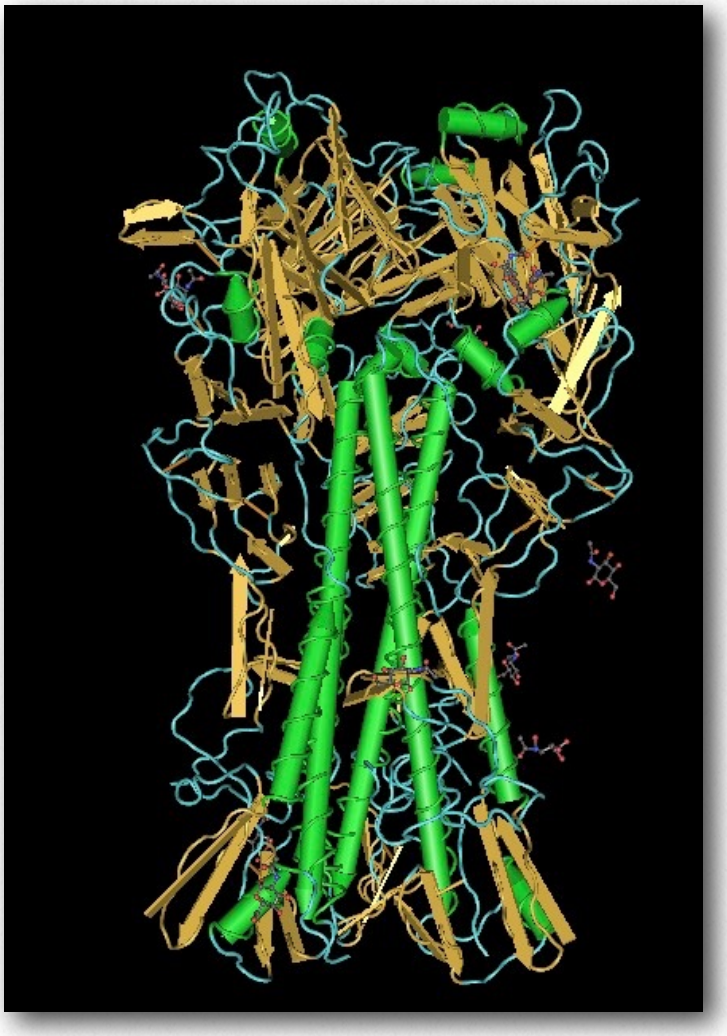

Figure 2.180 - Hemagglutinin

Some viral glycoproteins from hepatitis C virus may attach to lectins on the surface of liver cells in their infectious cycle. The bacterium *Helicobacter pylori* uses a cell surface lectin to bind oligosaccharides on epithelial cells lining the stomach. One lectin known as ricin is a very powerful toxin. It is produced in the endosperm of seeds of the castor oil plant and is of concern as a bioterrorism weapon as a result of its acute toxicity when inhaled or ingested.

Lectins were discovered originally in plants and have been most studied in legumes, but lectins are now known to be widely dispersed in nature. In the immune system, a mannan binding lectin (MBL) helps mediate the first defenses against microorganisms. Other immune system lectins are thought to modulate inflammatory processes and probably play a role in self/non-self recognition that is at the root of rejection of transplanted organs.

Biofuels

In an era of diminishing energy sources, interest in using fuels made by biological processes is growing. Biofuels are made by biological systems and are commonly metabolic products of plants, yeast, and/or bacteria. A common output product is ethanol (used in gasoline) or methane (natural gas) and a common starting material is cellulose

from plant metabolism. In biofuel production with these materials, plant material containing cellulose is digested a) enzymatically (by the enzyme cellulase); b) chemically (with strong acids); or c) biologically (yeast/bacteria) to yield the glucose sugars comprising it. Fermentation of those sugars by yeasts/bacteria can yield ethanol while alternative metabolism by other bacteria can yield methane.

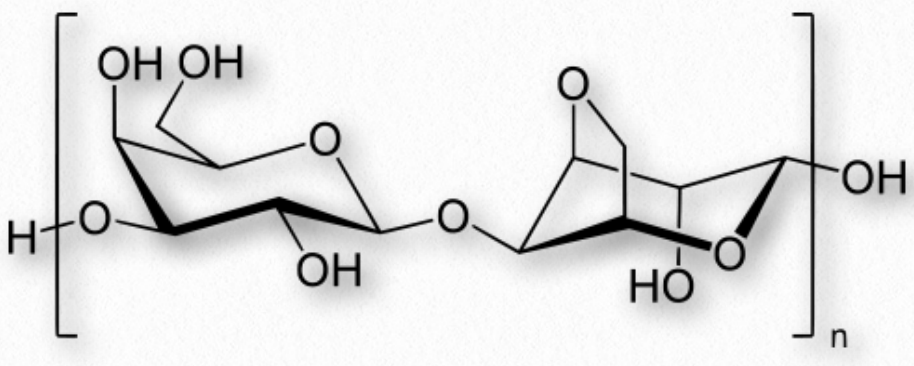

Figure 2.182 - Repeating unit of agarose - 3,6-anhydro-L-galactopyranose

Agar/agarose

A polysaccharide product that has numerous uses in laboratories is agar/agarose. Agarose is a polysaccharide polymer of D-galactose and 3,6-anhydro-L-galactopyranose that is extracted from seaweed and has a repeating structure shown in Figure 2.182. Addition of agaropectin creates the material known as agar. Both substances make gel-like structures when boiled in water and then cooled. Agar is commonly used to make plates for culturing microorganisms (Figure 2.183) and agarose is the common support of agarose gels (Figure 2.184) used to separate DNA fragments in electrophoresis.

Figure 2.181 Biofuel-powered bus

Glycosaminoglycans

Another variation on the polysaccharide theme is found in

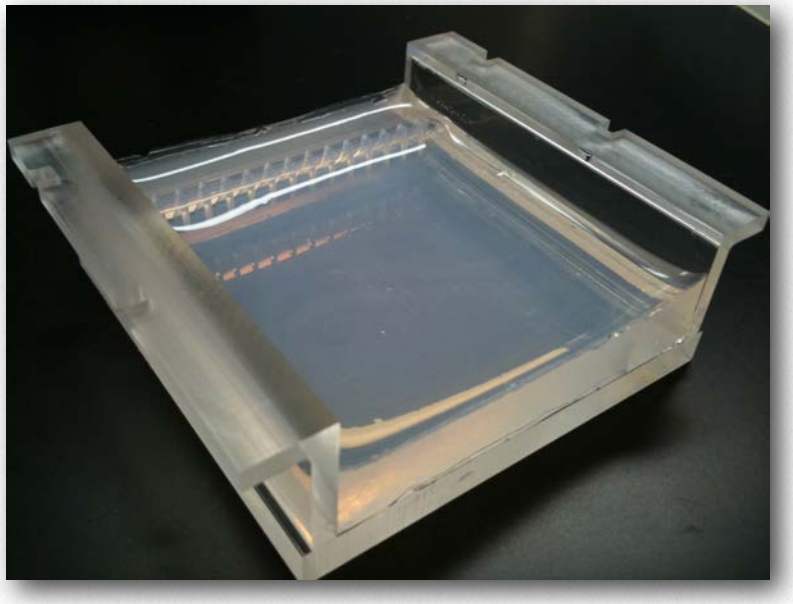

Figure 2.184 - Agarose gel

Wikipedia

polymers known as the glycosaminoglycans. Previously known as mucopolysaccharides, glycosaminoglycans are polymers of unbranched repeating disaccharides. The repeating units of the disaccharide core of the molecules typically have an amino sugar (N-acetylglucosamine or N-acetylgalactosamine) and a uronic sugar (glucuronic acid or iduronic acid) or galactose. Glycosaminoglycans vary considerably in molecular mass, disaccharide structure, and sulfation. The presence of uronic acid residues and sulfates in glycosaminoglycans causes them to be polyanionic. As such, they are capable of binding many cations including sodium, potassium, and calcium. Glycosaminoglycans are organized in four groups - those found in connective tissue (linked to collagen) and they also act as lubricants for joints (hyaluronic acid in synovial fluid), as anti-clotting agents (heparin) and as components of mucus where they help to protect against infection.

Chondroitin sulfate

Chondroitin sulfate (Figure 2.185) is a glycosaminoglycan found in cartilage with a repeating disaccharide structure of

- a modified glucuronic acid and
- a modified N-acetylgalactosamine. At least one of the sugars of the disaccharide will have a covalently bound sulfate on it, giving the polymer a polyanionic character.

Chondroitin sulfate chains will typically have over 100 individual sugars and the chemical composition of each one can vary. It is a structural component of cartilage and

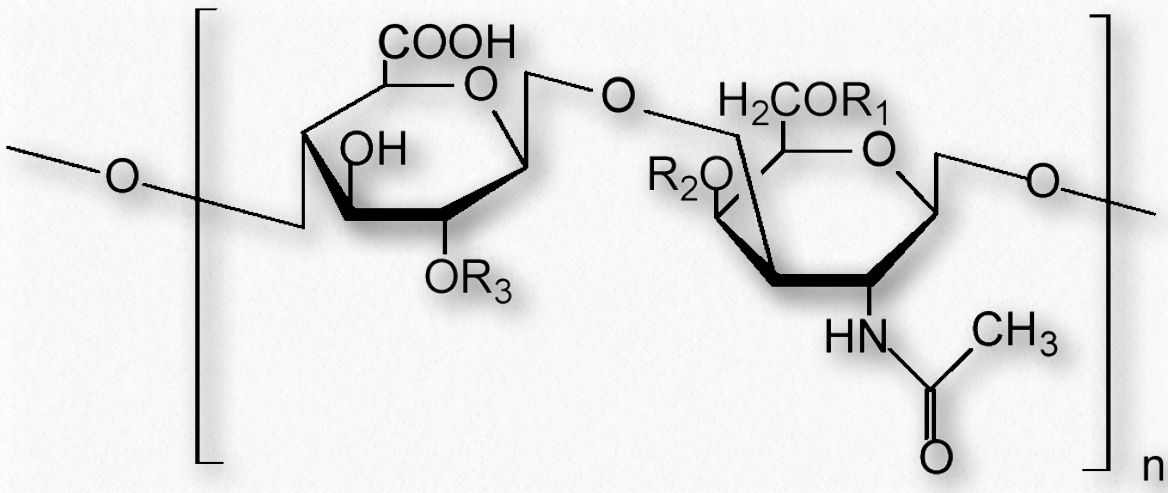

Figure 2.185 - Repeating disaccharide in chondroitin sulfate

helps to give it the ability to resist compression.

Chondroitin sulfate is used as a dietary supplement to treat joint pain and osteoarthritis, though its ability to provide relief is not clear. In cells, the compound is a component of the extracellular matrix. It can be linked to proteins through serine residues to form proteoglycans, such as aggrecan, versican, brevican, and neurocan. These substances are prominent in the extracellular matrix of the brain. In the form of aggrecan, chondroitin sulfate is a major component of cartilage. Loss of chondroitin sulfate from cartilage is an issue in osteoarthritis.

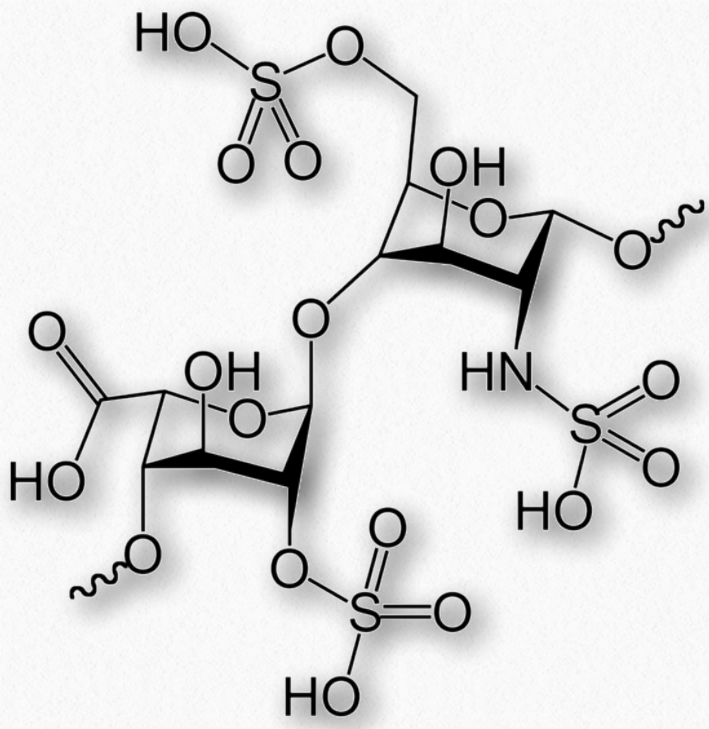

Figure 2.186 - Repeating sulfated disaccharide in heparin

Heparin

Heparin (Figures 2.186 & 2.187) is a modified polysaccharide whose biological function is unclear, but whose ability to prevent clotting of blood is used for medical purposes. Heparin does not dissolve blood clots. Rather, it acts to prevent conversion of fibrinogen to fibrin (see HERE).

Whether or not heparin is actually used by the body for its anticoagulation property is uncertain. It is stored in the secretory granules of mast cells and released at the point of injury and it has been proposed it is a protection against bacteria and other foreign materials.

Heparin has abundant sulfates and is, in fact, the molecule with the highest negative charge density known. Its size varies from 3 kDa to 30 kDa, with an average of about 15 kDa. The repeating disaccharide of 2-O-sulfated iduronic acid and 6-O-sulfated, N-

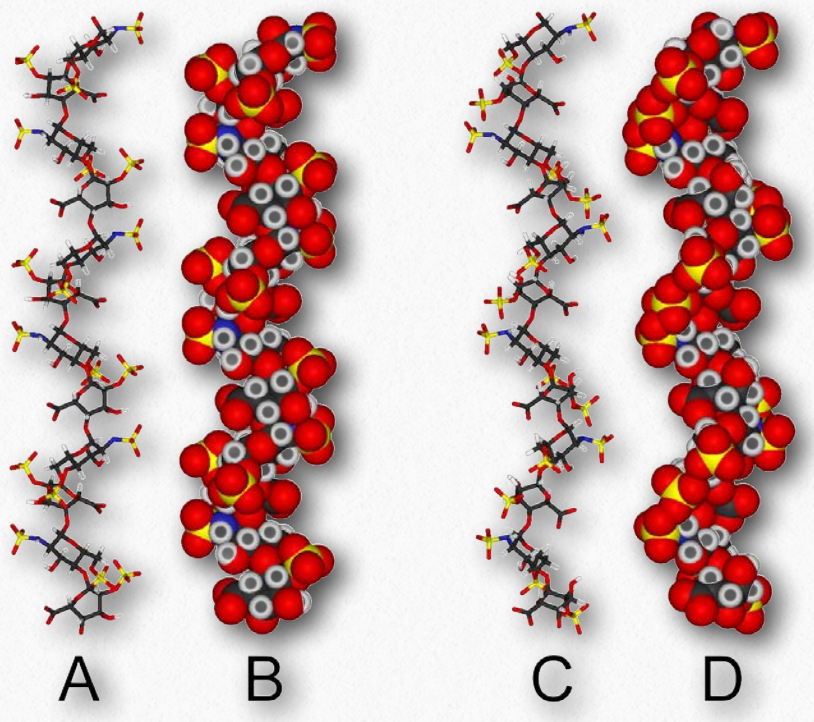

Figure 2.187 - Two structures for heparin

sulfated glucosamine, occupies about 85% of the molecule. Copper salts of heparin help stimulate the synthesis of blood vessels (angiogenic).

Hyaluronic acid

Hyaluronic acid (also known as hyaluronan or hyaluronate) is a glycosaminoglycan found in connective, epithelial, and nerve tissues. It is an unusual glycosaminoglycan (Figure 2.188), lacking sulfate, is made by hyaluronan synthases on the inner face of the plasma membrane and has a molecular weight in the millions. An average adult body contains about 15 grams of HA, one third of which is replaced every day. The repeating unit in hyaluronic acid is a disaccharide structure of D-glucuronic acid joined to D-N-acetylglucosamine. The compound, which can have upwards of 25,000 units of the disaccharide, is delivered directly into the extracellular matrix by enzymes from its plasma membrane site of synthesis.It is an important component of the extracellular matrix, where it assists in cell proliferation and migration. The polymer provides an open hydrated matrix to facilitate general cell migration whereas directed cell migration occurs *via* the interaction between hyaluronic acid and specific cell surface receptors. HA interaction with the receptor RHAMM (Receptor for Hyaluronan Mediated Motility) has been shown to be involved in wound repair as well as tumor progression.

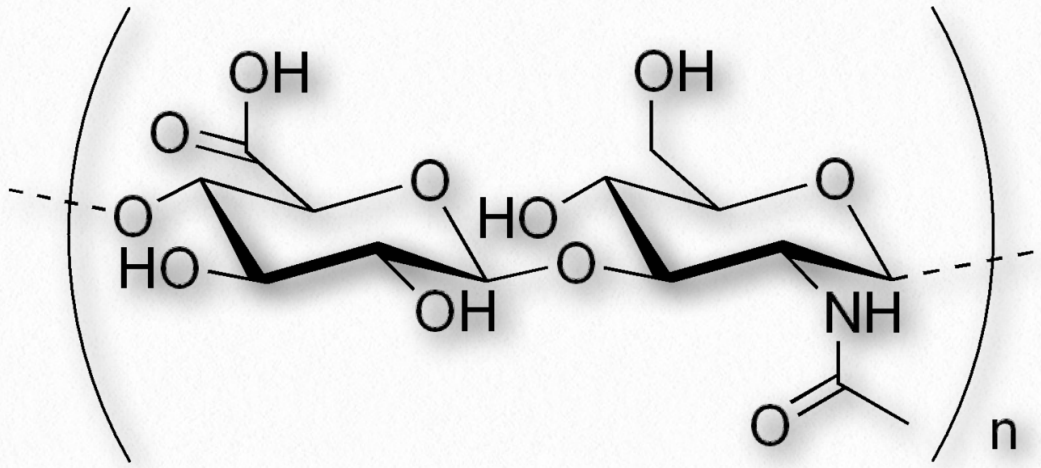

Figure 2.188 - Repeating disaccharide of hyaluronic acid

YouTube Lectures by Kevin HERE & HERE

Synovial Fluid

The function of hyaluronic acid has traditionally been described as providing lubrication in synovial fluid (the lubricating material in animal joints - Figure 2.189). Along with the proteoglycan called lubricin, hyaluronic acid turns water into lubricating material. Hyaluronic acid is present as a coat around each cell of articular cartilage and forms complexes with proteoglycans that absorb water, giving resilience (resistance to compression) to cartilage. Aging causes a decrease in size of hyaluronans, but an increase in concentration.

Function in skin

Hyaluronic acid is a major component of skin and has functions in tissue repair. With exposure to excess UVB radiation, cells in the

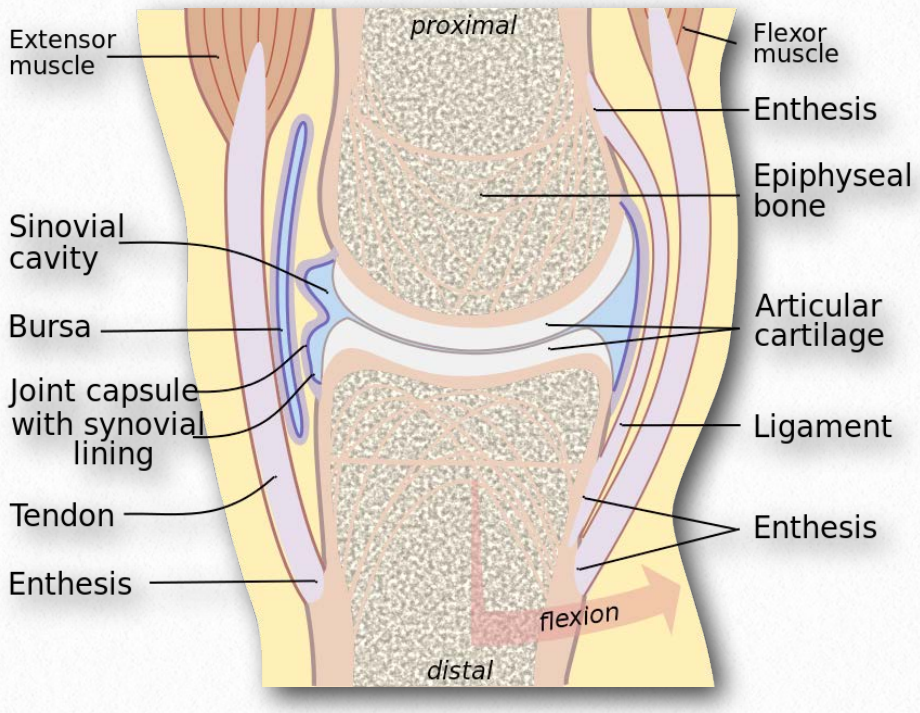

Figure 2.189 - Synovial fluid in joint lubrication

Wikipedia

dermis produce less hyaluronan and increase its degradation.

For some cancers the plasma level of hyaluronic acid correlates with malignancy. Hyaluronic acid levels have been used as a marker for prostate and breast cancer and to follow disease progression. The compound can to used to induce healing after cataract surgery. Hyaluronic acid is also abundant in the granulation tissue matrix that replaces a fibrin clot during the healing of wounds. In wound healing, it is thought that large polymers of hyaluronic acid appear early and they physically make room for white blood cells to mediate an immune response.

Breakdown

Breakdown of hyaluronic acid is catalyzed by enzymes known as hyaluronidases. Humans have seven types of such enzymes, some of which act as tumor suppressors. Smaller hyaluronan fragments can induce inflammatory response in macrophages and dendritic cells after tissue damage. They can also perform pro-angiogenic functions.

Proteoglycans

Glycosaminoglycans are commonly found attached to proteins and these are referred to as proteoglycans. Linkage between the protein and the glycosaminoglycan is made through a serine side-chain. Proteoglycans are made by glycosylation of target proteins in the Golgi apparatus.

Structure & Function: Lipids and Membranes

Lipids

Lipids are a diverse group of molecules that all share the characteristic that at least a portion of them is hydrophobic. Lipids play many roles in cells, including serving as energy storage (fats/oils), constituents of membranes (glycerophospholipids, sphingolipids, cholesterol), hormones (steroids), vitamins (fat soluble), oxygen/electron carriers (heme), among others. For lipids that are very hydrophobic, such as fats/oils, movement and storage in the aqueous environment of the body requires special structures. Other, amphipathic lipids, such as glycerophospholipids and sphingolipids spontaneously organize themselves into lipid bilayers when placed in water. Interestingly, major parts of many lipids can be derived from acetyl-CoA.

YouTube Lectures by Kevin
HERE & HERE

Fatty acids

The most ubiquitous lipids in cells are the fatty acids. Found in fats, glycerophospholipids, sphingolipids and serving as as

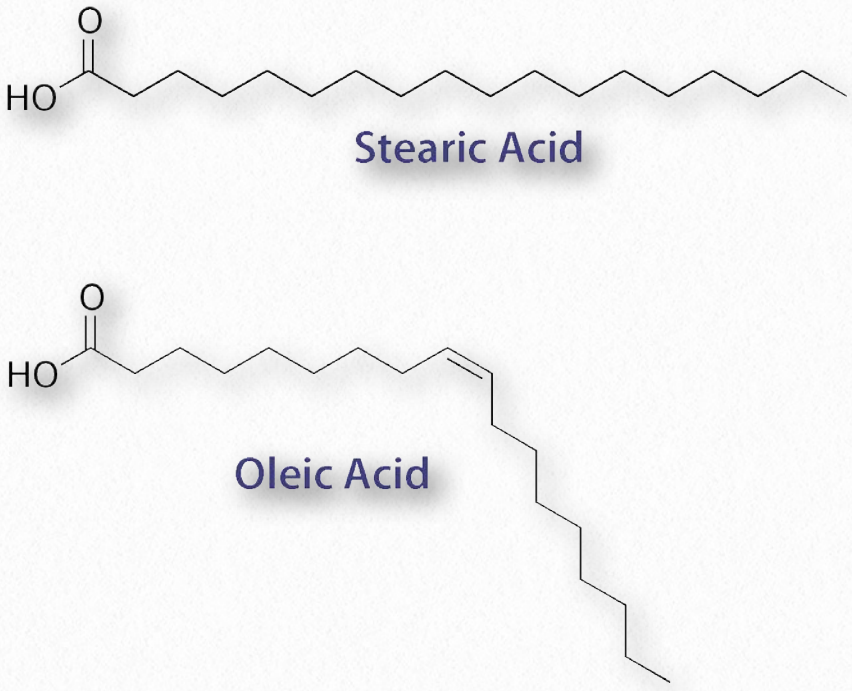

Figure 2.190 - Saturated fatty acid (stearic acid) and unsaturated fatty acid (oleic acid)

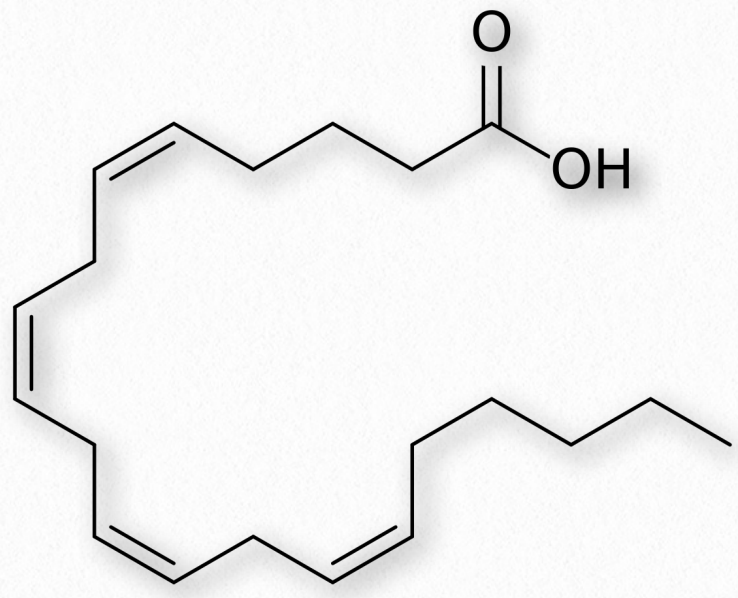

Figure 2.191 - Arachidonic acid - A polyunsaturated fatty acid

Wikipedia

membrane anchors for proteins and other biomolecules, fatty acids are important for energy storage, membrane structure, and as precursors of most classes of lipids. Fatty acids, as can be seen from Figure 2.190 are characterized by a polar head group and a long hydrocarbon tail. Fatty acids with hydrocarbon tails that lack any double bonds are described as saturated, while those with one or more double bonds in their tails are known as unsaturated fatty acids. The effect of double bonds on the fatty acid tail is to introduce a kink, or bend, in the tail, as shown for oleic acid. Stearic acid, a saturated fatty acid, by contrast has a straight hydrocarbon tail. Figures 2.190-2.194 show the most common saturated and unsaturated fatty acids. Fatty acids with unsaturated tails have a lower melting temperature than those with satu-

Figure 2.193 - Unsaturated fatty acids. Right column Indicates number of carbons and double bonds

Wikipedia

Biochemically, the double bonds found in fatty acids are predominantly in the *cis* configuration. So-called *trans* fats arise as a chemical by-product of partial hydrogenation of vegetable oil. In humans, consumption of *trans* fat raises low density lipoprotein (LDL) levels and lowers high density lipoprotein (HDL) levels. Each is thought to contribute to the risk of developing coronary artery disease. The most

rated tails of the same length. Shorter tails also decrease melting temperature. These properties carry over to the fats/oils containing them.

Fatty acids with more than one double bond are called polyunsaturated. Plants are excellent sources of unsaturated and polyunsaturated fatty acids. The position of the double bond(s) in fatty acids has important considerations both for their synthesis and for their actions in the body.

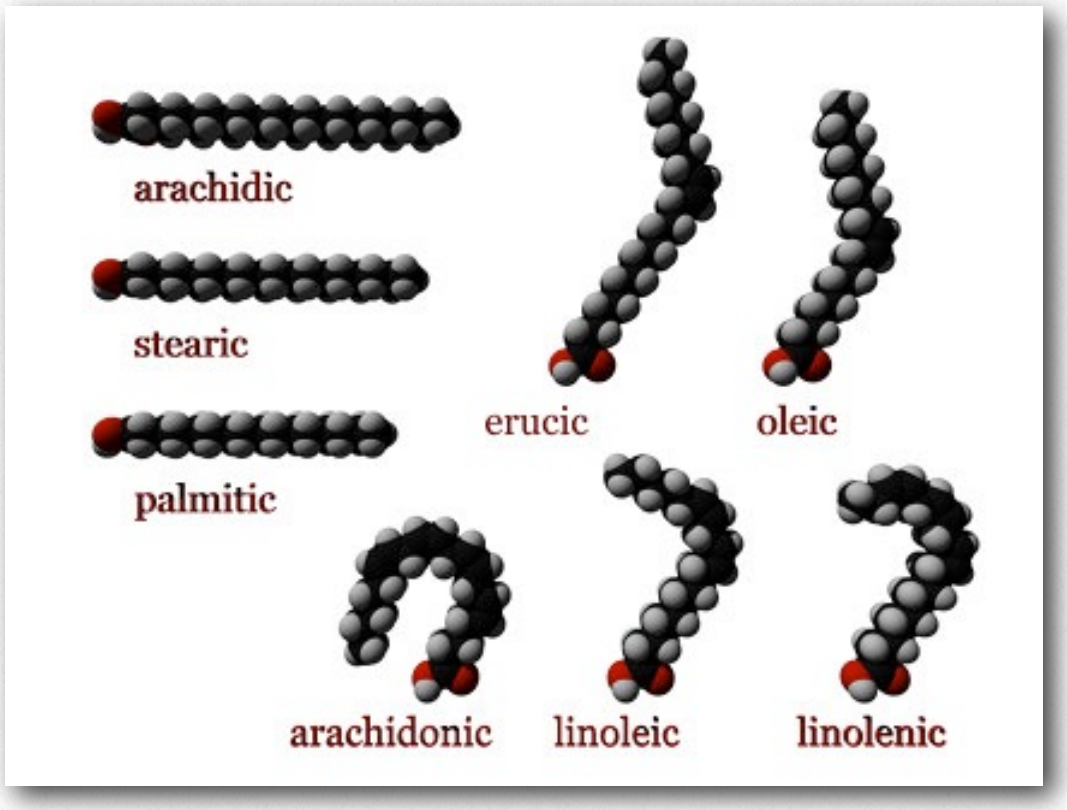

Figure 2.194 - Fatty acid models. Carboxyl end labeled in red

Wikipedia

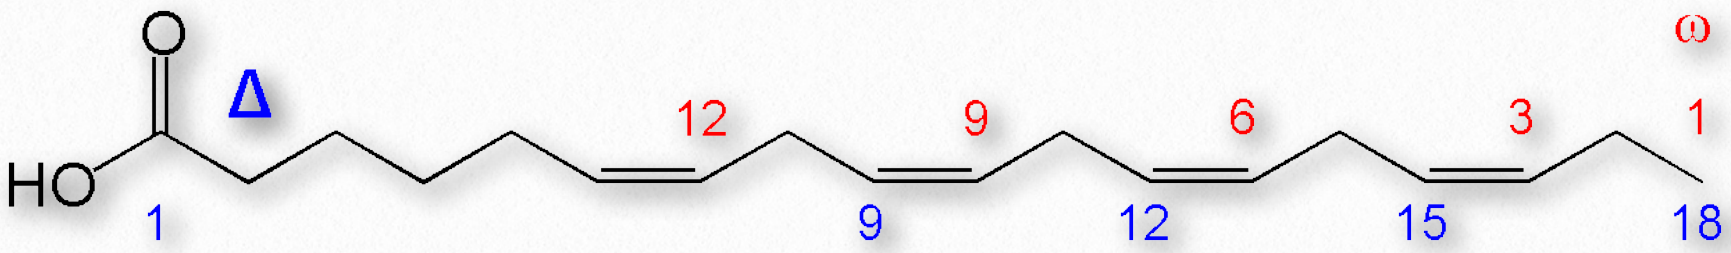

Figure 2.195 - Δ and ω numbering systems for fatty acids

Image by Pehr Jacobson

common fatty acids in our body include palmitate, stearate, oleate, linolenate, linoleate, and arachidonate. Two notable shorter fatty acids are nonanoic (9 carbons) and decanoic acid (10 carbons), both of which appear to have anti-seizure effects. Decanoic acid directly inhibits excitatory neurotransmission in the brain and may contribute to the anticonvulsant effect of the ketogenic diet.

Numbering

Figure 2.195 shows two different systems for locating double bonds in a fatty acid. The ω system counts carbons starting with the methyl end (shown in red) while the Δ system counts from the carboxyl end (shown in blue). For example, an ω-3 (omega 3) fatty acid would have a double bond at the third carbon from the methyl end. In the Δ system, a fatty acid that has a *cis* double bond at carbon 6, counting from the carboxyl end, would be written as cis-Δ^6.

Fatty acids are described as essential fatty acids if they must be in the diet (can't be synthesized by the organism) and non-essential fatty acids if the organism can synthesize them. Humans and other animals lack the desaturase enzymes necessary to make double bonds at positions greater than Δ-9, so fatty acids with double bonds beyond this position must be obtained in the diet. Linoleic acid and linolenic acid, both fall in this category. Related unsaturated fatty acids can be made from these fatty acids, so the presence of linoleic and linolenic acids in the diet eliminates the need to have all unsaturated fatty acids in the diet.

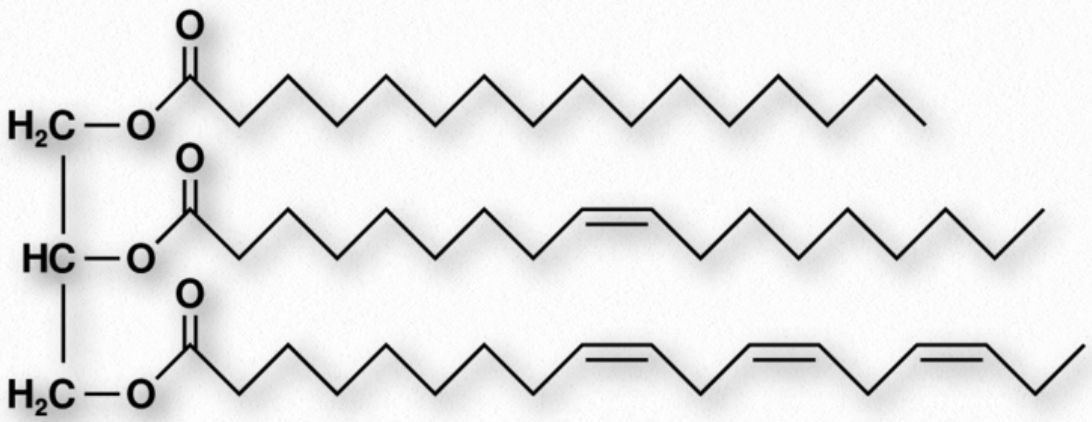

Figure 2.196 - Structure of a fat/oil

Both linoleic and linolenic acid contain 18 carbons, but linoleic acid is an ω-6 fatty acid, whereas linolenic acid is an ω-3 fatty acid. Notably, ω-6 fatty acids tend to be pro-inflammatory, whereas ω-3 fatty acids are lesser so.

Fats/oils

Fats and oils are the primary energy storage forms of animals and are also known as triacylglycerols and triglycerides, since they consist of a glycerol molecule linked via ester bonds to three fatty acids (Figure 2.196). Fats and oils have the same basic structure. We give the name fat to those compounds that are solid at room temperature and the name oil to those that are liquid at room temperature. Note that biological oils are not the same as petroleum oils.

Increasing the number of unsaturated fatty acids (and the amount of unsaturation in a given fatty acid) in a fat decreases the melting temperature of it. Organisms like fish, which live in cool environments, have fats with more unsaturation and this is why fish oil contains polyunsaturated fatty acids.

Adipocytes

Fats are stored in the body in specialized cells known as adipocytes. Enzymes known as lipases release fatty acids from fats by hydrolysis reactions (Figure 2.197). Triacylglycercol lipase (pancreatic - Figure 2.198) is able to cleave the first two fatty ac-

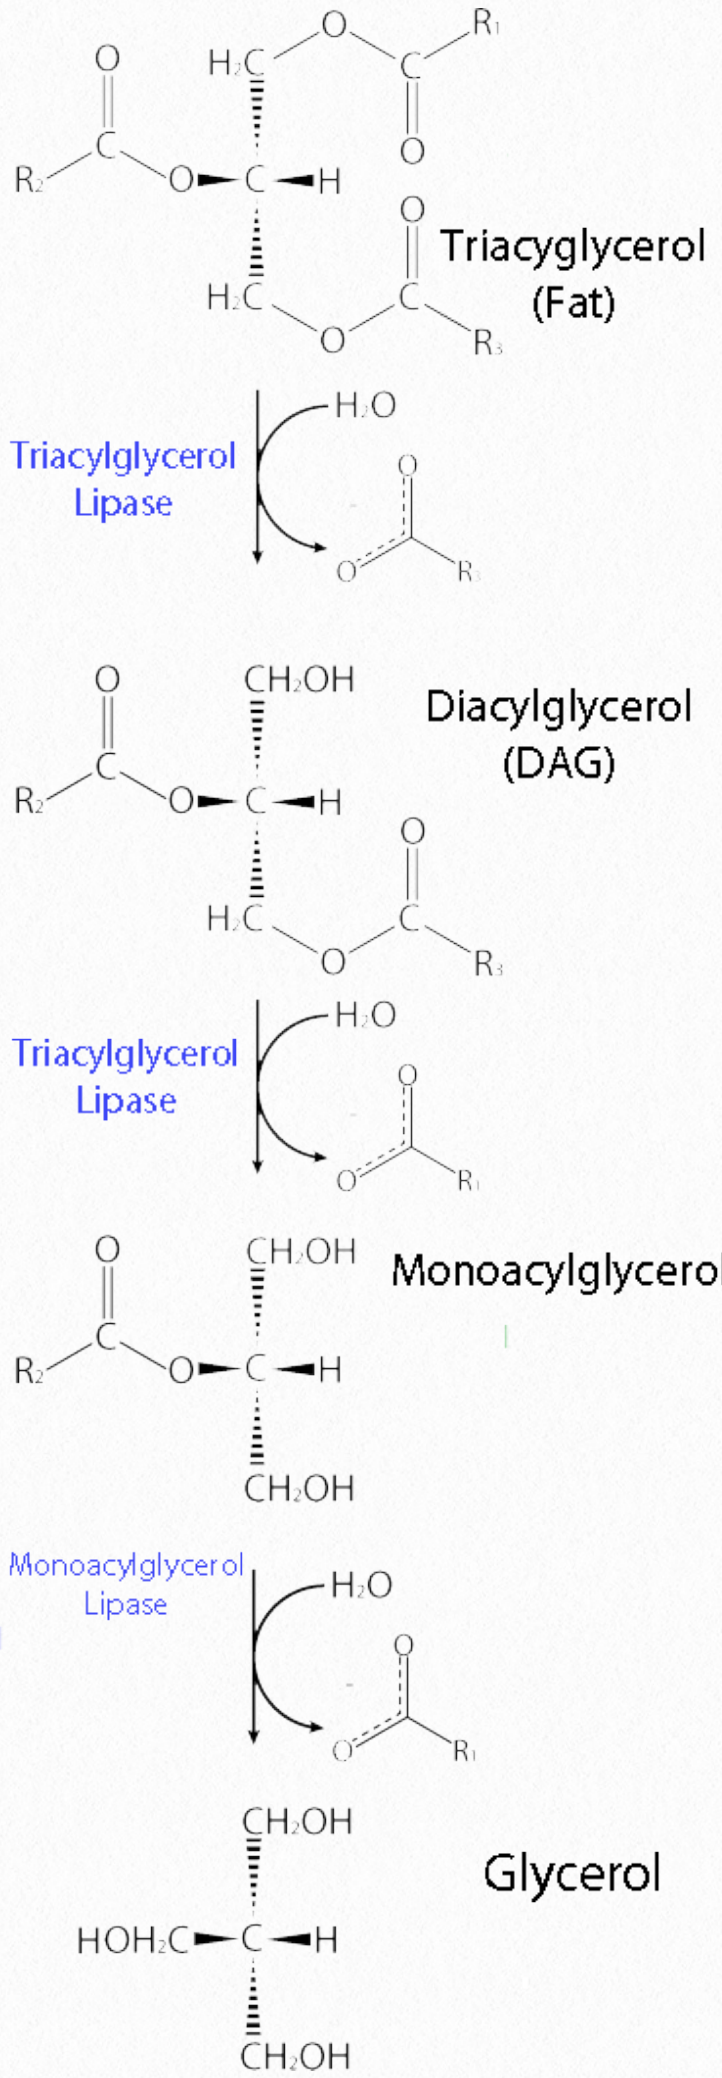

Figure 2.197 - Lipase action on a fat
Image by Aleia Kim

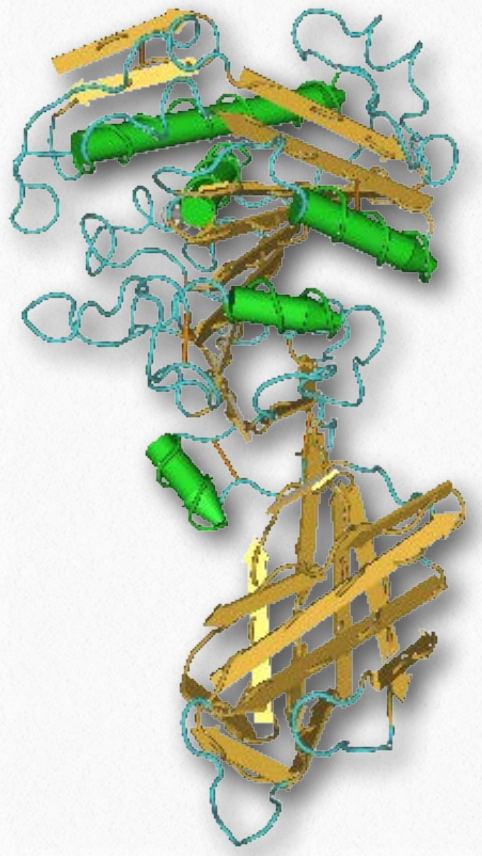

Figure 2.198 - Pancreatic lipase

ids from the fat. A second enzyme, monoacylglycerol lipase, cleaves the last fatty acid. Fats can be synthesized by replacing the phosphate on phosphatidic acid with a fatty acid.

Glycerophospholipids

Glycerophospholipids (phosphoglycerides) are important components of the lipid bilayer of cellular membranes. Phosphoglycerides are structurally related to fats, as both are derived from phosphatidic acid (Figure 2.199). Phosphatidic acid is a simple glycerophospholipid that is usually converted into phosphatidyl compounds. These are made by esterifying various groups, such as ethanolamine, serine, choline, inositol, and others (Figure 2.200) to the phosphate of phosphatidic acid. All of these compounds form lipid bilayers in aqueous solution , due to their amphiphilic nature.

YouTube Lectures by Kevin HERE & HERE

Phosphatidylethanolamines

Since all glycerolipids can have a variety of fatty acids at positions 1 and 2 on the glycerol, they all are families of compounds. The phosphatidylethanolamines are found in all living cells and are one of the most common phosphatides, making up about 25% of them. They are common constituents of brain tissue and in the spinal cord, making up as much as 45% of the total phospholipids. Phosphatidylethanolamines are asymmetrically distributed across membranes, being preferentially

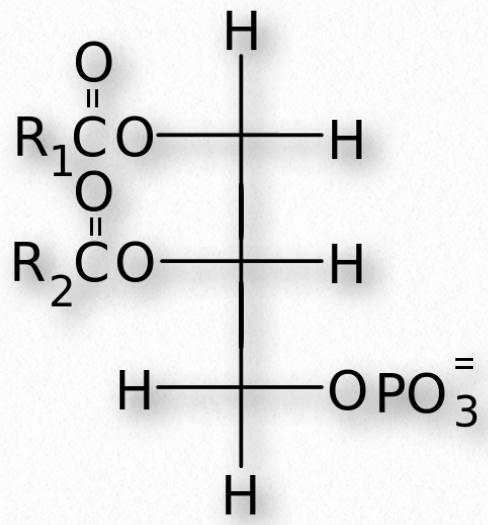

Figure 2.199 - Structure of phosphatidic acid. R_1 and R_2 are alkyl groups of fatty acids.

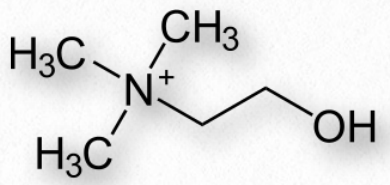
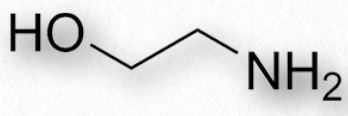
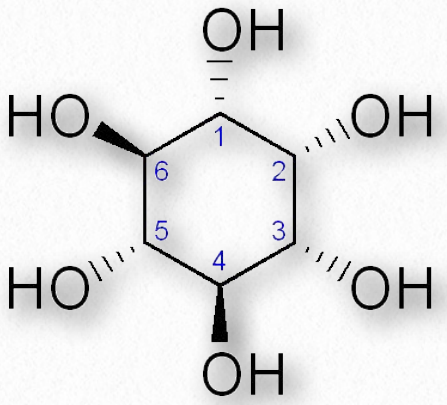


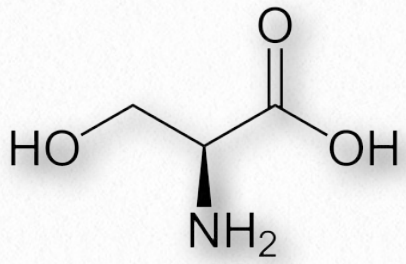
Choline



Ethanolamine



Inositol



Serine

Figure 2.200 - Four common components of phosphatides

Wikipedia

located on the inner leaflet (closest to the cytoplasm) of the plasma membrane. Metabolically, phosphatidylethanloamines are precursors of phosphatidylcholines.

Phosphatidylserines

Phosphatidylserines are another group of phosphatidyl compounds that are preferentially distributed across the lipid bilayer of the plasma membrane. Like the phosphatidylethanolamines, phosphatidylserines are preferentially located on the inner leaflet of the plasma membrane. When apoptosis (cell suicide) occurs, the preferential distribution is lost and the phosphatidylserines appear on the outer leaflet where they serve as a signal to macrophages to bind and destroy the cell.

Phosphatidylcholines

Phosphatidylcholines (Figure 2.201) are another group of important membrane components. They tend to be found more commonly on the outer leaflet of the plasma membrane. Nutritionally, the compounds are readily obtained from eggs and soybeans. Phosphatidylcholines are moved across membranes by Phosphatidylcholine transfer protein (PCTP). This protein, which is sensitive to the levels of phosphatidylcholines, acts to stimulate the activity of a thioesterase (breaks thioester bonds, such as acyl-CoAs) and activates PAX3 transcription factors.

Cardiolipins

Cardiolipins are an unusual set of glycerophospholipids in containing two diacylglycerol backbones joined in the middle

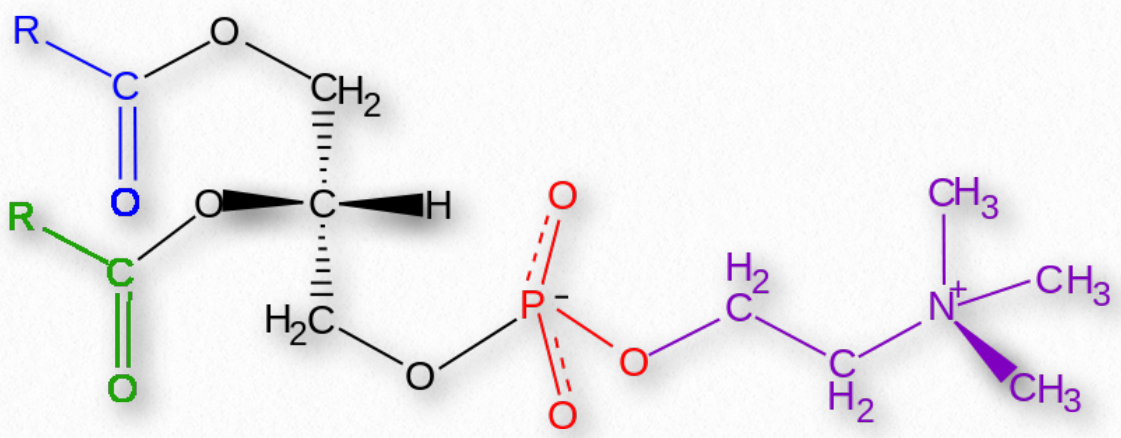


Figure 2.201 - Phosphatidylcholine

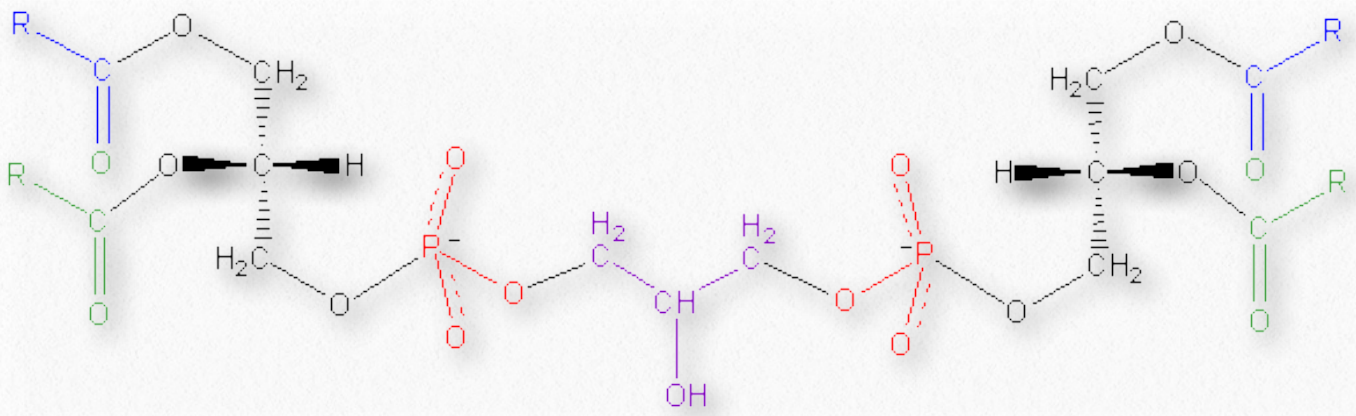

Figure 2.202 - Cardiolipin

by a diphosphoglycerol (Figure 2.202). It is an important membrane lipid, constituting about 20% of the inner mitochondrial membrane and is found in organisms from bacteria to humans. In both plants and animals, it is found almost totally in the inner mitochondrial membrane.

The molecules appear to be required for both Complex IV and Complex III of the electron transport chain to maintain its structure. The ATP synthase enzyme (Complex V) of the oxidative phosphorylation system also binds four molecules of cardiolipin. It has been proposed that cardiolipin functions as a proton trap in the process of proton pumping by Complex IV.

Cardiolipin also plays a role in apoptosis. As shown in Figure 2.203, oxidation of cardiolipin by a cardiolipin-specific oxygenase causes cardiolipin to move from the inner mitochondrial membrane to the outer one, helping to form a permeable pore and facilitating

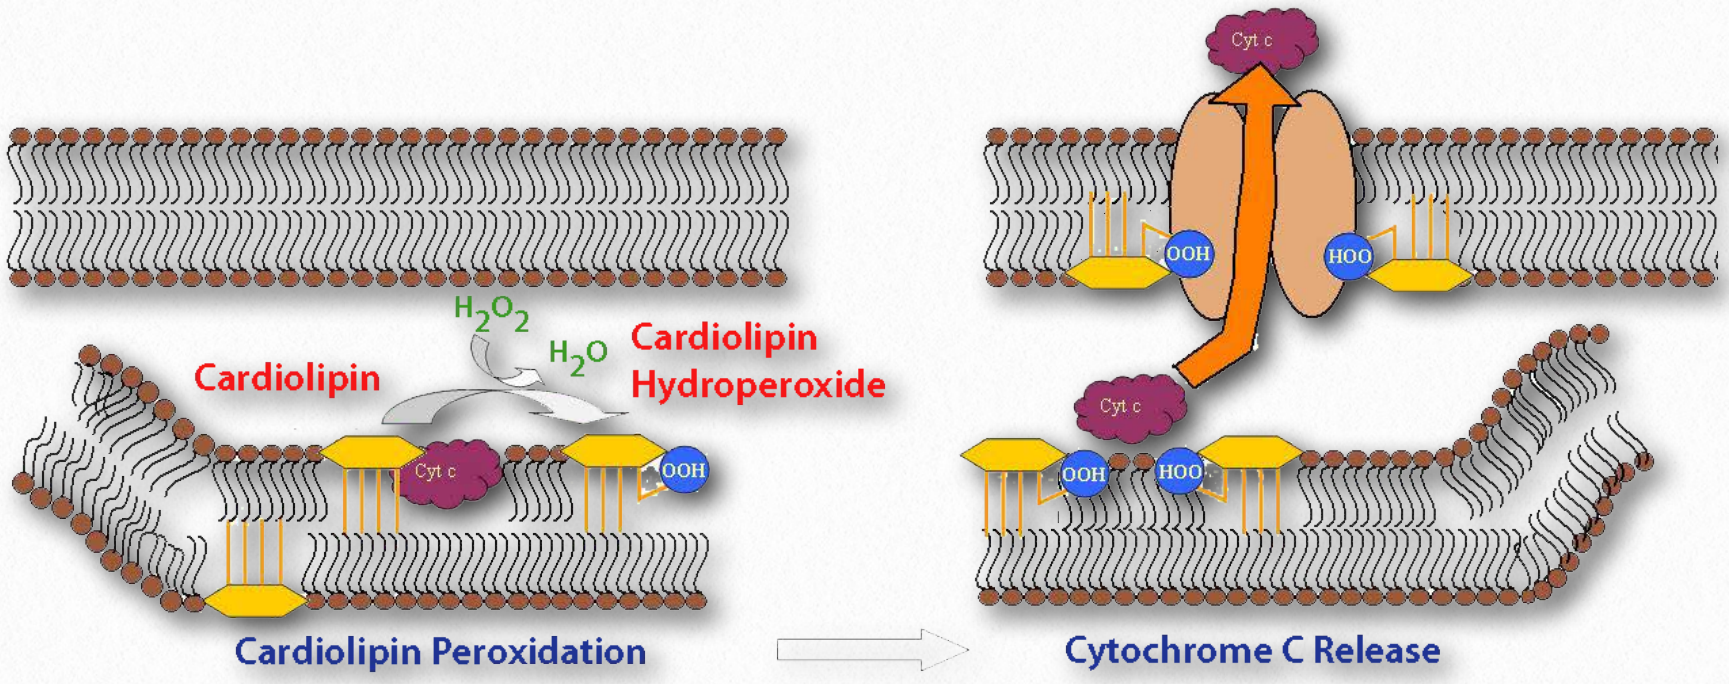

Figure 2.203 - Cardiolipin oxidation and the release of cytochrome C in apoptosis

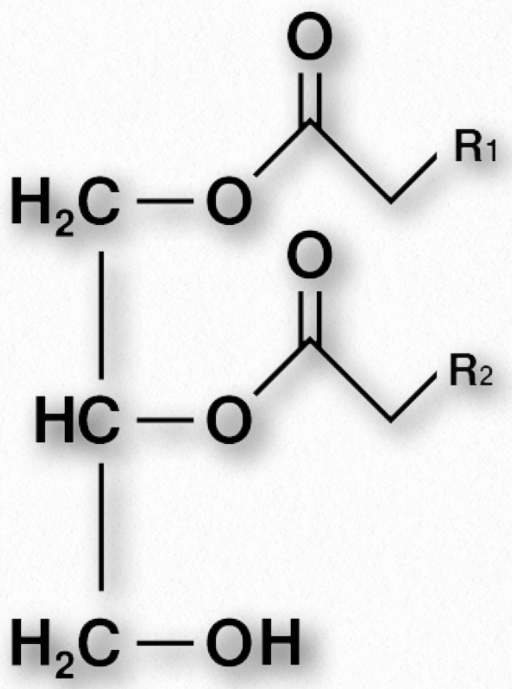

Figure 2.204 - Diacylglycerol

the transport of cytochrome c out of the intermembrane space and into the cytoplasm - a step in the process of apoptosis.

Diacylglycerol

Diacylglycerol (also called diglyceride and DAG - Figure 2.204) is an important intermediate in metabolic pathways. It is produced, for example, in the first step of the hydrolysis of fat and is also produced when membrane lipids, such as PIP_2 (phosphatidylinositol-4,5-bisphosphate) are hydrolyzed by phospholipase C in a signaling cascade.

DAG is itself a signaling compound, binding to protein kinase C to activate it to phosphorylate substrates. Synthesis of DAG begins with glycerol-3-phosphate, which gains two fatty acids from two acyl-CoAs to form phosphatidic acid. Dephosphorylation of phosphatidic acid produces DAG. DAG can also be rephosphorylated by DAG kinase to re-make phosphatidic acid or another fatty acid can be added to make fat.

Inositol

Though technically not a lipid itself, inositol is found in many lipids. Inositol is a derivative of cyclohexane containing six hydroxyl groups - one on each carbon (Figure 2.205. It has nine different stereoisomers of which one, *cis*-1,2,3,5-*trans*-4,6-cyclohexanehexol (called myo-inositol) is the most common. It has a sweet taste (half that of sucrose).

Numerous phosphorylated forms of the compound exist, from a single phosphate to six (one on each carbon). Phytic acid, for example, in plants, has six phosphates (Figure 2.206) that it uses to store phosphate. Inositol is produced from glucose and was once considered vitamin B_8, but is made by the body in adequate amounts, so it is not now considered a vitamin. Phosphorylated forms of inositol are found in phosphoinositides, such as PIP_2 and PIP_3, both of which are important in signaling processes. Some of these include insulin sig-

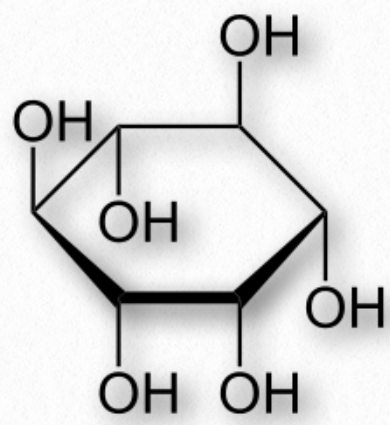

Figure 2.205 - Inositol

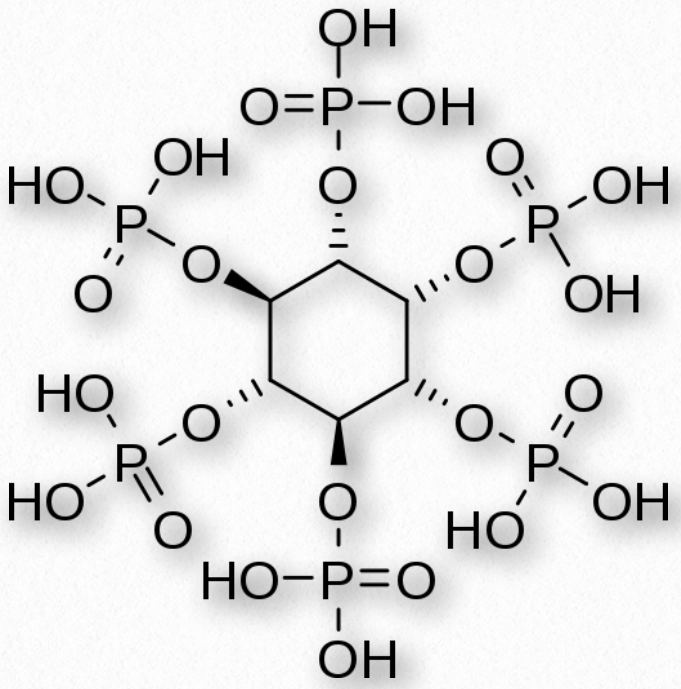

Figure 2.206 - **Phytic acid**

naling, fat catabolism, calcium regulation, and assembly of the cytoskeleton.

Phosphoinositides

Compounds based on phosphatidylinositol (PI) are often called phosphoinositides. These compounds have important

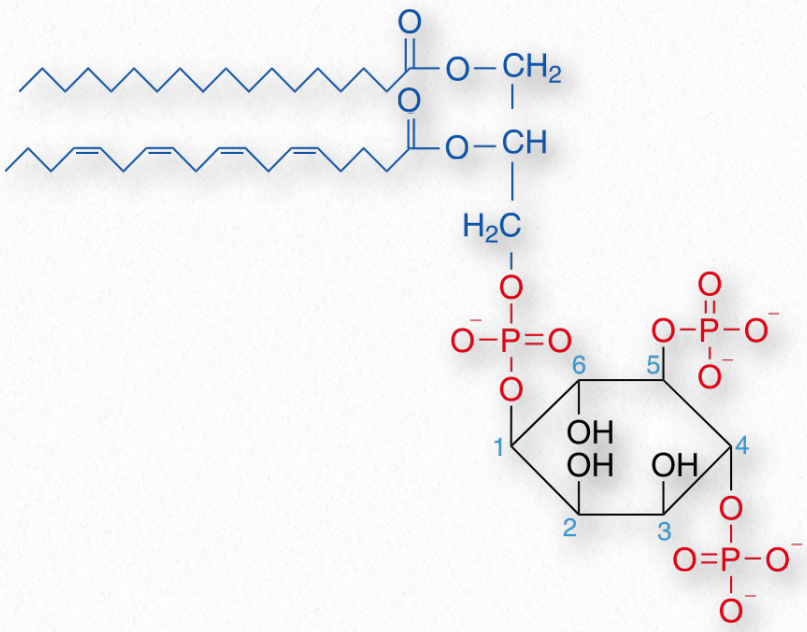

Figure 2.207 - **Structure of PIP_2**

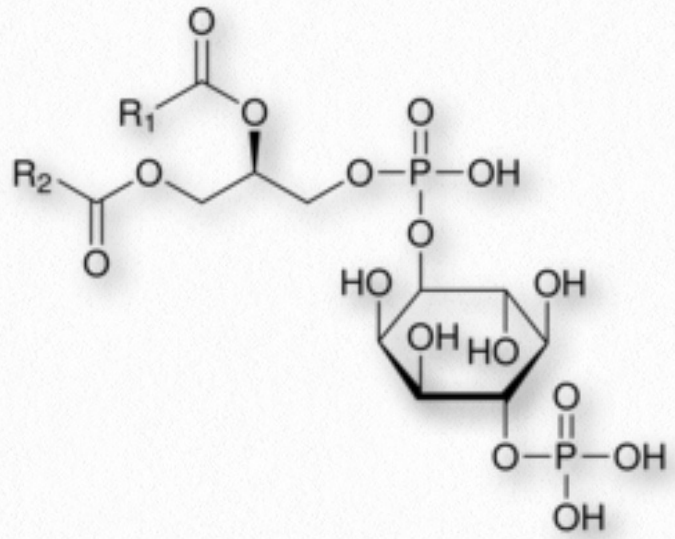

Figure 2.208 - **Phosphatidylinositol-4-phosphate**

roles in signaling and membrane trafficking. Hydroxyls on carbons 3,4, and 5 of the inositol ring are targets for phosphorylation by a variety of kinases. Seven different combinations are used. Steric hindrance inhibits phosphorylation of carbons 2 or 6. Naming of these phosphorylated compounds follows generally as PI(#P)P, PI(#P, #P)P, or PI(#P, #P, #P)P where #P refers to the number of the carbon where a phosphate is located. For example, PI(3)P refers to a phosphatidyl compound with a phosphate added to carbons 3 of the inositol ring, whereas PI(3,4,5)P is a phosphatidyl compound with a phosphate added to carbons 3,4,and 5.

YouTube Lectures by Kevin HERE & HERE

Phosphatidylinositol-4,5-bisphosphate

Phosphatidylinositol-4,5-bisphosphate (PIP2 - Figure 2.207) is a phospholipid of plasma membranes that functions in the

phospholipase C signaling cascade. In this signaling pathway, hydrolysis catalyzed by phospholipase C releases inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol. Synthesis of PIP_2 begins with phosphatidylinositol, which is phosphorylated at position 4 followed by phosphorylation at position 5 by specific kinases.

PIP_2 can be phosphorylated to form the signaling molecule known as phosphatidylinositol (3,4,5)-trisphosphate (PIP_3). Along with PIP_3, PIP_2 serves as a docking phospholipid for the recruitment of proteins that play roles in signaling cascades. Binding of PIP_2 is also required by inwardly directed potassium channels.

Phosphatidylinositol (3,4,5)-trisphosphate

Phosphatidylinositol (3,4,5)-trisphosphate (PIP_3) is an important molecule for the activation of signaling proteins, such as AKT, which activates anabolic signaling pathways related to growth and survival. PIP_3 can be dephosphorylated by phosphatase PTEN to yield PIP2 and can be synthesized from PIP_2 by kinase action of Class I PI 3-kinases. Kinase activity to synthesize PIP_3 results in movement of PIP_3-binding proteins to the plasma membrane. They include Akt/PKB, PDK1, Btk1, and ARNO and each is activated by binding to PIP_3.

Plasmalogens

A special class of the glycerophospholipids are the plasmalogens (Figure 2.209). They differ in containing a vinyl ether linkage at position 1 of glycerol, in contrast to other glycerophopsholipids, which have an ester linkage at this position. Position 2 of each is an ester. The precursor for the ether linkage is typically a 16 or 18 carbon saturated alcohol or an 18 carbon unsaturated alcohol.

At the phosphate tail, the most commonly attached groups are ethanolamine or choline. Plasmalogens are found abundantly in

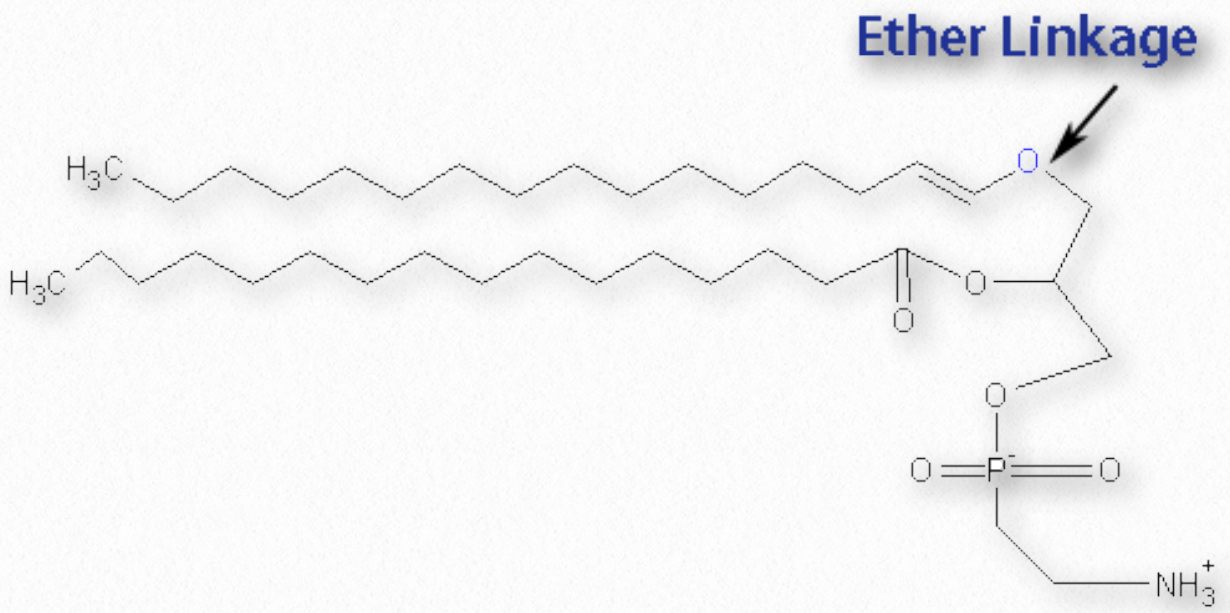

Figure 2.209 - Plasmalogen - A vinyl ether lipid

Wikipedia

humans in heart (30-40% of choline phospholipids). 30% of the glycerophospholipids in brain are plasmalogens and 70% of the ethanolamine lipids of the myelin sheath of nerve cells are plasmalogens.

Though their function is not understood, it is believed that plasmalogens may provide some protection against reactive oxygen species and have roles in signaling.

Lecithin

Lecithin is a generic term for a combination of lipid substances that includes phosphoric acid, glycerol, glycolipids, triglycerides, and phospholipids. Lecithin is a wetting agent helpful with emulsification and encapsulation and is even used as an anti-sludge additive in motor lubricants. Lecithin is used in candy bars to keep cocoa and cocoa butter from separating. Though considered safe as a food ingredient, lecithin can be converted by gut bacteria to trimethylamine-N-oxide which may contribute to cholesterol deposition and atherosclerosis.

Sphingolipids

Fatty acids are also components of a broad class of molecules called sphingolipids. Sphingolipids are structurally similar to glycerophospholipids, though they are synthesized completely independently of them starting with palmitic acid and the amino acid serine. Sphingolipids are named for the amino alcohol known as sphingosine (Figure 2.210), though they are not directly synthesized from it. Figure 2.211 shows the generalized structure of sphingolipids.

If the R-group is a hydrogen, the molecule is called a ceramide. When the R-group is phosphoethanolamine the resulting molecule is sphingomyelin, an important compo-

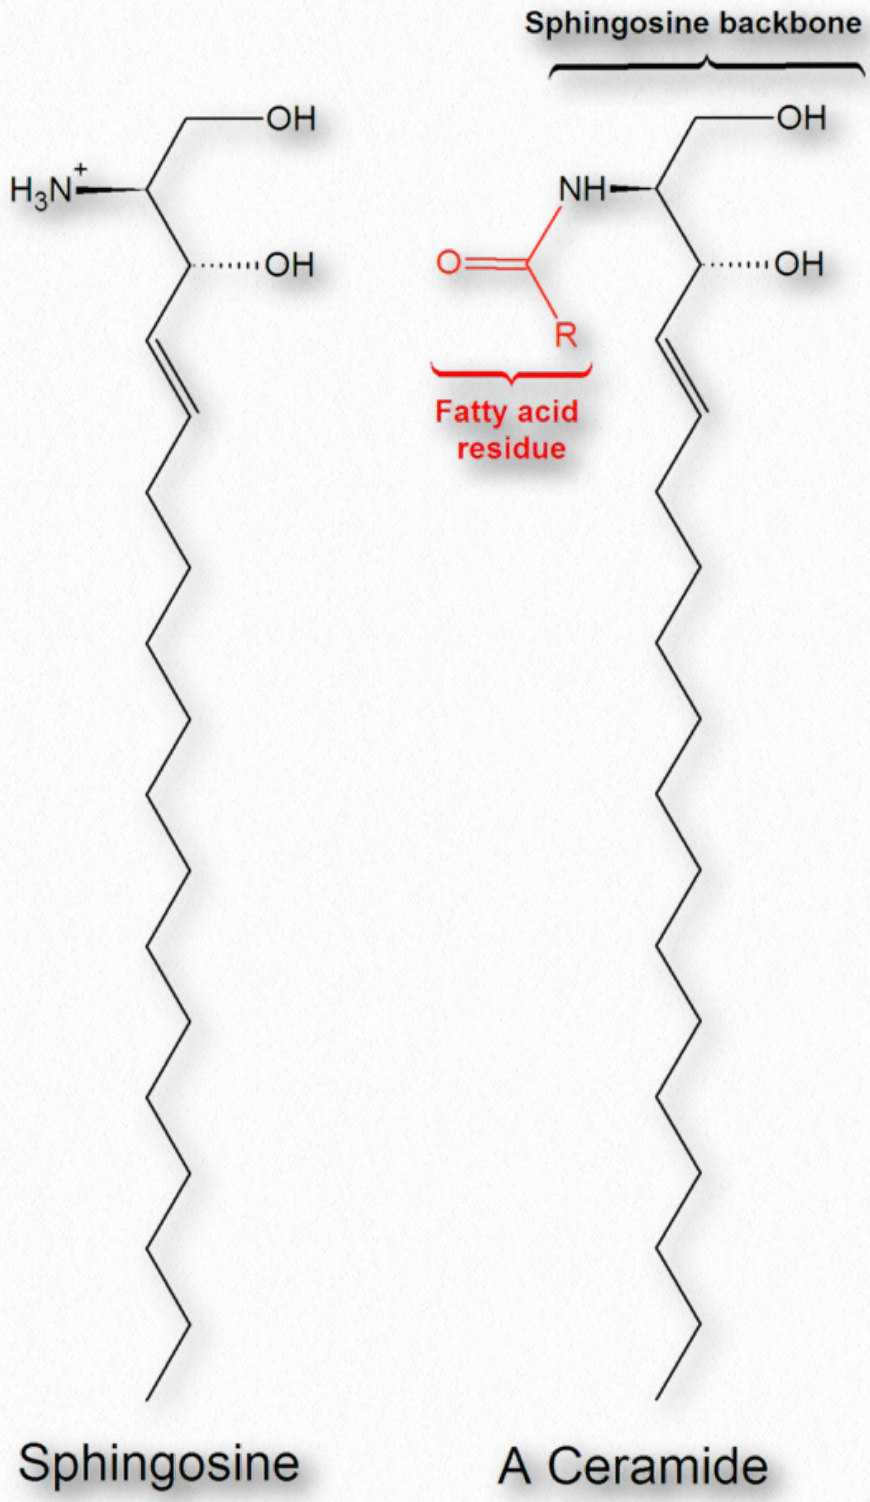

Figure 2.210 - Sphingosine and a ceramide made from it

Wikipedia

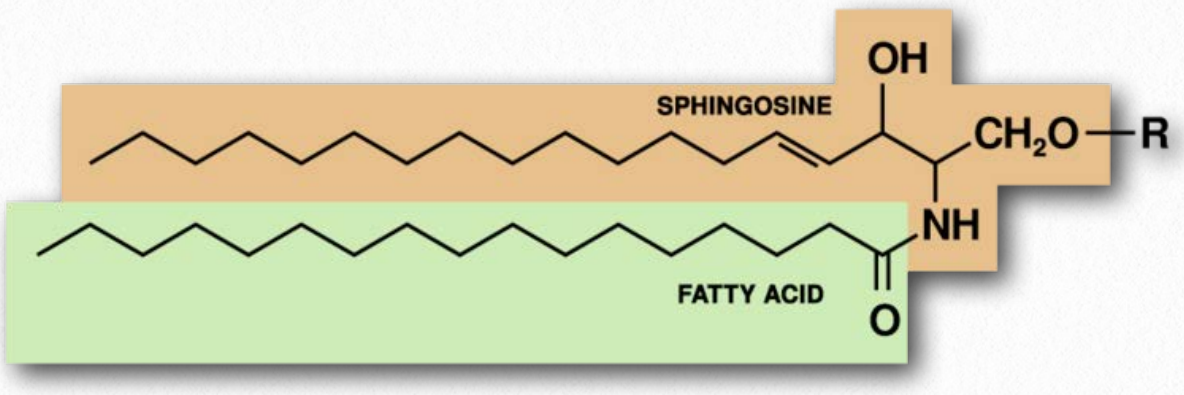

Figure 2.211 Schematic structure of a sphingolipid

nent of the myelin sheath and lipid membranes. If a single, simple sugar is instead added, a cerebroside is created (Figure 2.212). Addition of a complex oligosaccharide creates a ganglioside.

Complex sphingolipids may play roles in cellular recognition and signaling. Sphingolipids are found most abundantly in plasma membrane and are almost completely absent from mitochondrial and endoplasmic reticulum membranes. In animals, dietary sphingolip-

Wikipedia

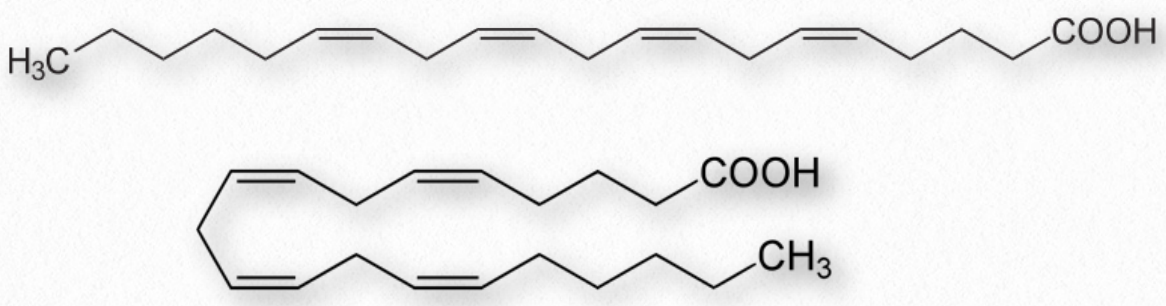

Figure 2.213 - Arachidonic acid drawn as straight (top) and bent (bottom)

ids have been linked to reduced colon cancer, reductions in LDLs, and increases in HDLs. Like the glycerophospholipids, sphingolipids are amphiphilic. Most sphingolipids except sphingomyelin do not contain phosphate.

Eicosanoids

Fatty acids made from omega-6 and omega-3 fatty acids include three important fatty acids containing 20 carbons. They include arachidonic acid (an ω-6 fatty acid with four double bonds (Δ-5,8,11,14) - Figure 2.213), eicosapentaenoic acid (an ω-3 fatty acid with five double bonds, and dihomo-γ-linolenic acid (an ω-6 fatty acid with three double bonds). The class of compounds known as eicosanoids is made by oxidation of these compounds. Subclasses include include prostaglandins, prostacyclins, thromboxanes, lipoxins, leukotrienes, and endocannabinoids (Figures 2.214-2.219). Eicosanoids play important roles affecting inflammation, immunity, mood, and behavior.

YouTube Lectures by Kevin HERE & HERE

Prostaglandins

A collection of molecules acting like hormones, prostaglandins are derived from arachidonic acid and have many differing (even conflicting) physiological effects. These include constriction or dilation of vascular smooth muscle cells, induction of labor, regulation of inflammation, and action on the thermoregulatory center of the hypothalamus to induce fever, among others.

Prostaglandins are grouped with the thromboxanes (below) and prostacyclins (below), as prostanoids. The prostanoids, which all contain 20 carbons are a subclass of the eicosanoids. Prostaglandins are found

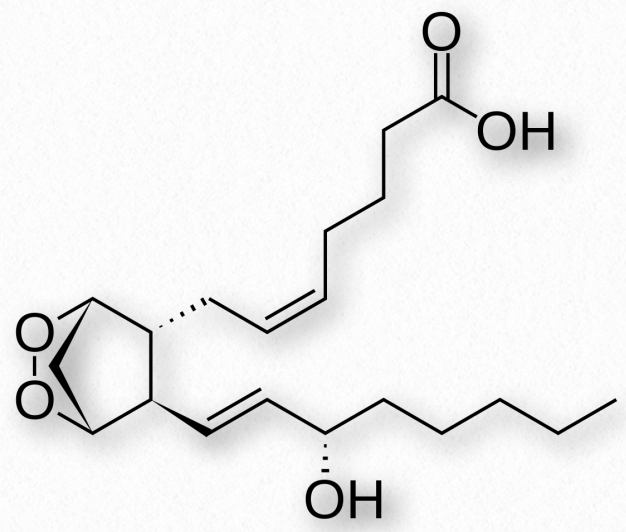

Figure 2.214 - Prostaglandin PGH_2

in most tissues of higher organisms. They are autocrine or paracrine compounds produced from essential fatty acids. The primary precursor of the prostaglandins is the fatty acid known as arachidonic acid and the prostaglandin made from it is known as PGH2 (Figure 2.214), which, in turn is a precursor of other prostaglandins, as well as the prostacyclins and thromboxanes.

Interesting prostaglandins

PGD_2 - inhibits hair follicle growth, vasodilator, causes bronchial constriction, higher in lungs of asthmatics than others.

PGE_2 (Figure 2.215) - exerts effects in labor (soften cervix, uterine contraction), stimulates bone resorption by osteoclasts, induces fever, suppresses T-cell receptor signaling, vasodilator, inhibits release of noradrenalin from sympathetic nerve terminals. It is a potent activator of the Wnt signaling pathway.

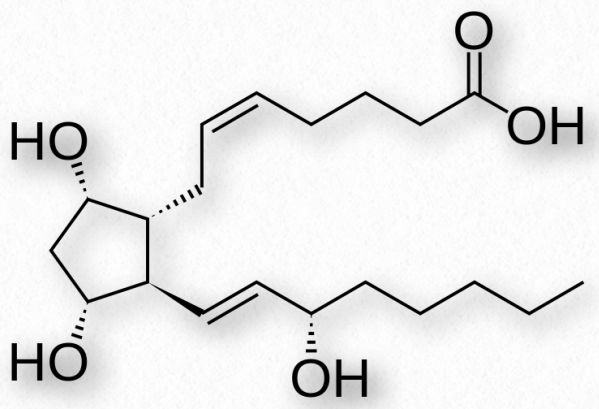

Figure 2.216 - **Prostaglandin $F_{2\alpha}$**

A prostaglandin can have opposite effects, depending on which receptor it binds to. Binding of PGE_2 to the EP_1 receptor causes bronchoconstriction and smooth muscle contraction, whereas binding of the same molecule to the EP_2 receptor causes bronchodilation and smooth muscle relaxation.

PGF2α (Figure 2.216)- uterine contractions, induces labor, bronchoconstriction.

PGI2 - vasodilation, bronchodilation, inhibition of platelet aggregation.

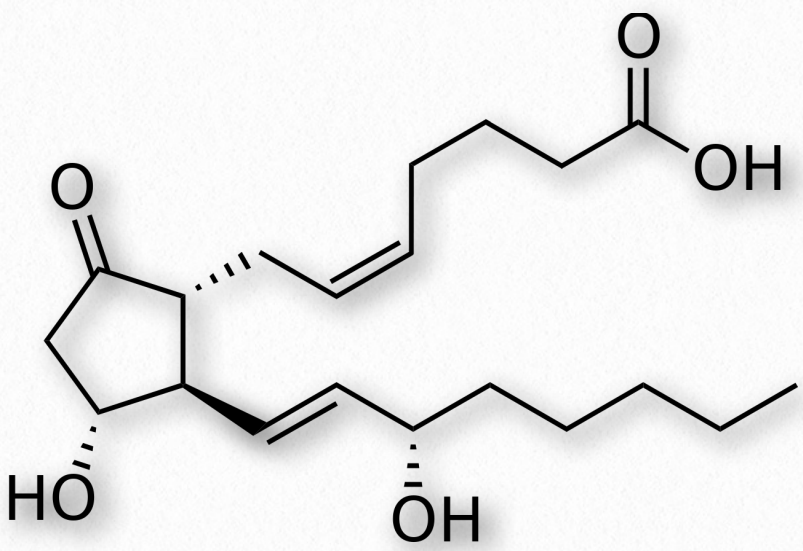

Figure 2.215 **Prostaglandin E_2**

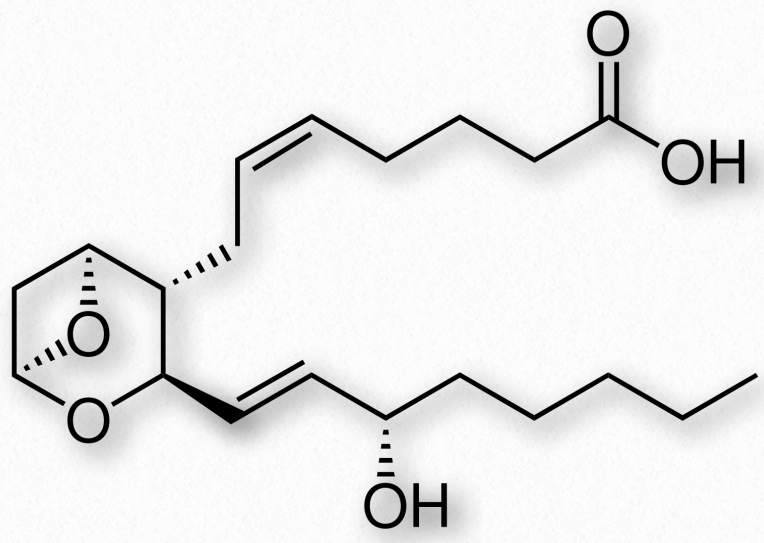

Figure 2.217 **Thromboxane A_2**

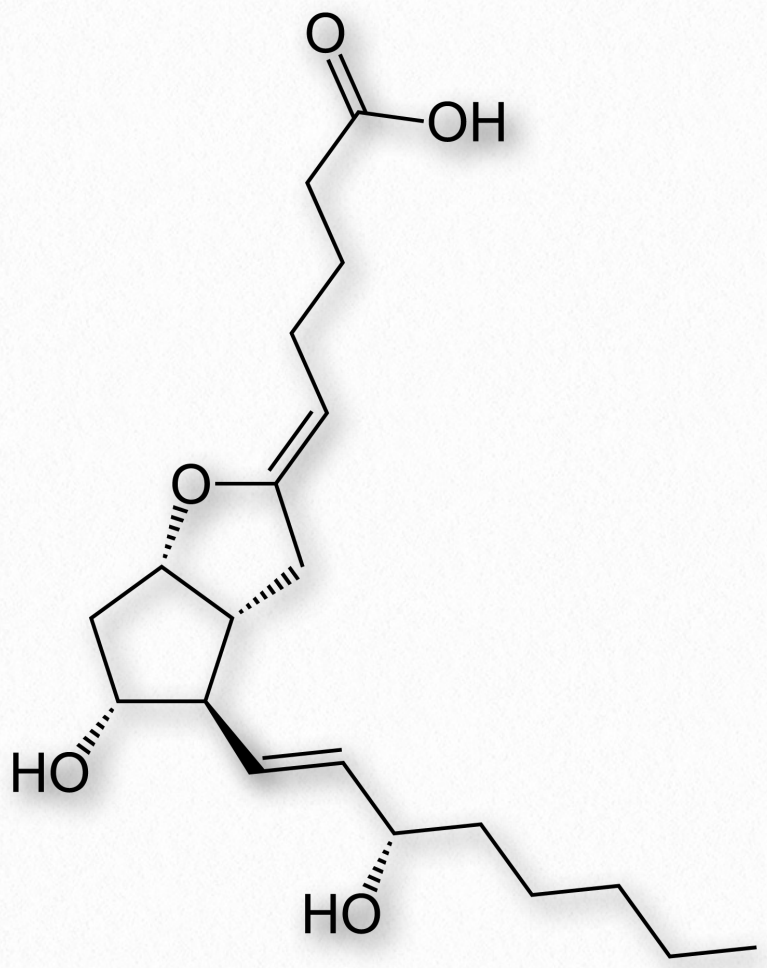

Figure 2.218 - **Prostacyclin**

Thromboxanes

Thromboxanes play roles in clot formation and named for their role in thrombosis. They are potent vasoconstrictors and facilitate platelet aggregation. They are synthesized in platelets, as well. The anti-clotting effects of aspirin have their roots in the inhibition of synthesis of PGH_2, which is the precursor of the thromboxanes. The most common thromboxanes are A_2 (Figure 2.217) and B_2.

Prostacyclin

Prostacyclin (also known as prostaglandin I_2 or PGI_2 - Figure 2.218) counters the effects of thromboxanes, inhibiting platelet activation and acting as vasodilators. It is produced from PGH_2 by action of the enzyme prostacyclin synthase.

Leukotrienes

Another group of eicosanoid compounds are the leukotrienes (Figure 2.219). Like prostaglandins, leukotrienes are made from arachidonic acid. The enzyme catalyzing their formation is a dioxygenase known as arachidonate 5-lipoxygenase. Leukotrienes are involved in regulating immune responses. They are found in leukocytes and other immunocompetent cells, such as neutrophils, monocytes, mast cells, eosinophils, and basophils. Leukotrienes are associated with production of histamines and prostaglandins, which act as mediators of inflammation. Leukotrienes also trigger contractions in the smooth muscles of the bronchioles. When overproduced, they may pay a role in asthma and allergic reactions. Some treatments for asthma aim at inhibiting production or action of leukotrienes.

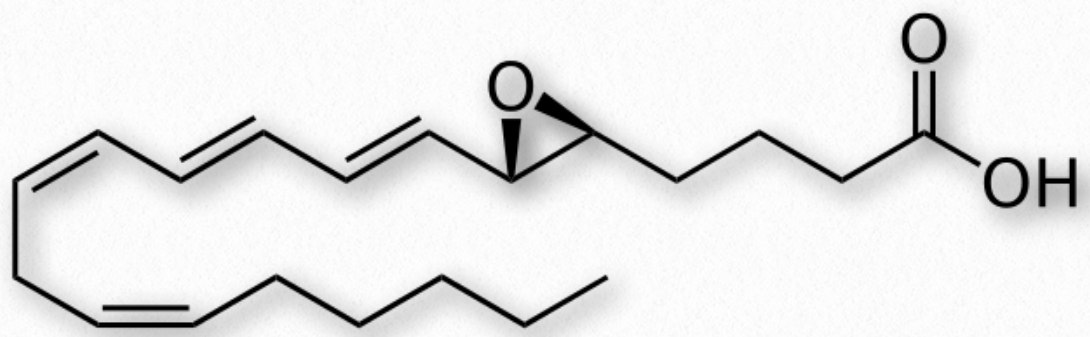

Figure 2.219 - **Leukotriene A_4 (LTA_4)**

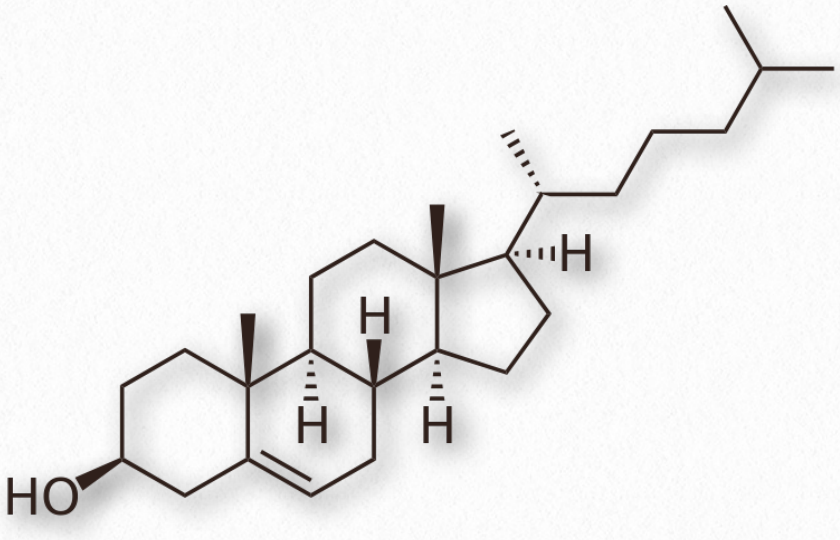

Figure 2.220 - **Structure of cholesterol**

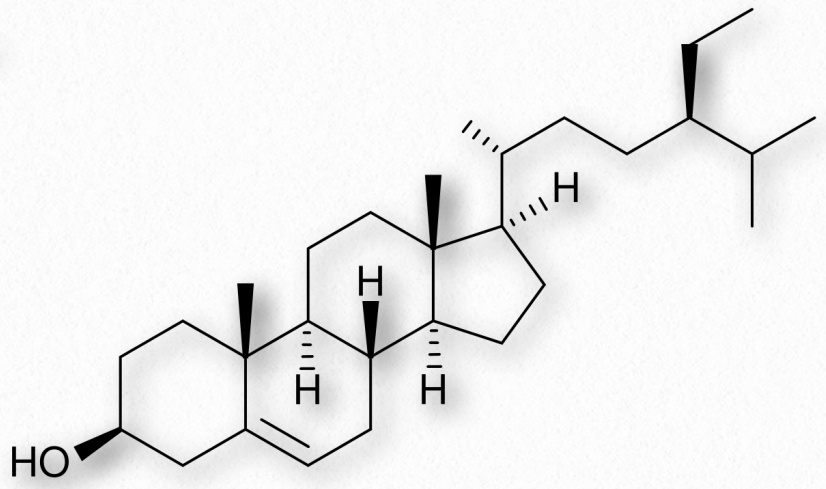

Figure 2.221 - **Sitosterol - A phytosterol**

Cholesterol

Arguably, no single biomolecule has generated as much discussion and interest as has cholesterol (Figure 2.220). Certainly, from the perspective of the Nobel Prize committee, no small molecule even comes close, with 13 people having been awarded prizes for work on it. Evidence for cholesterol's importance comes from the study of brain tissue where it comprises 10-15% of the dry mass.

Membrane flexibility

In animal cells, cholesterol provides for membrane flexibility that allows for cellular movement that is in contrast to plant and bacterial cells with fixed structures. Cholesterol is made in many cells of the body, with the liver making the greatest amount. The anabolic pathway leading to synthesis of cholesterol is known as the isoprenoid pathway and branches of it lead to other molecules including other fat-soluble vitamins.

Cholesterol is only rarely found in prokaryotes (*Mycoplasma*, which requires it for growth, is an exception) and is found in only trace amounts in plants. Instead, plants synthesize similar compounds called phytosterols (Figure 2.221). On average, the body of a 150 pound adult male makes about 1 gram

Figure 2.222 - **Margarine - A common source of *trans* fat**

Wikipedia

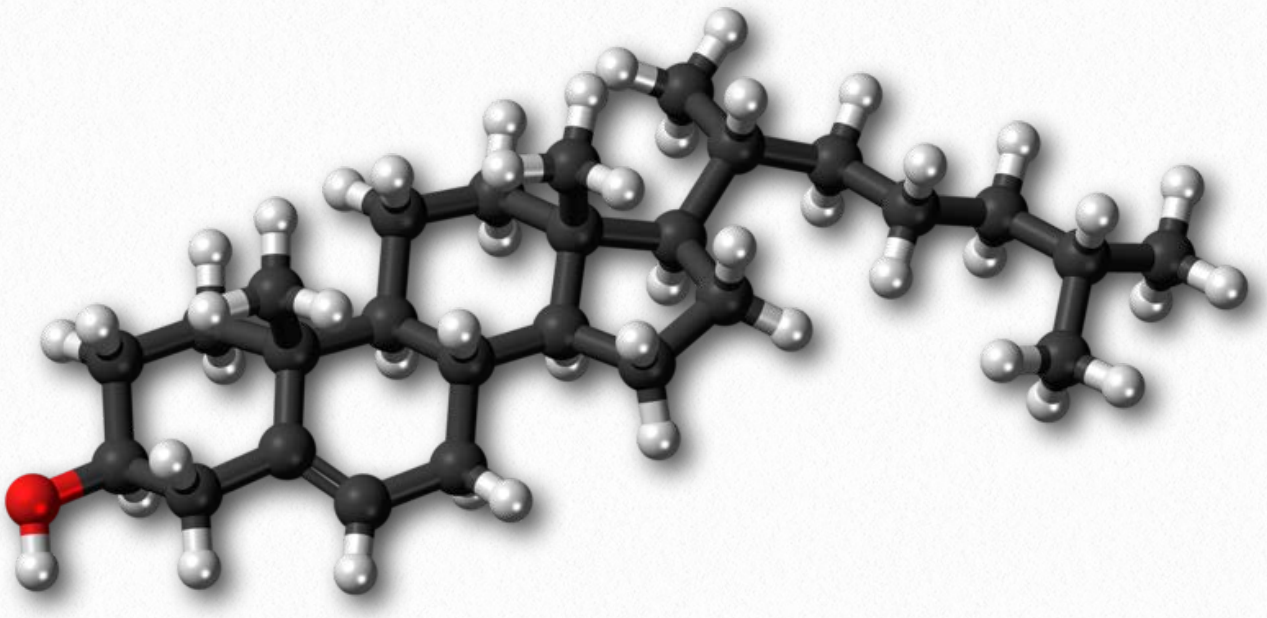

Figure 2.223 - Cholesterol - Ball and stick model

of cholesterol per day, with a total content of about 35 grams.

Packaging

Cholesterol's (and other lipids') hydrophobicity requires special packaging into lipoprotein complexes (called chylomicrons, VLDLs, IDLs, LDLs, and HDLs) for movement in the lymph system and bloodstream. Though cholesterol can be made by cells, they also take it up from the blood supply by absorbing cholesterol-containing LDLs directly in a process called receptor-mediated endocytosis.

Oxidative damage to LDLs can lead to formation of atherosclerotic plaques and this is why cholesterol has gotten such a negative image in the public eye. The liver excretes cholesterol through the bile for elimination into the digestive system, but the compound is recycled there.

YouTube Lectures by Kevin HERE & HERE

Reducing cholesterol levels

Strategies for reducing cholesterol in the body focus primarily on three areas - reducing consumption, reducing endogenous synthesis, and reducing the recycling. Dietary considerations, such as saturated fat versus unsaturated fat consumption are currently debated. Dietary *trans* fats, though, correlate with incidence of coronary heart disease. Consumption of vegetables may provide some assistance with reducing levels of cholesterol recycled in the digestive system, because plant phytosterols compete with cholesterol

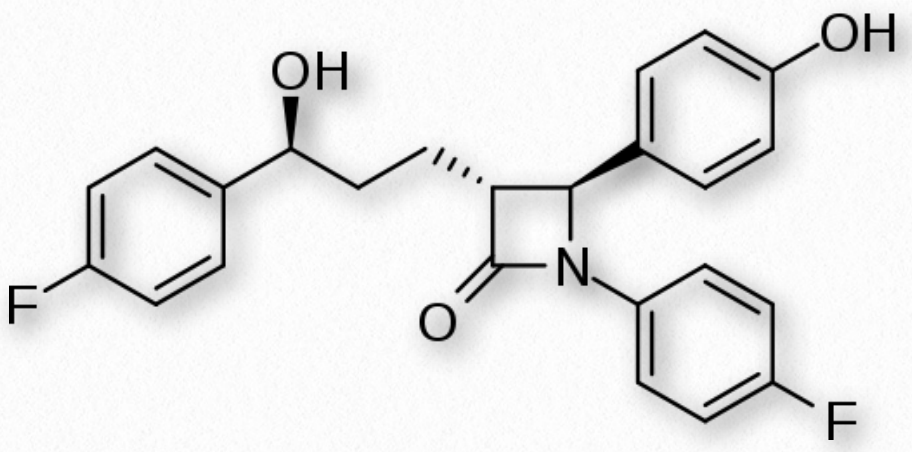

Figure 2.224 - Ezetimibe - An inhibitor of cholesterol absorption

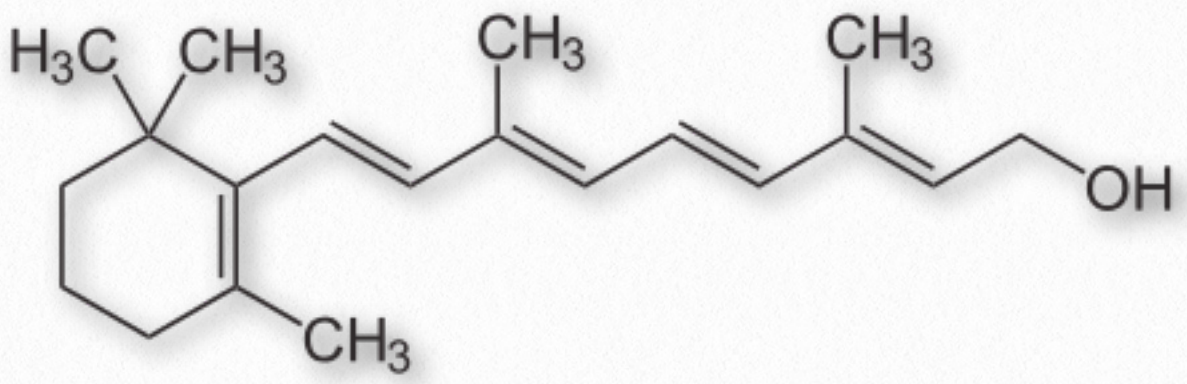

Figure 2.225 - All-*trans* retinol

for reabsorption and when this happens, a greater percentage of cholesterol exits the body in the feces. Drugs related to penicillin are also used to inhibit cholesterol recycling. One of these is ezetimibe, shown in Figure 2.224.

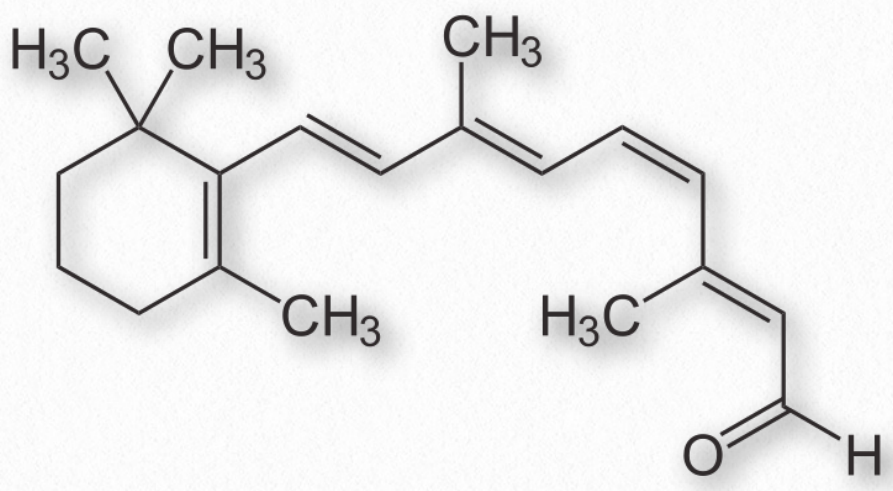

Figure 2.226 - 11-cis retinal

Genetic defects in the cholesterol movement system are a cause of the rare disease known as familial hypercholesterolemia in which the blood of afflicted individuals contains dangerously high levels of LDLs. Left untreated, the disease is often fatal in the first 10-20 years of life. While LDLs have received (and deserve) a bad rap, another group of lipoprotein complexes known as the HDLs (high density lipoprotein complexes) are known as "good cholesterol" because their levels correlate with removal of debris (including cholesterol) from arteries and reduce inflammation.

Membrane function

In membranes, cholesterol is important as an insulator for the transmission of signals in nerve tissue and it helps to manage fluidity of membranes over a wide range of temperatures. Stacked in the lipid bilayer, cholesterol decreases a membrane's fluidity and its permeability to neutral compounds, as well as protons and sodium ions. Cholesterol may

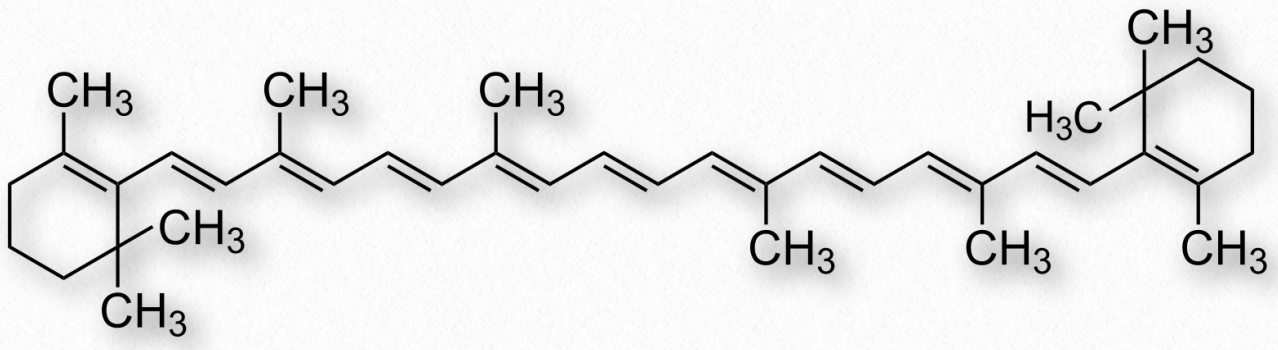

Figure 2.227 - β-Carotene

play a role in signaling by helping with construction of lipid rafts within the cell membrane.

Vitamin A

Vitamin A comes in three primary chemical forms, retinol (storage in liver - Figure 2.225), retinal (role in vision - Figure 2.226), and retinoic acid (roles in growth and development). All vitamin A forms are diterpenoids and differ only in the chemical form of the terminal group. Retinol is mostly used as the storage form of the vitamin.

Retinol is commonly esterified to a fatty acid and kept in the liver. In high levels, the compound is toxic. Retinol is obtained in the body by hydrolysis of the ester or by reduction of retinal. Importantly, neither retinal nor retinol can be made from retinoic acid. Retinoic acid is important for healthy skin and teeth, as well as bone growth. It acts in differentiation of stem cells through a specific cellular retinoic acid receptor.

Sources

Good sources of vitamin A are liver and eggs, as well as many plants, including carrots, which have a precursor, β-carotene (Figure 2.227) from which retinol may be made by action of a dioxygenase.

Light sensitivity

The conjugated double bond system in the side chain of vitamin A is sensitive to light and can flip between *cis* and *trans* forms on exposure to it. It is this response to light that makes it possible for retinal to have a role in vision in the rods and cones of the eyes. Here, the aldehyde form (retinal) is bound to the

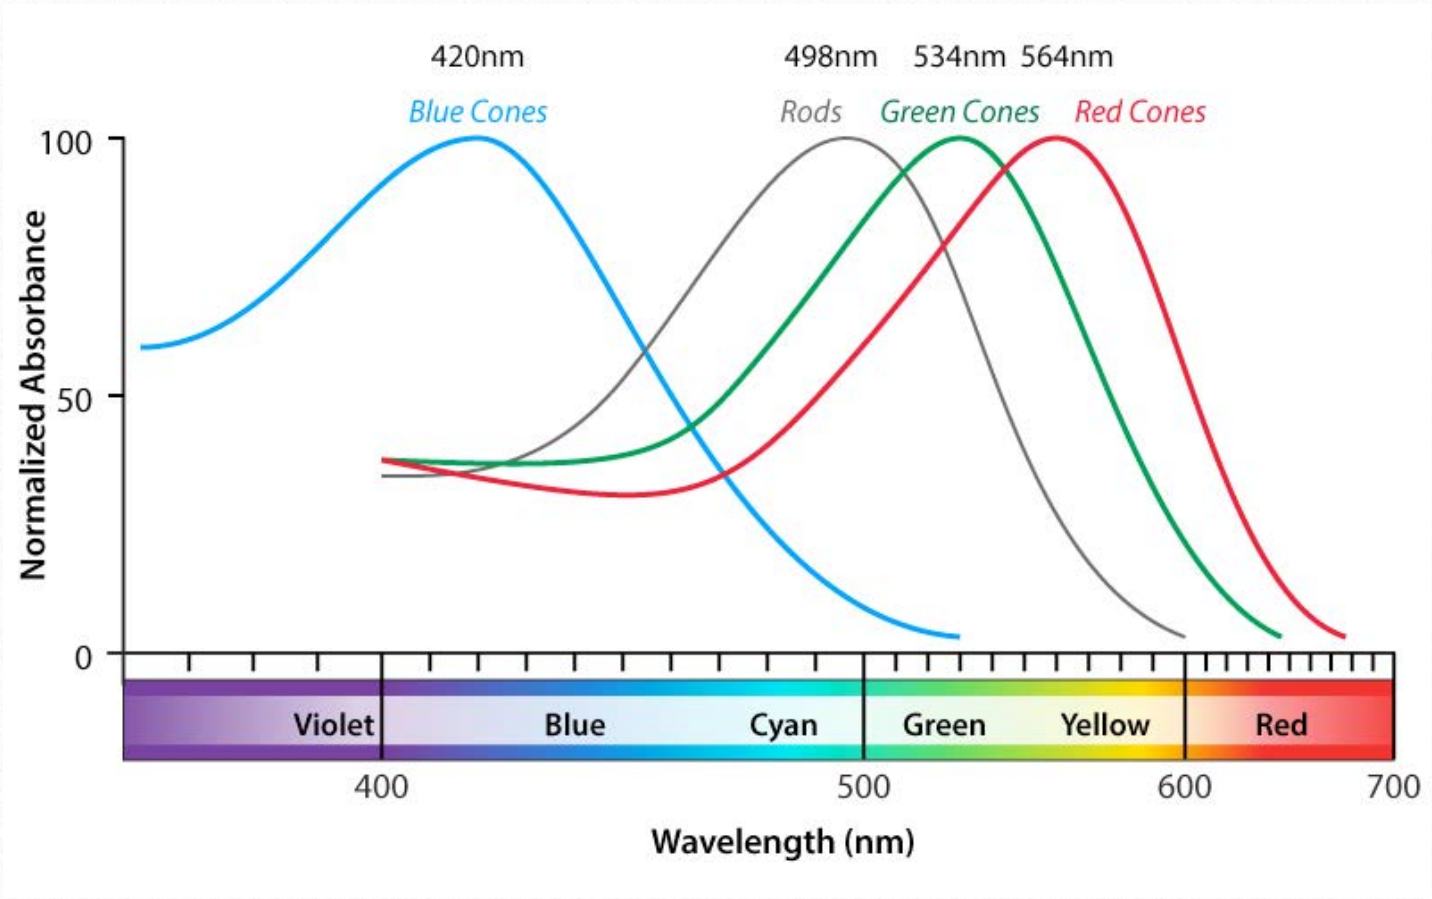

Figure 2.228 - Color sensitivity for cones and rods

Image by Aleia Kim

protein rhodopsin in the membranes of rod and cone cells.

When exposed to light of a particular wavelength, the "tail" of the retinal molecule will flip back and forth from *cis* to *trans* at the double bond at position 11 of the molecule. When this happens, a nerve signal is generated that signals the brain of exposure to light. Slightly different forms of rhodopsin have different maximum absorption maxima allowing the brain to perceive red, green and blue specifically and to assemble those into the images we see (Figure 2.228). Cones are the cells responsible for color vision, whereas rods are mostly involved in light detection in low light circumstances.

Deficiency and surplus

Deficiency of vitamin A is common in developing countries and was inspiration for the design and synthesis of the genetically-modified golden rice, which is used as a source of vitamin A to help prevent blindness in children. Overdose of vitamin A, called hypervitaminosis A is dangerous and can be fatal. Excess vitamin A is also suspected to be linked to osteoporosis. In smokers, excess vitamin A is linked to an increased rate of lung cancer, but non-smokers have a reduced rate.

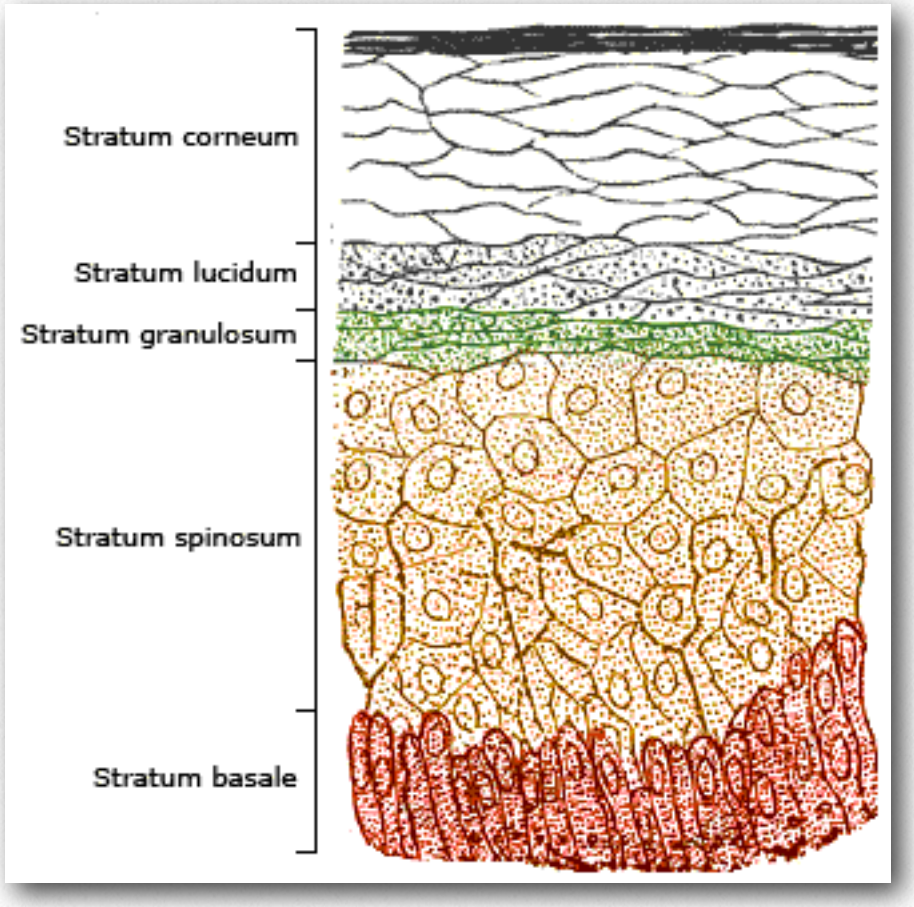

Figure 2.230 - Layers of the skin. Outside is at top.

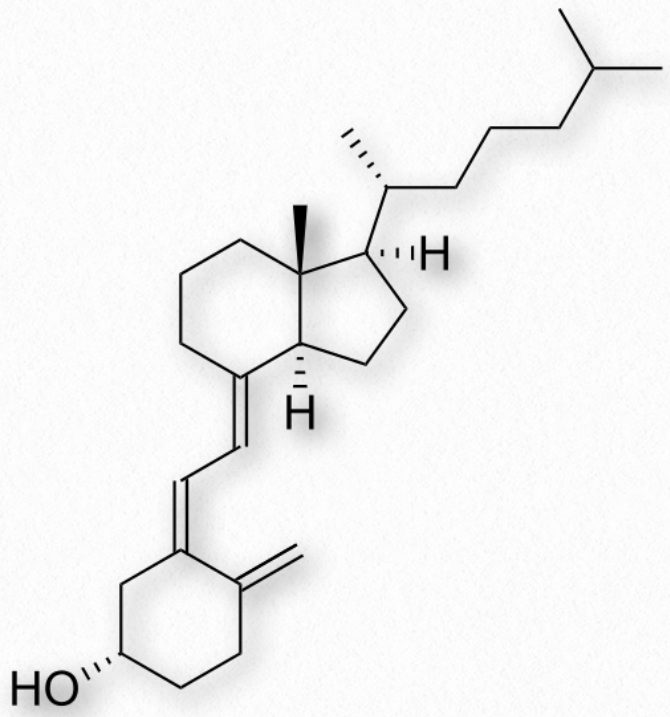

Figure 2.229 - Cholecalciferol - Vitamin D_3

Vitamin D

The active form of vitamin D plays important roles in the intestinal absorption of calcium and phosphate and thus in healthy bones. Technically, vitamin D isn't even a vitamin, as it is a compound made by the

body. Rather, it behaves more like a hormone.

Derived from ultimately from cholesterol, vitamin D can be made in a reaction catalyzed by ultraviolet light. In the reaction, the intermediate 7-dehydrocholesterol is converted to cholecalciferol (vitamin D_3) by the uv light (Figure 2.229). The reaction occurs most readily in the bottom two layers of the skin shown in Figure 2.230.

Forms of vitamin D

Five different compounds are referred to as vitamin D. They are

Vitamin D_1 - A mixture of ergocalciferol and lumisterol
Vitamin D_2 - Ergocalciferol
Vitamin D_3 - Cholecalciferol
Vitamin D_4 - 22-Dihydroergocalciferol
Vitamin D_5 - Sitocalciferol

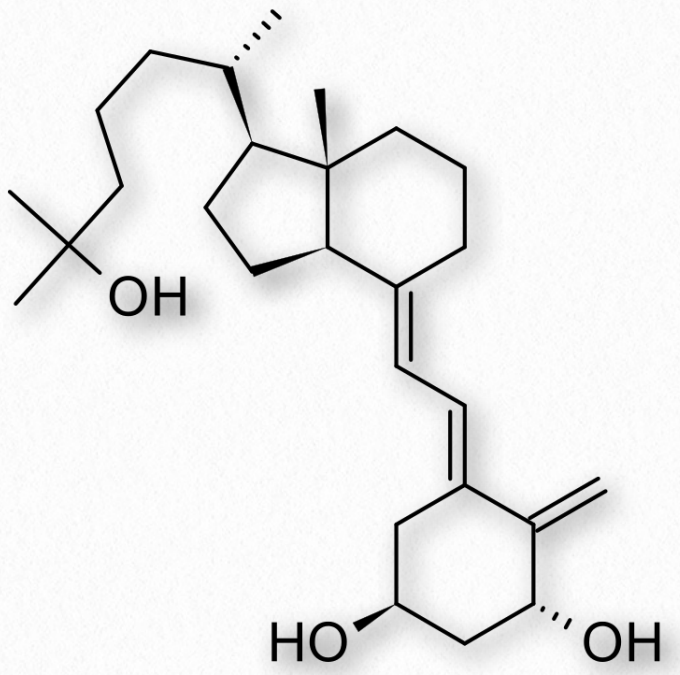

Figure 2.231 - Calcitriol - Active form of vitamin D

Vitamin D_3 is the most common form used in vitamin supplements and it and vitamin D_2 are commonly obtained in the diet, as well. The active form of vitamin D, calcitriol (Figure 2.231), is made in the body in controlled amounts. This proceeds through two steps from cholecalciferol. First, a hydroxylation in the liver produces calcidiol and a second hydroxylation in the kidney produces calcitriol. Monocyte macrophages can also synthesize vitamin D and they use is as a cytokine to stimulate the innate immune system.

Mechanism of action

Calcitriol moves in the body bound to a vitamin D binding protein, which delivers it to target organs. Calcitriol inside of cells acts by binding a vitamin D receptor (VDR), which results in most of the vitamin's physiological effects. After binding calcitriol, the VDR migrates to the nucleus where it acts as a transcription factor to control levels of expression of calcium transport proteins (for example) in the intestine. Most tissues respond to VDR bound to calcitriol and the result is moderation of calcium and phosphate levels in cells.

Deficiency/excess

Deficiency of vitamin D is a cause of the disease known as rickets, which is characterized

by soft, weak bones and most commonly is found in children. It is not common in the developed world, but elsewhere is of increasing concern.

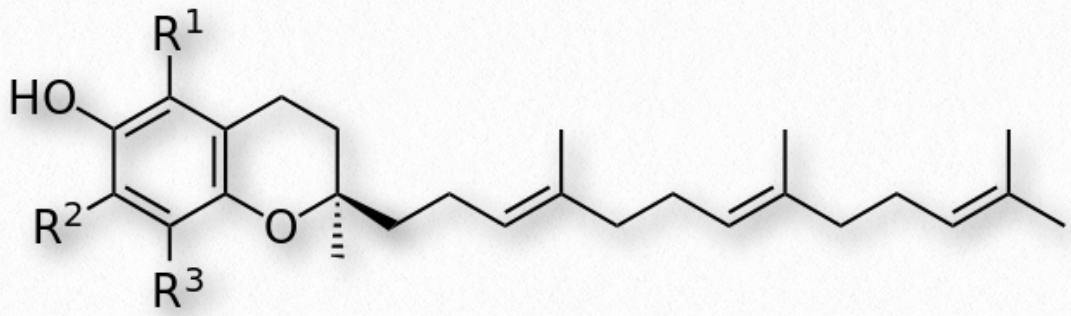

Figure 2.233 - Structure of tocotrienols

Excess of vitamin D is rare, but has toxic effects, including hypercalcemia, which results in painful calcium deposits in major organs. Indications of vitamin D toxicity are increased urination and thirst. Vitamin D toxicity can lead to mental retardation and many other serious health problems.

Vitamin E

Vitamin E comprises a group of two compounds (tocopherols and tocotrienols - Figure 2.232) and stereoisomers of each. It is commonly found in plant oils. The compounds act in cells as fat-soluble antioxidants. α-tocopherol (Figure 2.233), the most active form of the vitamin, works 1) through the glutathione peroxidase protective system and 2) in membranes to interrupt lipid peroxidation chain reactions. In both actions, vitamin E reduces levels of reactive oxygen species in cells.

YouTube Lectures by Kevin HERE & HERE

Action

Vitamin E scavenges oxygen radicals (possessing unpaired electrons) by reacting with them to produce a tocopheryl radical. This vitamin E radical can be converted back to its original form by a hydrogen donor. Vitamin C is one such donor. Acting in this way, Vitamin E helps reduce oxidation of easily oxidized compounds in the lipid peroxidation reactions (Figure 2.234).

Vitamin E also can affect enzyme activity. The compound can inhibit action of protein kinase C in smooth muscle and simultaneously activate catalysis of protein phosphatase 2A to remove phosphates, stopping smooth muscle growth.

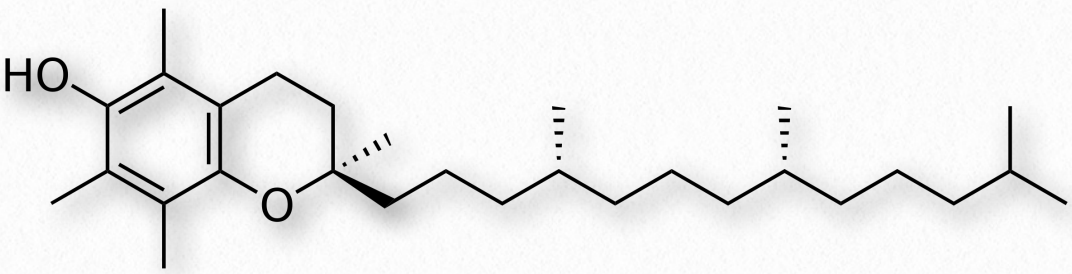

Figure 2.232 α-tocopherol - The most biologically active form of vitamin E

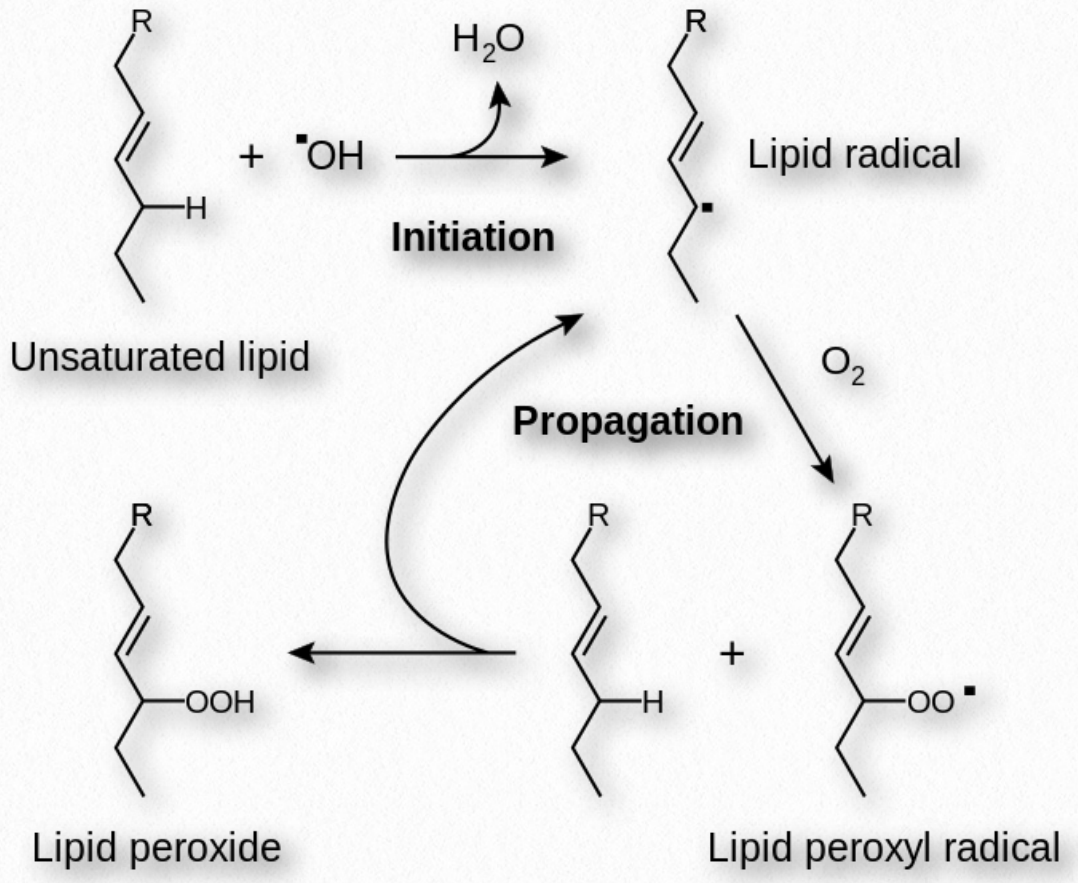

Figure 2.234 - Lipid peroxidation reactions

Deficiency/excess

Deficiency of vitamin E can lead to poor conduction of nerve signals and other issues arising from nerve problems. Low levels of the vitamin may be a factor in low birth weights and premature deliveries. Deficiency, however, is rare, and not usually associated with diet.

Excess Vitamin E reduces vitamin K levels, thus reducing the ability to clot blood. Hypervitaminosis of vitamin E in conjunction with aspirin can be life threatening. At lower levels, vitamin E may serve a preventative role with respect to atherosclerosis by reducing oxidation of LDLs, a step in plaque formation.

Vitamin K

Like the other fat-soluble vitamins, Vitamin K comes in multiple forms (Figure 2.235) and is stored in fat tissue in the body. There are two primary forms of the vitamin - K_1 and K_2 and the latter has multiple sub-forms . Vitamins K_3, K_4, and K_5 are

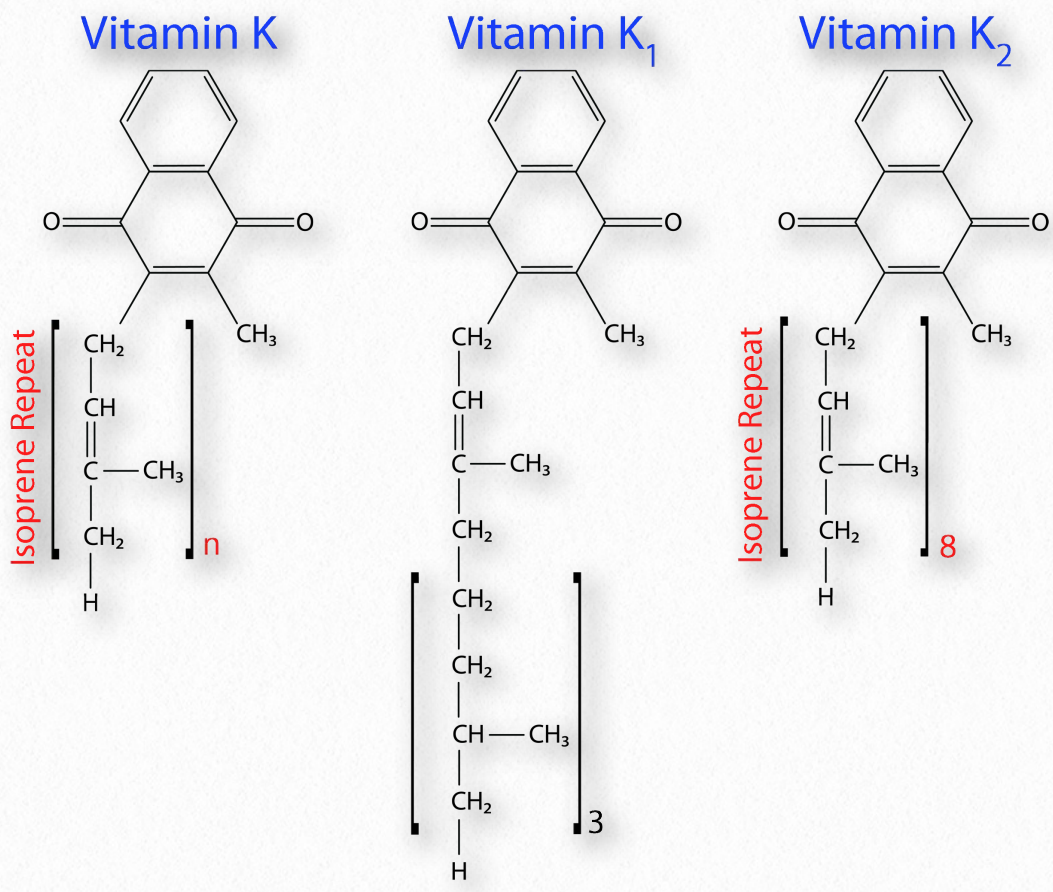

Figure 2.235 - Forms of vitamin K

Image by Pehr Jacobson

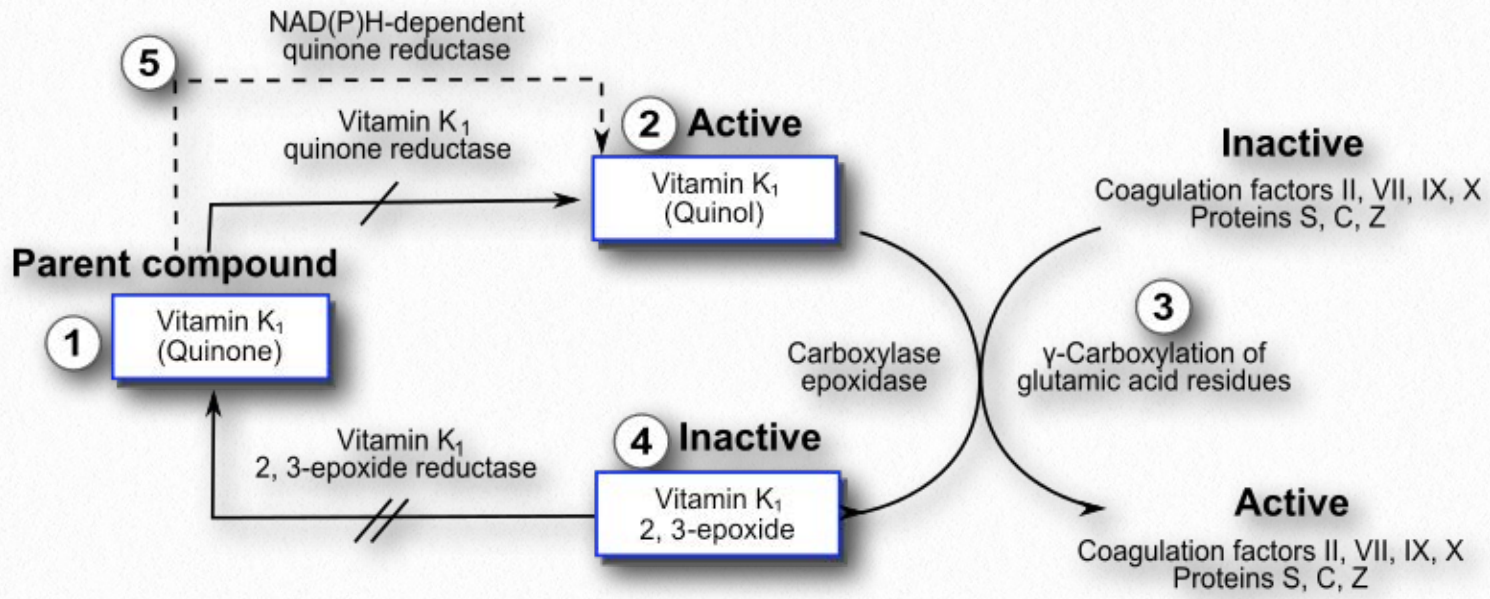

Figure 2.236 - Recycling of vitamin K

Wikipedia

made synthetically, not biologically.

Action

Vitamin K is used as a co-factor for enzymes that add carboxyl groups to glutamate side chains of proteins to increase their affinity for calcium. Sixteen such proteins are known in humans. They include proteins involved in blood clotting (prothrombin (called Factor II), Factors VII, IX, and X), bone metabolism (osteocalcin, also called bone Gla protein (BGP), matrix Gla protein (MGP), and periostin) and others.

Modification of prothrombin is an important step in the process of blood clotting (see HERE). Reduced levels of vitamin K result in less blood clotting, a phenomenon sometimes referred to as blood thinning. Drugs that block recycling of vitamin K (Figure 2.236) by inhibiting the vitamin K epoxide reductase, produce lower levels of the vitamin and are employed in treatments for people prone to excessive clotting. Warfarin (coumadin) is one such compound that acts in this way and is used therapeutically. Individuals respond to the drug differentially, requiring them to periodically be tested for levels of clotting they possess, lest too much or too little occur.

Sources

Vitamin K_1 is a stereoisomer of the plant photosystem I electron receptor known as phylloquinone and is found abundantly in green, leafy vegetables. Phylloquinone is one source of vitamin K, but the compound binds tightly to thylakoid membranes and tends to have low bioavailability. Vitamin K_2 is produced by microbes in the gut and is a primary source of the vitamin. Infants in the first few days before they establish their gut flora and

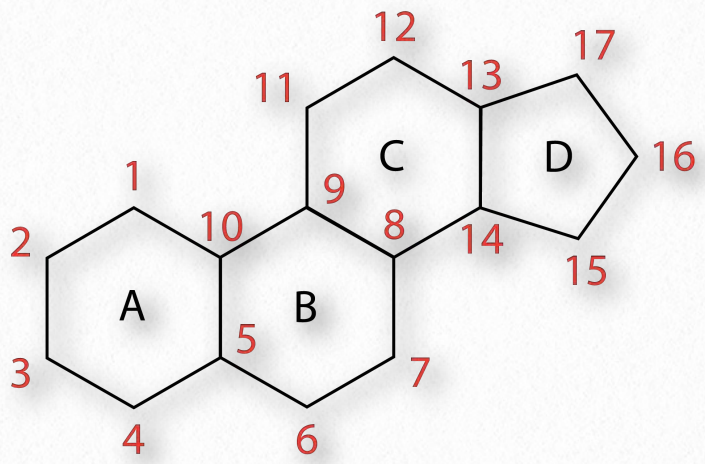

Figure 2.237 - Steroid numbering scheme

Image by Pehr Jacobson

people taking broad spectrum antibiotics may have reduced levels, as a result. Dietary deficiency is rare in the absence of damage to the small bowel. Others at risk of deficiency include people with chronic kidney disease and anyone suffering from a vitamin D deficiency. Deficiencies produce symptoms of easy bruising, heavy menstrual bleeding, anemia, and nosebleeds.

Steroids

Steroids, such as cholesterol are found in membranes and act as signaling hormones in traveling through the body.

Steroid hormones are all made from cholesterol and are grouped into five categories - mineralocorticoids (21 carbons), glucocorticoids (21 carbons), progestagens (21 carbons), androgens (19 carbons), and estrogens (18 carbons).

Mineralocorticoids

Mineralocorticoids are steroid hormones that influence water and electrolyte balances. Aldosterone (Figure 2.238) is the primary mineralocorticoid hormone, though other steroid hormones (including progesterone) have some functions like it. Aldosterone stimulates kidneys to reabsorb sodium, secrete potassium, and passively reabsorb water. These actions have the effect of increasing blood pressure and blood volume. Mineralocorticoids are produced by the zona glomerulosa of the cortex of the adrenal gland.

Glucocorticoids

Glucocorticoids (GCs) bind to glucocorticoid receptors found in almost every vertebrate animal cell and act in a feedback mechanism in the immune system to reduce its activity. GCs are used to treat diseases associated with overactive immune systems. These include allergies, asthma, and autoimmune dis-

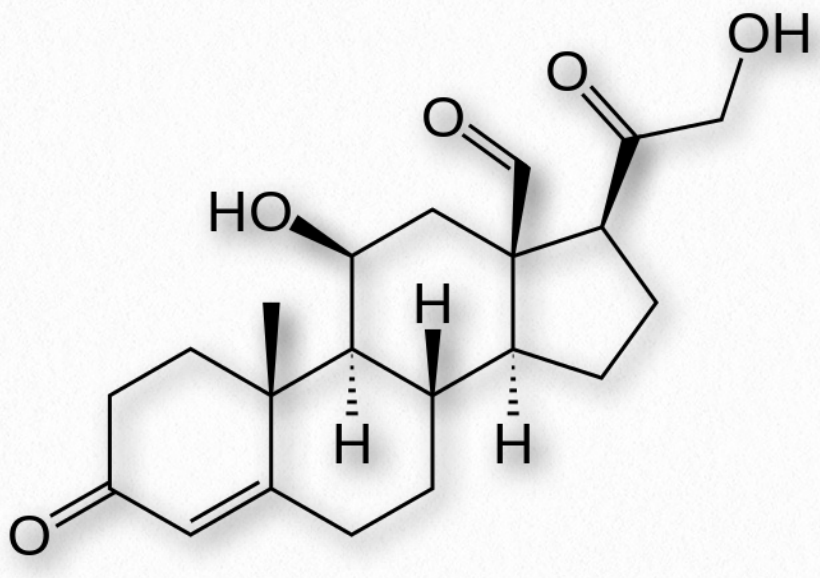

Figure 2.238 - Aldosterone - A mineralocorticoid

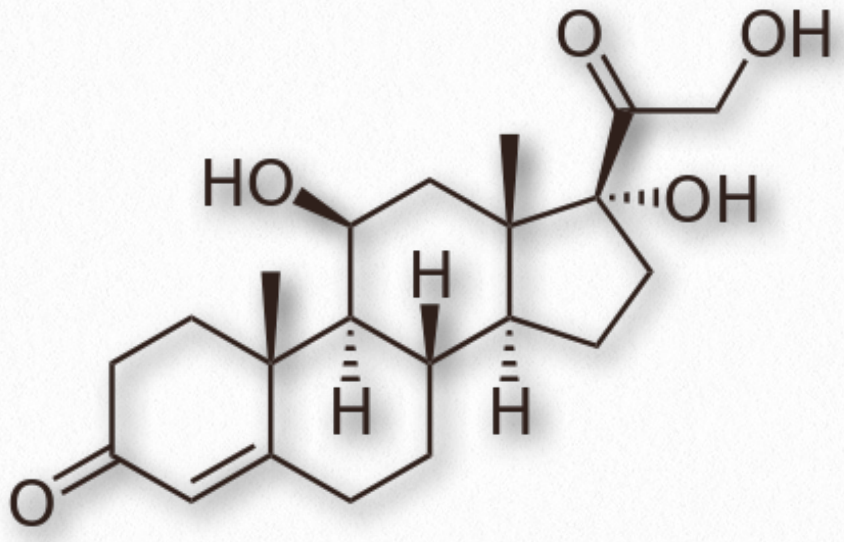

Figure 2.239 - Cortisol - A glucocorticoid

eases. Cortisol (Figure 2.239) is an important glucocorticoid with cardiovascular, metabolic, and immunologic functions. The synthetic glucocorticoid known as dexamethasone has medical applications for treating rheumatoid arthritis, bronchospasms (in asthma), and inflammation due to its increased potency (25-fold) compared to cortisol. Glucocorticoids are produced primarily in the zona fasciculata of the adrenal cortex.

Progestagens

Progestagens (also called gestagens) are steroid hormones that work to activate the progesterone receptor upon binding to it. Synthetic progestagens are referred to as progestins. The most common progestagen is progesterone (also called P4 - Figure 2.240) and it has functions in maintaining pregnancy. Progesterone is produced primarily in the diestrus phase of the estrous cycle by the corpus luteum of mammalian ovaries. In pregnancy, the placenta takes over most progesterone production.

Androgens

Androgens are steroid hormones that act by binding androgen receptors to stimulate development and maintenance of male characteristics in vertebrates. Androgens are precursors of estrogens (see below). The primary androgen is testosterone (Figure 2.241). Other important androgens include dihydrotestosterone (stimulates differentiation of penis, scrotum, and prostate in embryo) and androstenedione (common precursor of male and female hormones).

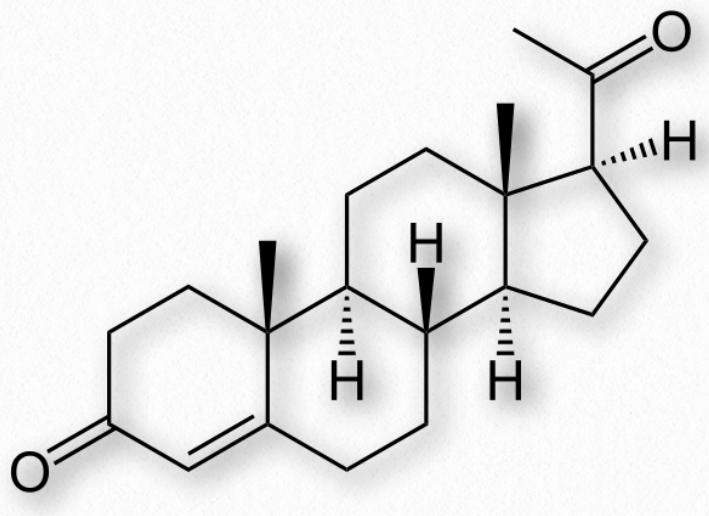

Figure 2.240 Progesterone - A progestagen

Estrogens

The estrogen steroid hormones are a class of compounds with important roles in menstrual and estrous cycles. They are the most important female sex hormones. Estrogens act by

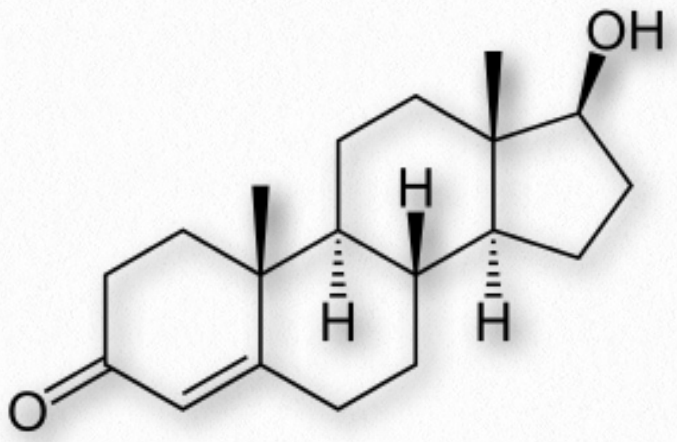

Figure 2.241 - Testosterone - An androgen

activating estrogen receptors inside of cells. These receptors, in turn, affect expression of many genes. The major estrogens in women include estrone (E_1), estradiol (E_2 - Figure 2.242), and estriol (E_3). In the reproductive years, estradiol predominates. During pregnancy, estriol predominates and during menopause, estrone is the major estrogen.

Estrogens are made from the androgen hormones testosterone and androstenedione in a reaction catalyzed by the enzyme known as aromatase. Inhibition of this enzyme with aromatase inhibitors, such as exemestane, is a strategy for stopping estrogen production. This may be part of a chemotherapeutic treatment when estrogen-responsive tumors are present.

YouTube Lectures by Kevin HERE & HERE

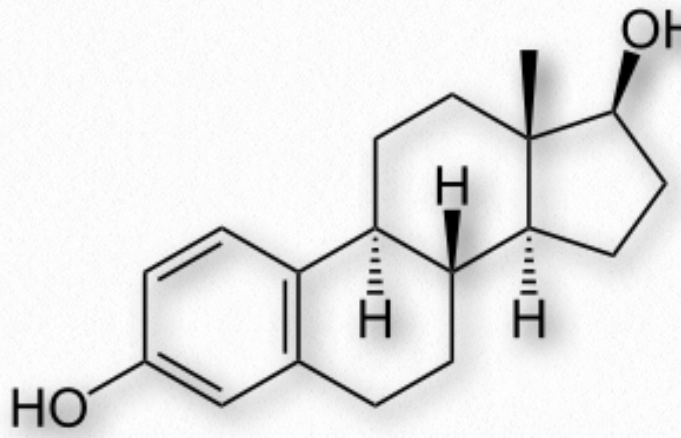

Figure 2.242 - Estradiol - An estrogen

Cannabinoids

Cannabinoids are a group of chemicals that bind to and have effects on brain receptors (cannabinoid receptors), repressing neurotransmitter release. Classes of these compounds include endocannabinoids (made in the body), phytocannabinoids (made in plants, such as marijuana), and synthetic cannabinoids (man-made).

Endocannabinoids are natural molecules derived from arachidonic acid. Cannabinoid receptors are very abundant, comprising the largest number of G-protein-

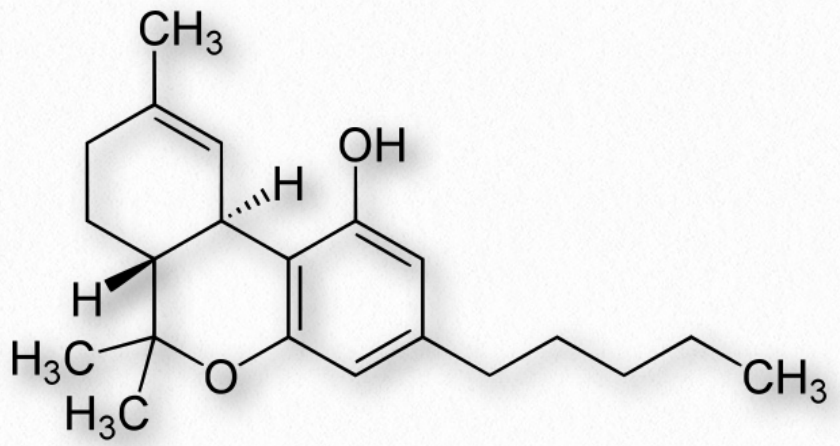

Figure 2.243 - Tetrahydrocannabinol - Active ingredient in marijuana

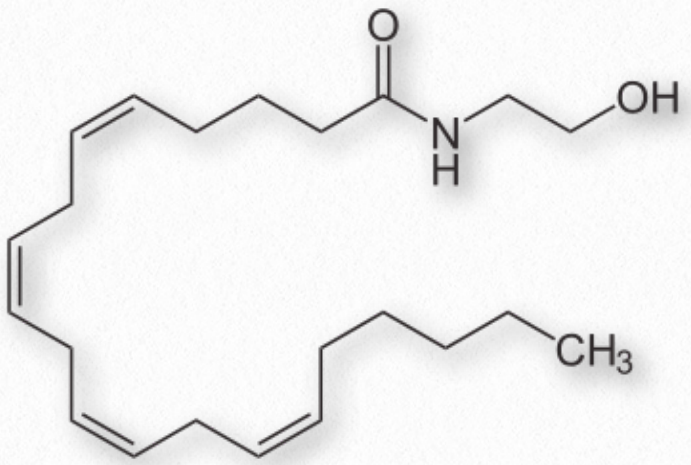

Figure 2.244 - Anandamide - An endocannabinoid

coupled receptors found in brain. The best known phytocannabinoid is Δ-9-tetrahydrocannabinol (THC), the primary psychoactive ingredient (of the 85 cannabinoids) of marijuana (Figure 2.243).

Anandamide

Anandamide (N-arachidonoylethanolamine - Figure 2.244) is an endocannabinoid neurotransmitter derived from arachidonic acid. It exerts its actions primarily through the CB1 and CB2 cannabinoid receptors, the same ones bound by the active ingredient in marijuana, Δ9-tetrahydrocannabinol. Anandamide has roles in stimulating eating/appetite and affecting motivation and pleasure. It has been proposed to play a role in "runners high," an analgesic effect experienced from exertion, especially among runners. Anandamide appears to impair memory function in rats.

Anandamide has been found in chocolate and two compounds that mimic its effects (N-oleoylethanolamine and N-linoleoylethanolamine) are present as well. The enzyme fatty acid amide hydrolase (FAAH) breaks down anandamide into free arachidonic acid and ethanolamine.

Lipoxins

Lipoxins (Figure 2.245) are eicosanoid compounds involved in modulating immune responses and they have anti-inflammatory effects. When lipoxins appear in inflammation it begins the end of the process. Lipoxins act to attract macrophages to apoptotic cells at the site of inflammation and they are engulfed. Lipoxins further act to start the resolution phase of the inflammation process.

At least one lipoxin (aspirin-triggered LX4) has its synthesis stimulated by aspirin. This occurs as a byproduct of aspirin's acetylation of COX-2. When this occurs, the enzyme's catalytic activity is re-directed to synthesis of 15R-hydroxyeicosatetraenoic acid (HETE) instead of prostaglandins.

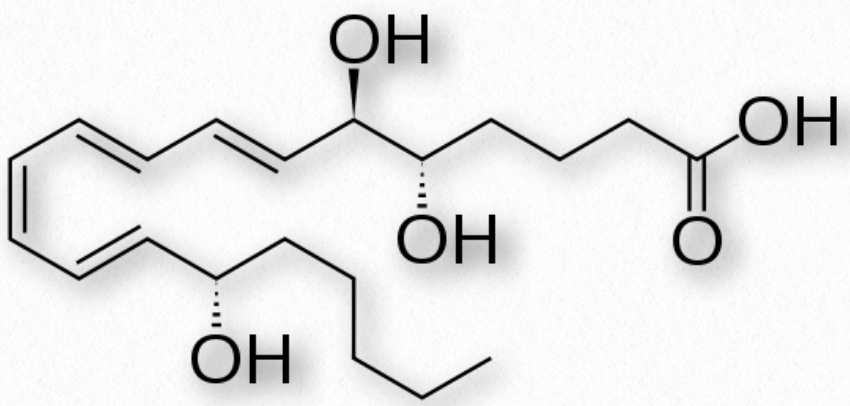

Figure 2.245 - Lipoxin A4

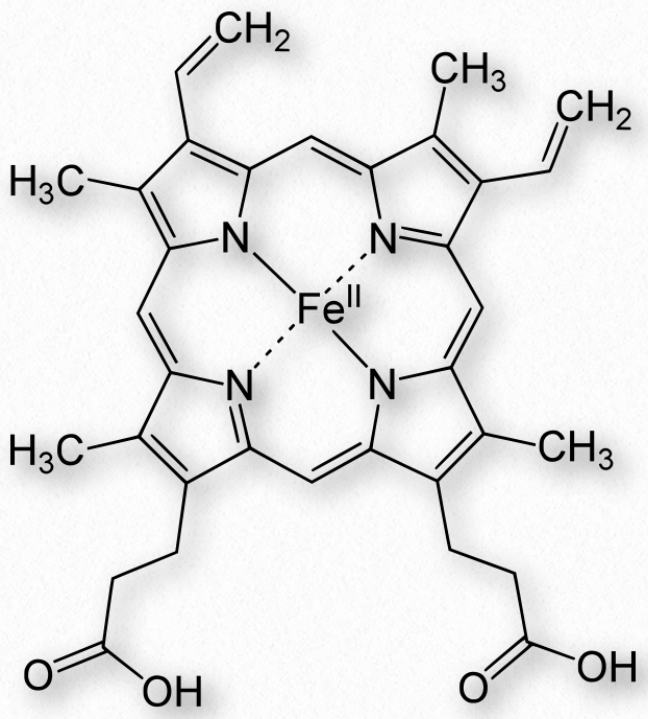

Figure 2.246 - Structure of heme B

15R-HETE is a procursor of 15-epimer lipoxins, including aspirin-triggered LX4.

Heme

Heme groups are a collection of protein/enzyme cofactors containing a large heterocyclic aromatic ring known as a porphyrin ring with a ferrous (Fe^{++}) ion in the middle. An example porphyrin ring with an iron (found in Heme B of hemoglobin), is shown in Figure 2.246. When contained in a protein, these are known collectively as hemoproteins (Figure 2.247).

Heme, of course, is a primary component of hemoglobin, but it is also found in other proteins, such as myoglobin, cytochromes, and the enzymes catalase and succinate dehydrogenase. Hemoproteins function in oxygen transport, catalysis, and electron transport. Heme is synthesized in the liver and bone marrow in a pathway that is conserved across a wide range of biology.

Porphobilinogen

Porphobilinogen (Figure 2.248) is a pyrrole molecule involved in porphyrin metabolism. It is produced from aminolevulinate by action of the enzyme known as ALA dehydratase. Porphobilinogen is acted upon by the enzyme porphobilinogen deaminase. Deficiency of the latter enzyme (and others in porphyrin metabolism) can result in a condition known as porphyria, which results in accumulation of porphobilinogen in the cytoplasm of cells. The disease can manifest itself with acute abdominal pain and numerous psychiatric issues. Both Vincent van Gogh and King

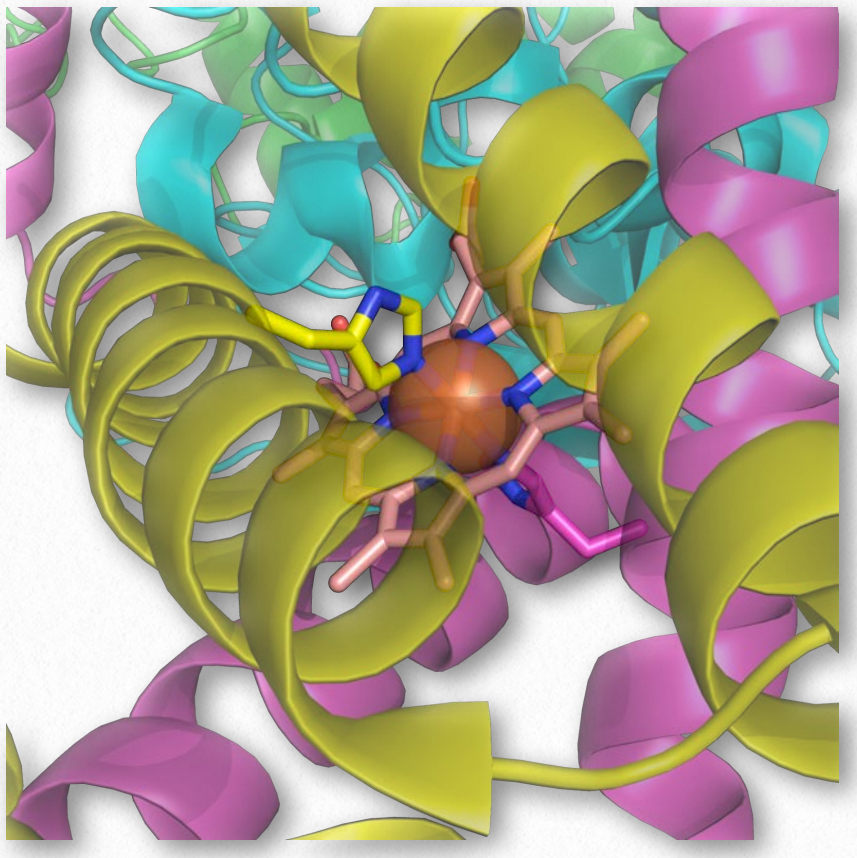

Figure 2.247 - Heme embedded in the succinate dehydrogenase hemoprotein
Wikipedia

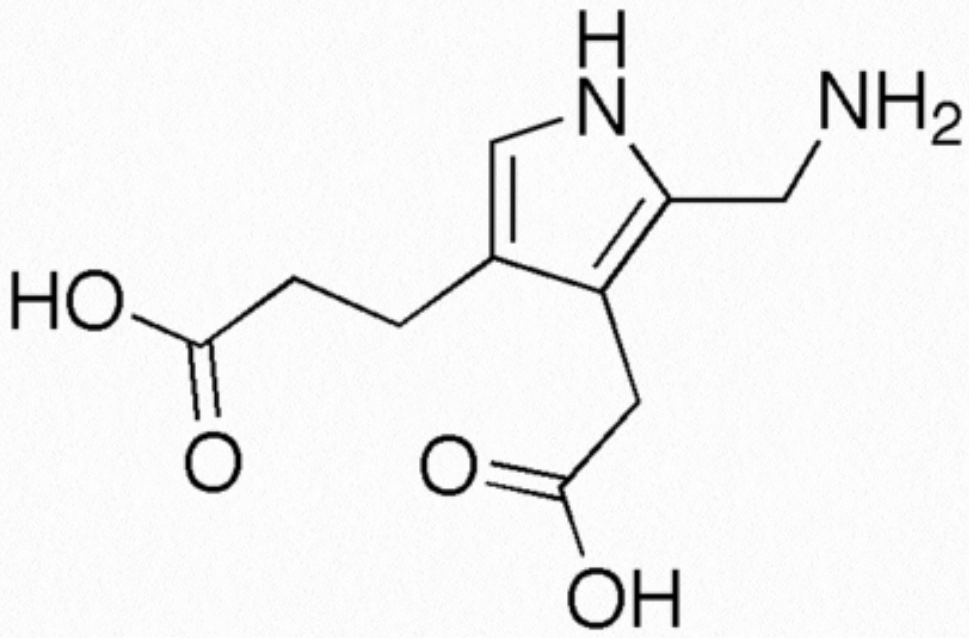

Figure 2.248 - Porphobilinogen

George III are suspected to have suffered from porphyria, perhaps causing the "madness of King George III." Porphyria is also considered by some to be the impetus for the legend of vampires seeking blood from victims, since the color of the skin in non-acute forms of the disease can be miscolored, leading some to perceive that as a deficiency of hemoglobin and hence the "thirst" for blood imagined for vampires.

Dolichols

Dolichol is a name for a group of non-polar molecules made by combining isoprene units together. Phosphorylated forms of dolichols play central roles in the N-glycosylation of proteins. This process, which occurs in the endoplasmic reticulum of eukaryotic cells, begins with a membrane-embedded dolichol pyrophosphate (Figure 2.249) to which an oligosaccharide is attached (also see HERE). This oligosaccharide contains three molecules of glucose, nine molecules of mannose and two molecules of N-acetylglucosamine.

Interestingly, the sugars are attached to the dolichol pyrophosphate with the pyrophosphate pointing outwards (away from) the endoplasmic reticulum, but after attachment, the dolichol complex flips so that the sugar portion is situated on the inside of the endoplasmic reticulum. There, the entire sugar complex is transferred to the amide of an asparagine side chain of a target protein.

The only asparagine side chains to which the attachment can be made are in proteins where the sequences Asn-X-Ser or Asn-X-Thr occur. Sugars can be removed/added after the transfer to the protein. Levels of dolichol in the

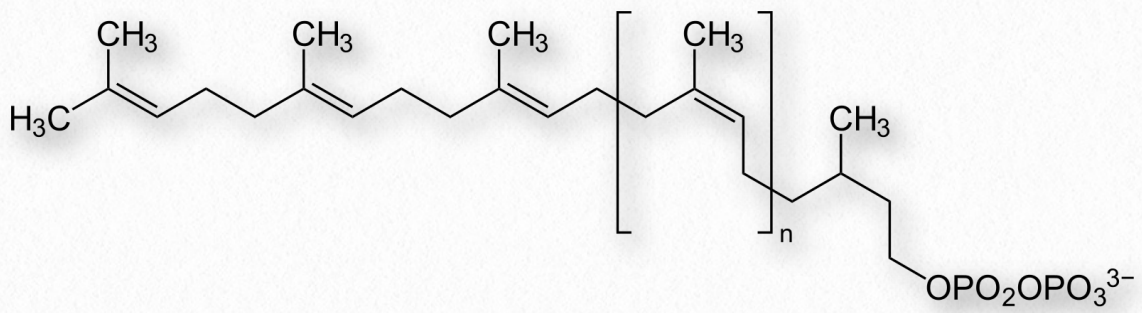

Figure 2.249 - Structure of dolichol pyrophosphate

Figure 2.250 - Pine tree resin - A source of terpenes

Wikipedia

human brain increase with age, but in neurodegenerative diseases, they decrease.

Terpenes

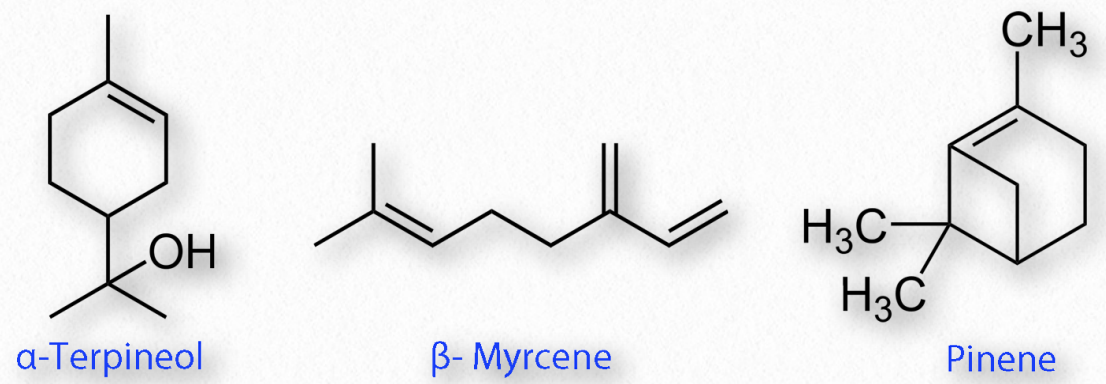
Terpenes are members of a class of nonpolar molecules made from isoprene units. Terpenes are produced primarily by plants and by some insects. Terpenoids are a related group of molecules that contain functional groups lacking in terpenes.

Terpenes have a variety of functions. In plants, they often play a defensive role protecting from insects. The name of terpene comes from turpentine, which has an odor like some of the terpenes. Terpenes are common components of plant resins (think pine) and they are widely used in medicines and as fragrances. Hops, for example, gain some of their distinctive aroma and flavor from terpenes. Not all terpenes, however have significant odor.

YouTube Lectures by Kevin HERE & HERE

Synthesis

Terpenes, like steroids, are synthesized starting with simple building blocks known as isoprenes. There are two of them - dimethylallyl pyrophosphate and the related isopentenyl pyrophosphate and (Figures 2.252 and 2.253) which combine 1-2 units at a time to make higher order structures. Terpene synthesis overlaps and includes steroid synthesis.



α-Terpineol β- Myrcene Pinene

Figure 2.251 - Three monoterpenes

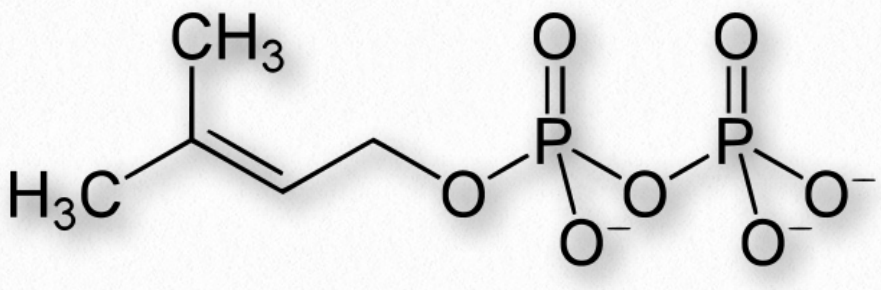


Figure 2.252 - Dimethylallyl pyrophosphate

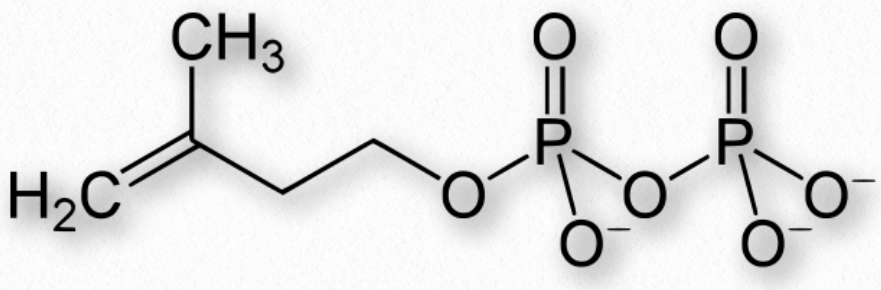

Figure 2.253 - Isopentenyl pyrophosphate

Terpenes and terpenoids are classified according to how many isoprene units they contain. They include hemiterpenes (one unit), monoterpenes (two units), sesquiterpenes (three units), diterpenes (four units), sesterterpenes (five units), triterpenes (six units), sesquarterpenes (seven units), tetraterpenes (eight units), polyterpenes (many units).

Another class of terpene-containing molecules, the norisoterpenoids arise from peroxidase-catalyzed reactions on terpene molecules.

Examples

Common terpenes include monoterpenes of terpineol (lilacs), limonene (citrus), myrcene (hops), linalool (lavender), and pinene (pine). Higher order terpenes include taxadiene (diterpene precursor of taxol), lycopene (tetraterpenes), carotenes (tetraterpenes), and natural rubber (polyterpenes).

Steroid precursors geranyl pyrophosphate (monoterpene derivative), farnesyl pyrophosphate (sesquiterpene derivative), and squalene (triterpene) are all terpenes or derivatives of them. Vitamin A and phytol are derived from diterpenes.

Caffeine

Caffeine is the world's most actively consumed psychoactive drug (Figure 2.255). A methylxanthine alkaloid, caffeine is closely

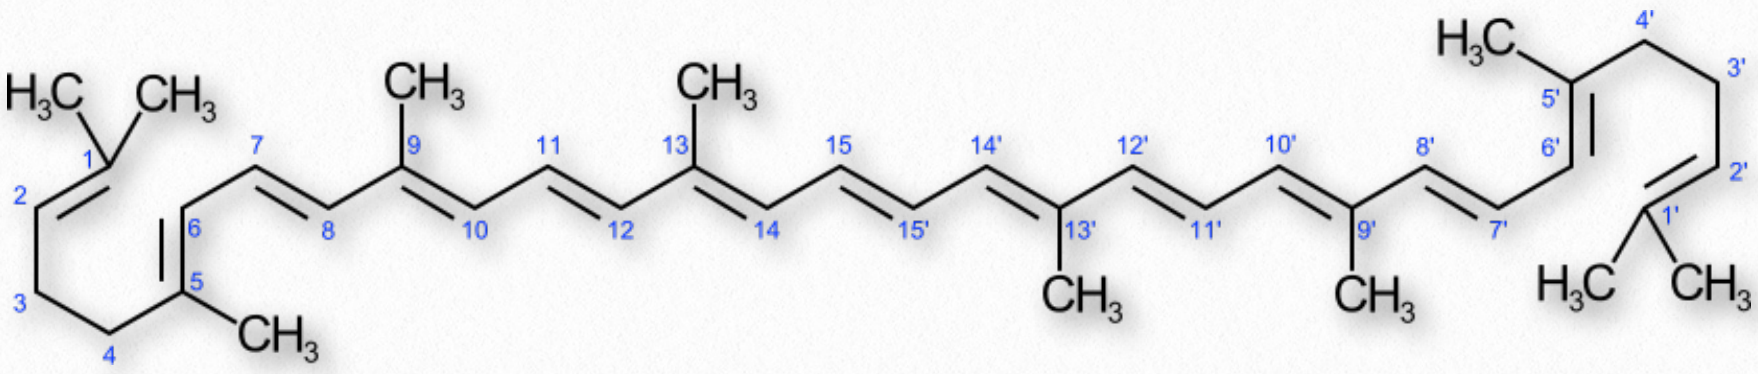

Figure 2.254 - Lycopene - A tetraterpene

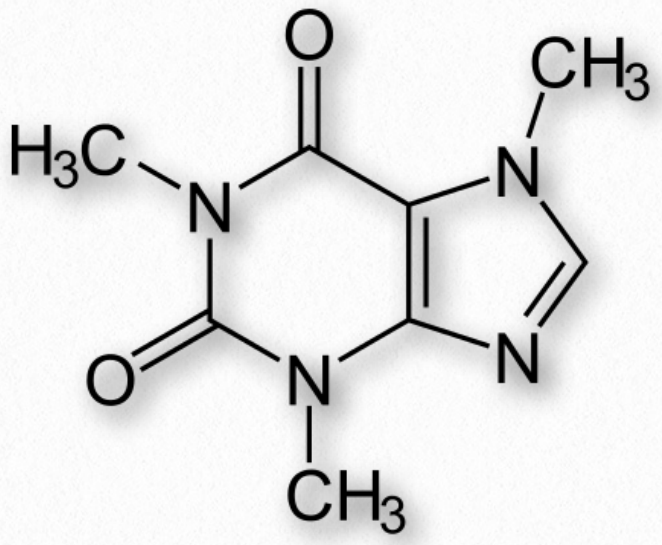

Figure 2.255 - Caffeine

related to adenine and guanine and this is responsible for many effects on the body. Caffeine blocks the binding of adenosine on its receptor and consequently prevents the onset of drowsiness induced by adenosine. Caffeine readily crosses the blood-brain barrier and stimulates release of neurotransmitters. Caffeine stimulates portions of the autonomic nervous system and inhibits the activity of phosphodiesterase. The latter has the result of raising cAMP levels in cells, which activates protein kinase A and activates glycogen breakdown, inhibits TNF-α and leukotriene synthesis, which results in reduction of inflammation and innate immunity.

Caffeine also has effects on the cholinergic system (acetylcholinesterase inhibitor), is an inositol triphosphate receptor 1 antagonist, and is a voltage independent activator of ryanodin receptors (a group of calcium channels found in skeletal muscle, smooth muscle, and heart muscle cells).

The half-life of caffeine in the body varies considerably. In healthy adults, it has a half-life of about 3-7 hours. Nicotine decreases the half-life and contraceptives and pregnancy can double it. The liver metabolizes caffeine, so the health of the liver is a factor in the half-life. CYP1A2 of the cytochrome P450 oxidase enzyme is primarily responsible. Caffeine is a natural pesticide in plants, paralyzing predator bugs.

Lipoprotein complexes and lipid movement in the body

Lipoprotein complexes are combinations of apolipoproteins and lipids bound to them that solubilize fats and other non-polar molecules, such as cholesterol, so they can travel in the bloodstream between various tissues of the body. The apolipoproteins provide the emulsification necessary for this. Lipoprotein complexes are formed in tiny “balls” with the water soluble apolipoproteins on the outside and non-polar lipids, such as fats, cholesteryl esters, and fat soluble vitamins on the inside.

They are categorized by their densities. These include (from highest density to the lowest) high density lipoproteins (HDLs), Low Density Lipoproteins (LDLs), Intermediate Density Lipoproteins (IDLs), Very Low Density Lipoproteins (VLDLs) and the chylomi-

Name	Lipoprotein Complex(es)	Function
ApoA-I	HDL	Promotes Fat Movement to Liver
ApoA-II	HDL	Inhibit LCAT
ApoA-IV	Chylomicrons / HDL	Activate LCAT
AboB-48	Chylomicrons	Cholesterol Transport
AboB-100	VLDL / LDL	Bind LDL Receptor
ApoC-I	VLDL / LDL	Unknown
ApoC-II	All	Activate Lipoprotein Lipase
ApoC-III	All	Inhibit Lipoprotein Lipase
ApoD	HDL	Unknown
ApoE	VLDL / Chylomicrons / HDL	Clearance of Chylomicrons Remnants and VLDLs

Figure 2.256 - Apolipoproteins

crons. These particles are synthesized in the liver and small intestines.

Apolipoproteins

Each lipoprotein complex contain a characteristic set of apolipoproteins, as shown in Figure 2.256. ApoC-II and ApoC-III are notable for their presence in all the lipoprotein complexes and the roles they play in activating (ApoC-II) or inactivating (ApoC-III) lipoprotein lipase. Lipoprotein lipase is a cellular enzyme that catalyzes the breakdown of fat from the complexes. ApoE (see below) is useful for helping the predict the likelihood of the occurrence of Alzheimer's disease in a patient.

Gene editing

ApoB-48 and ApoB-100 are interesting in being coded by the same gene, but a unique mRNA sequence editing event occurs that converts one into the other. ApoB-100 is made in the liver, but ApoB-48 is made in the small intestine. The small intestine contains an enzyme that deaminates the cyti-

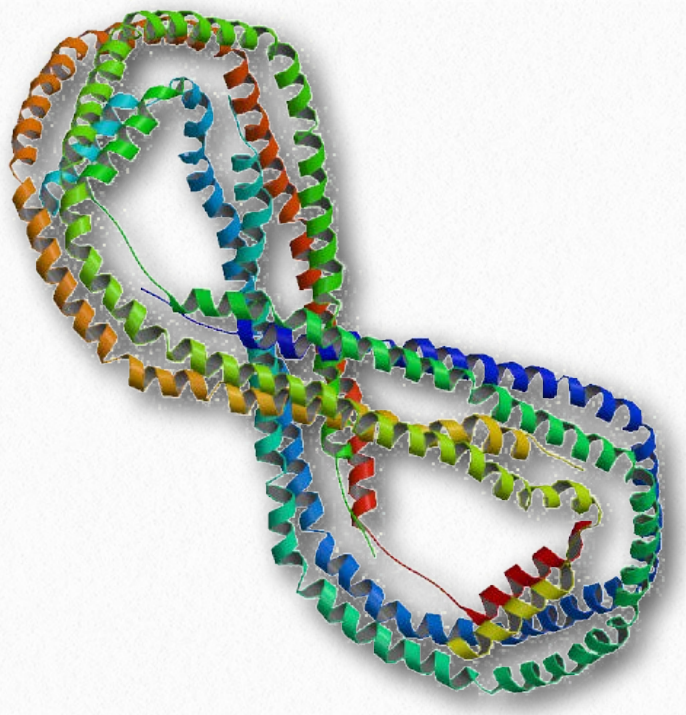

Figure 2.257 - ApoA-I

dine at nucleotide #2153 of the common mRNA. This changes it to a uridine and changes the codon it is in from CAA (codes for glutamine) to UAA (stop codon). The liver does not contain this enzyme and does not make the change in the mRNA. Consequently, a shorter protein is synthesized in the intestine (ApoB-48) than the one that is made in the liver (ApoB-100) using the same gene sequence in the DNA.

Movement

The movement of fats in the body is important because they are not stored in all cells. Only specialized cells called adipocytes store fat. There are three relevant pathways in the body for moving lipids. As described below, they are 1) the exogenous pathway; 2) the endogenous pathway, and 3) the reverse transport pathway.

Exogenous pathway

Dietary fat entering the body from the intestinal system must be transported, as appropriate, to places needing it or storing it. This is the function of the exogenous pathway of lipid movement in the body. All dietary lipids (fats, cholesterol, fat soluble vitamins, and other lipids) are moved by it. In the case of dietary fat, it begins its journey after ingestion first by being solubilized by bile acids in the intestinal tract. After passing through the stomach, pancreatic lipases clip two fatty acids from the fat, leaving a monoacyl glycerol. The fatty acids and monoacyl glycerol are absorbed by intestinal cells (enterocytes) and reassembled back into a fat, and then this is mixed with phospholipids, cholesterol esters, and apolipoprotein B-48 and processed to form chylomicrons (Figures 2.258 & 2.259) in the

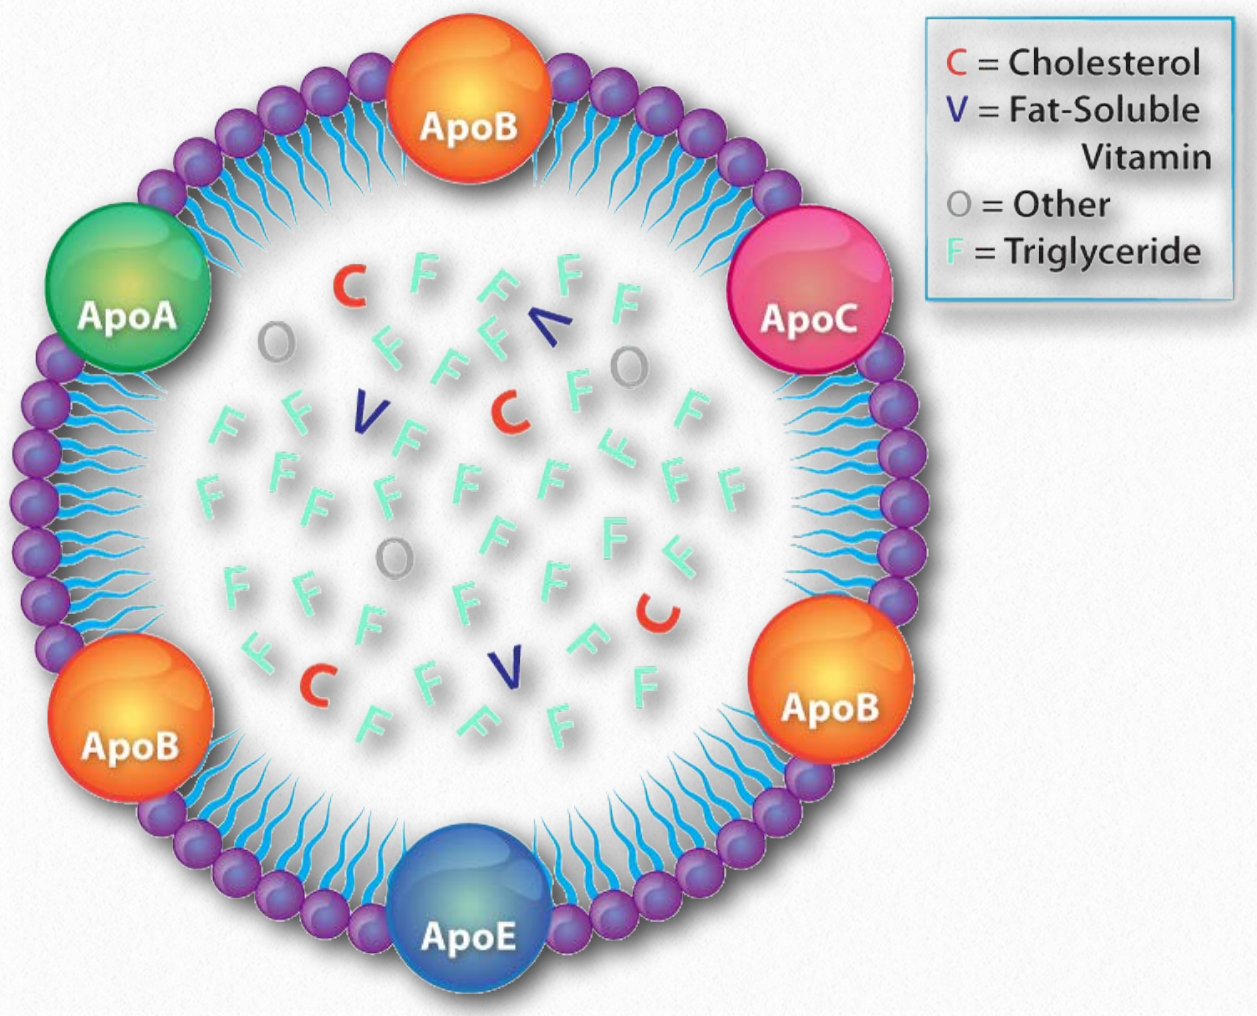

Figure 2.258 - Schematic diagram of a chylomicron

Image by Aleia Kim

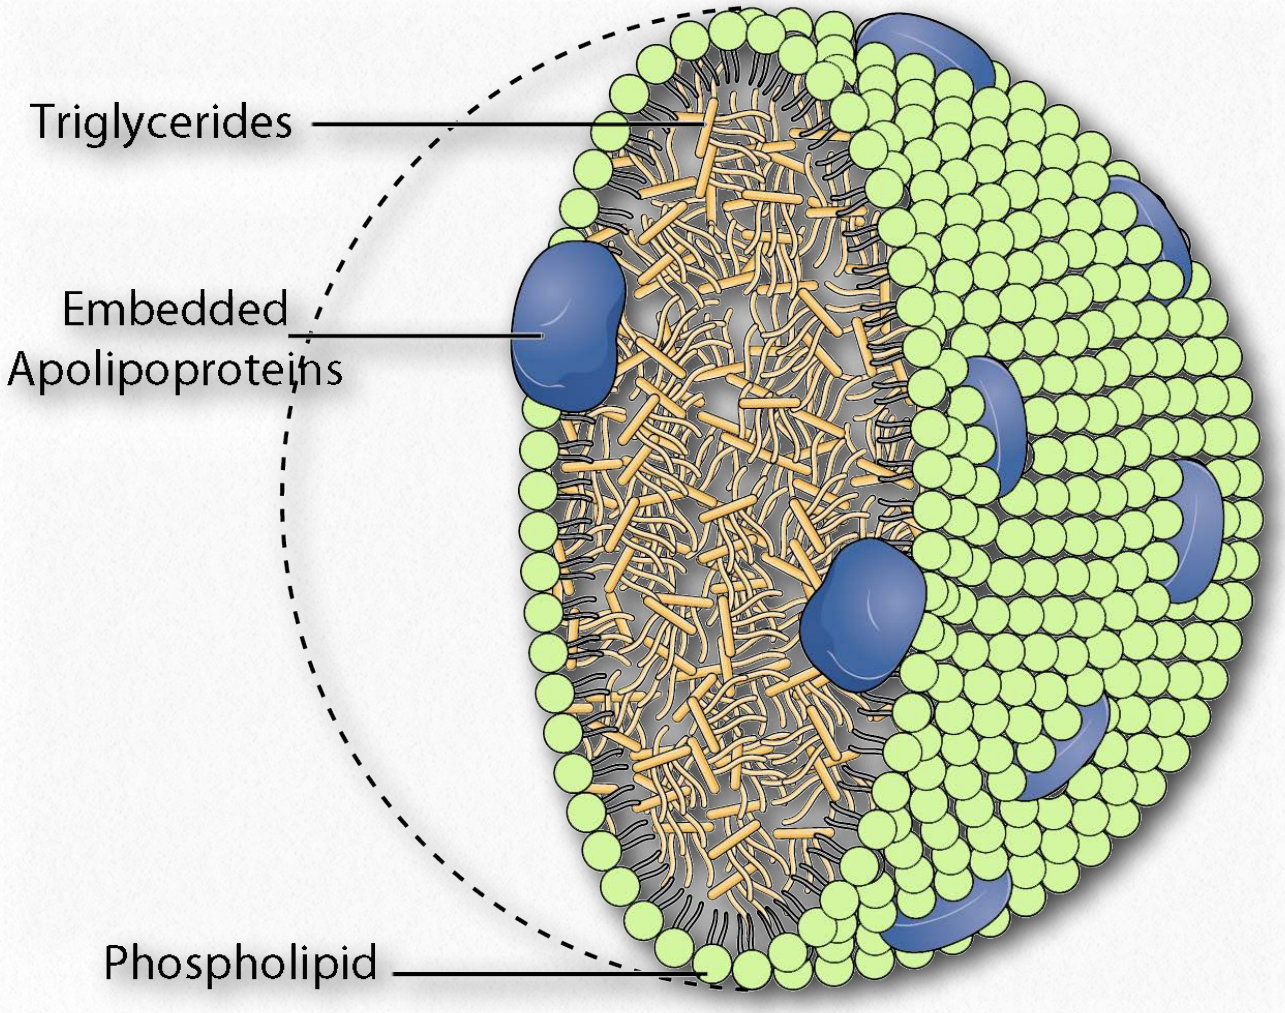

Figure 2.259 - Another perspective of a chylomicron

Wikipedia

Golgi apparatus and smooth endoplasmic reticulum.

Exocytosis

These are exocytosed from the cell into lymph capillaries called lacteals. The chylomicrons pass through the lacteals and enter the bloodstream via the left subclavian vein. Within the bloodstream, lipoprotein lipase breaks down the fats causing the chylomicron to shrink and become what is known as a chylomicron remnant. It retains its cholesterol and other lipid molecules.

The chylomicron remnants travel to the liver where they are absorbed (Figure 2.260).

This is accomplished by receptors in the liver that recognize and bind to the ApoE of the chylomicrons. The bound complexes are then internalized by endocytosis, degraded in the lysosomes, and the cholesterol is disbursed in liver cells.

Endogenous pathway

The liver plays a central role in managing the body's needs for lipids. When lipids are needed by the body or when the capacity of the liver to contain more lipids than is supplied by the diet, the liver packages up fats and cholesteryl esters into Very Low Density Lipoprotein (VLDL) complexes and exports them via the endogenous pathway. VLDL complexes contain ApoB-100, ApoC-I, ApoC-II, ApoC-III, and ApoE apolipoproteins. VLDLs enter the blood and travel to muscles and adipose tissue where lipoprotein lipase is activated by ApoC-II. In the muscle cells, the released fatty acids are taken up and oxidized. By contrast, in the adipoctyes, the fatty acids are taken up and reassembled back into triacylglycerides (fats) and stored in fat droplets. Re-

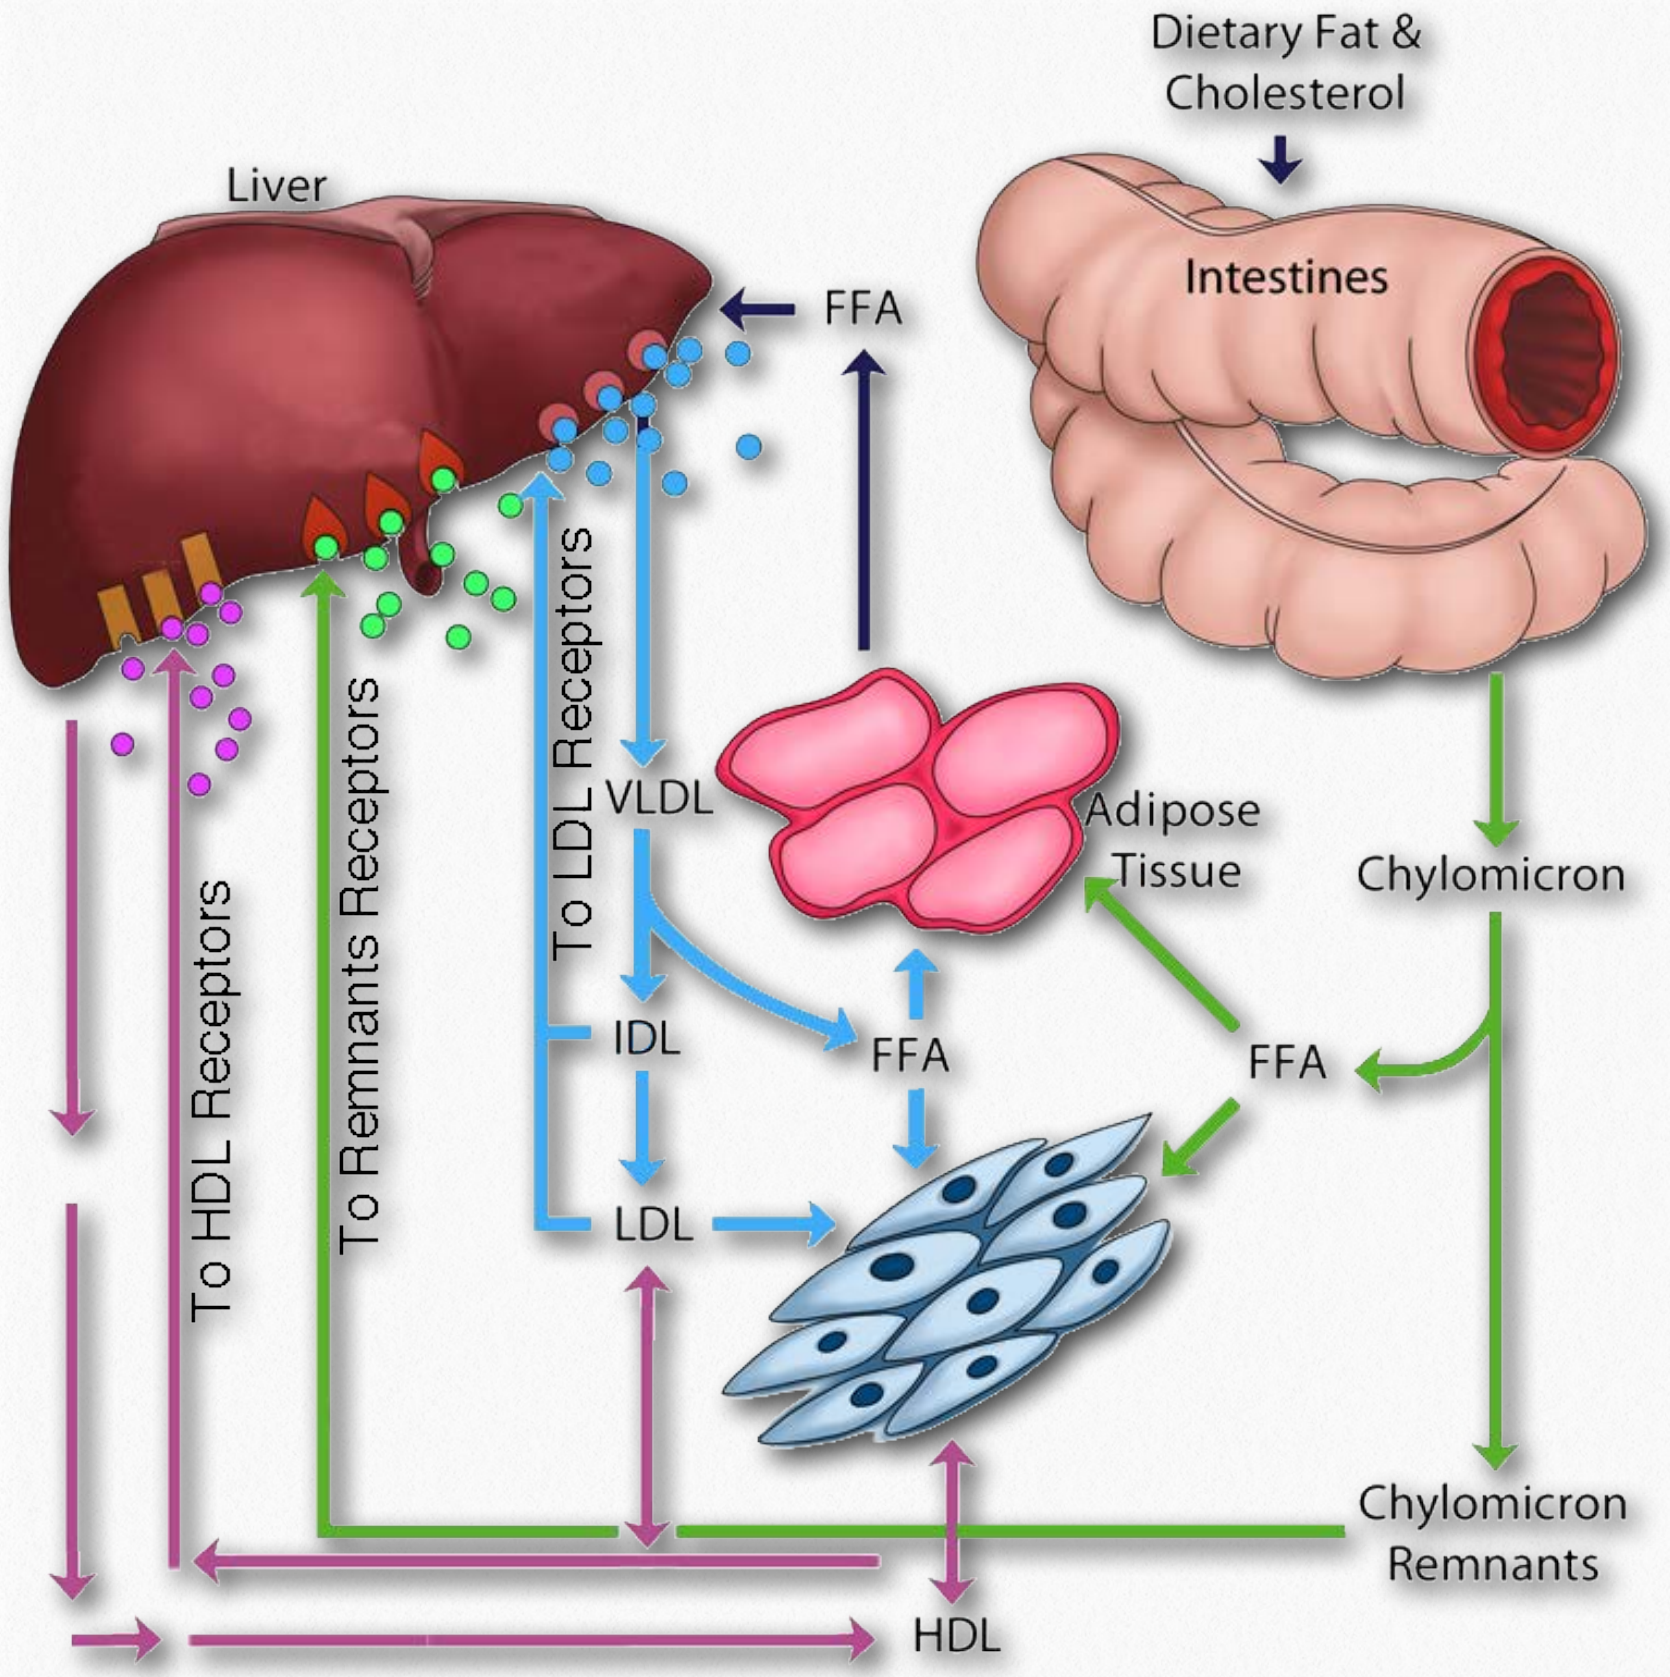

Figure 2.260 - Movement of lipids in the body - Green = exogenous pathway; Blue = endogenous pathway; Purple = reverse transport pathway

Image by Aleia Kim

moval of fat from the VLDLs causes them to shrink, first to Intermediate Density Lipoprotein (IDL) complexes (also called VLDL remnants) and then to Low Density Lipoprotein (LDL) complexes.

YouTube Lectures by Kevin HERE & HERE

Shrinking of VLDLs is accompanied by loss of apolipoproteins so that LDLs are comprised primarily of ApoB-100. This lipoprotein complex is important because cells have receptors for it to bind and internalize it by receptor-mediated endocytosis (Figure 2.261). Up until this point, cholesterol and cholesteryl esters have traveled in chylomicrons, VLDLs, and IDLs as fat has been stripped stripped away. For cholesterol compounds to get into the cell from the lipoprotein complexes, they must be internalized by cells and that is the job of receptor-mediated endocytosis.

Reverse transport pathway

Another important consideration of the movement of lipids in the body is the reverse transport pathway (Figure 2.260). It is also called the reverse cholesterol transport pathway, since cholesterol is the primary molecule involved. This pathway involves the last class of lipoprotein complexes known as the High Density Lipoproteins (HDLs). In contrast to the LDLs, which are commonly referred to as “bad cholesterol” (see below also), the HDLs are known as “good cholesterol.”

HDLs are synthesized in the liver and small intestine. They contain little or no lipid when made (called depleted HDLs), but serve the role of “scavenger” for cholesterol in the blood and from remnants of other (damaged) lipoprotein complexes in the blood. To perform its task, HDLs carry the enzyme known as lecithin-cholesterol acyl transferase (LCAT), which they use to form cholesteryl esters using fatty acids from lecithin (phosphatidylcholine) and then they internalize them.

The cholesterol used for this purpose comes from the bloodstream, from macrophages, and from foam cells (macrophage-LDL complexes - Figure 2.262). Addition of cholesteryl esters causes the HDL to swell and

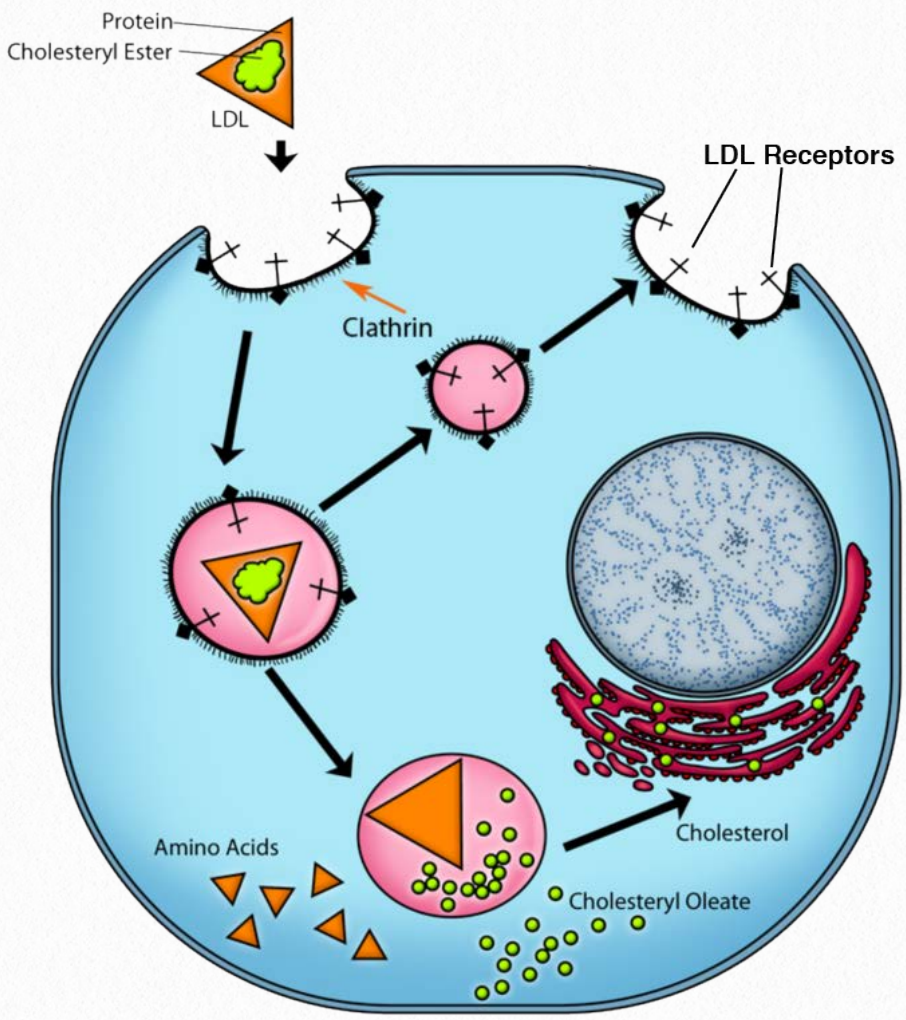

Figure 2.261 - The process of receptor-mediated endocytosis

Image by Aleia Kim

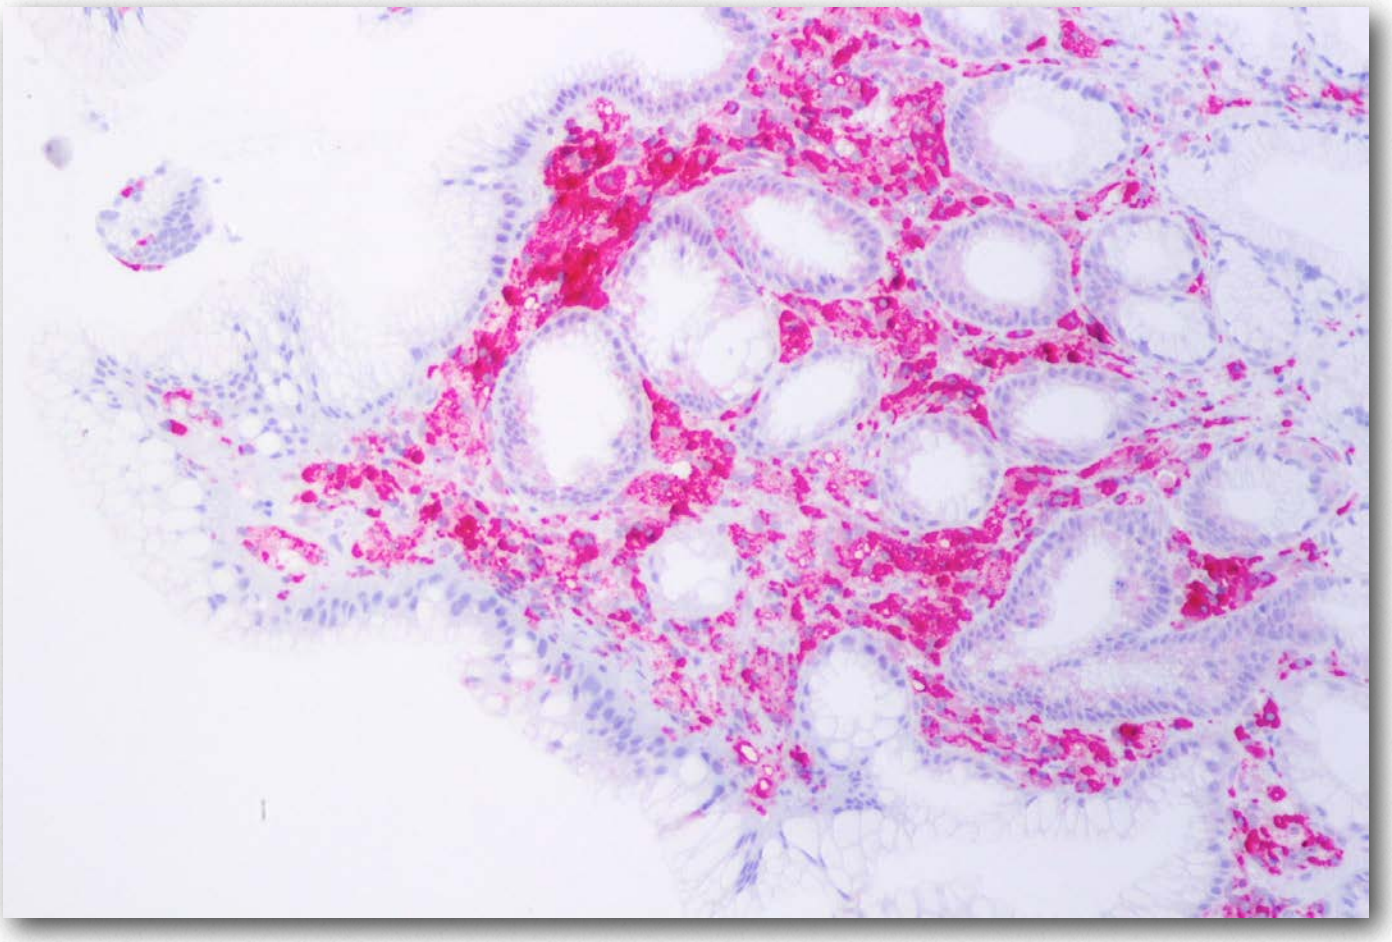

Figure 2.262 - Foam cell aggregate

Wikipedia

when it is mature, it returns its load of cholesterol back to the liver or, alternatively, to LDL molecules for endocytosis. HDLs have the effect of lowering levels of cholesterol and it is for that reason they are described as “good cholesterol.”

Regulation of lipid transfer

It is important that cells get food when they need it so some control of the movement of nutrients is critical. The liver, which plays the central role in modulating blood glucose levels, is also important for performing the same role for lipids. It accomplishes this task the use of specialized LDL receptors on its surface. Liver LDL receptors bind LDLs that were not taken up by other cells in their path through the bloodstream. High levels of LDLs are a signal to the liver to reduce the creation of VLDLs for release.

People with the genetic disease known as familial hypercholesterolemia, which manifests with dangerously high levels of LDLs, lack properly functioning LDL receptors on their liver cells.

In sufferers of this disease, the liver never gets the signal that the LDL levels are high. In fact, to the liver, it appears that all VLDLs and LDLs are being taken up by peripheral tissues, so it creates more VLDLs to attempt to boost levels. Untreated, the disease used to be fatal early, but newer drugs like the statins have significantly increased life spans of patients. Cellular needs for the contents of LDLs are directly linked to the levels of synthesis of LDL receptors on their membranes. As cells are needing more cholesterol, their synthesis of components for receptors goes up and it decreases as need diminishes.

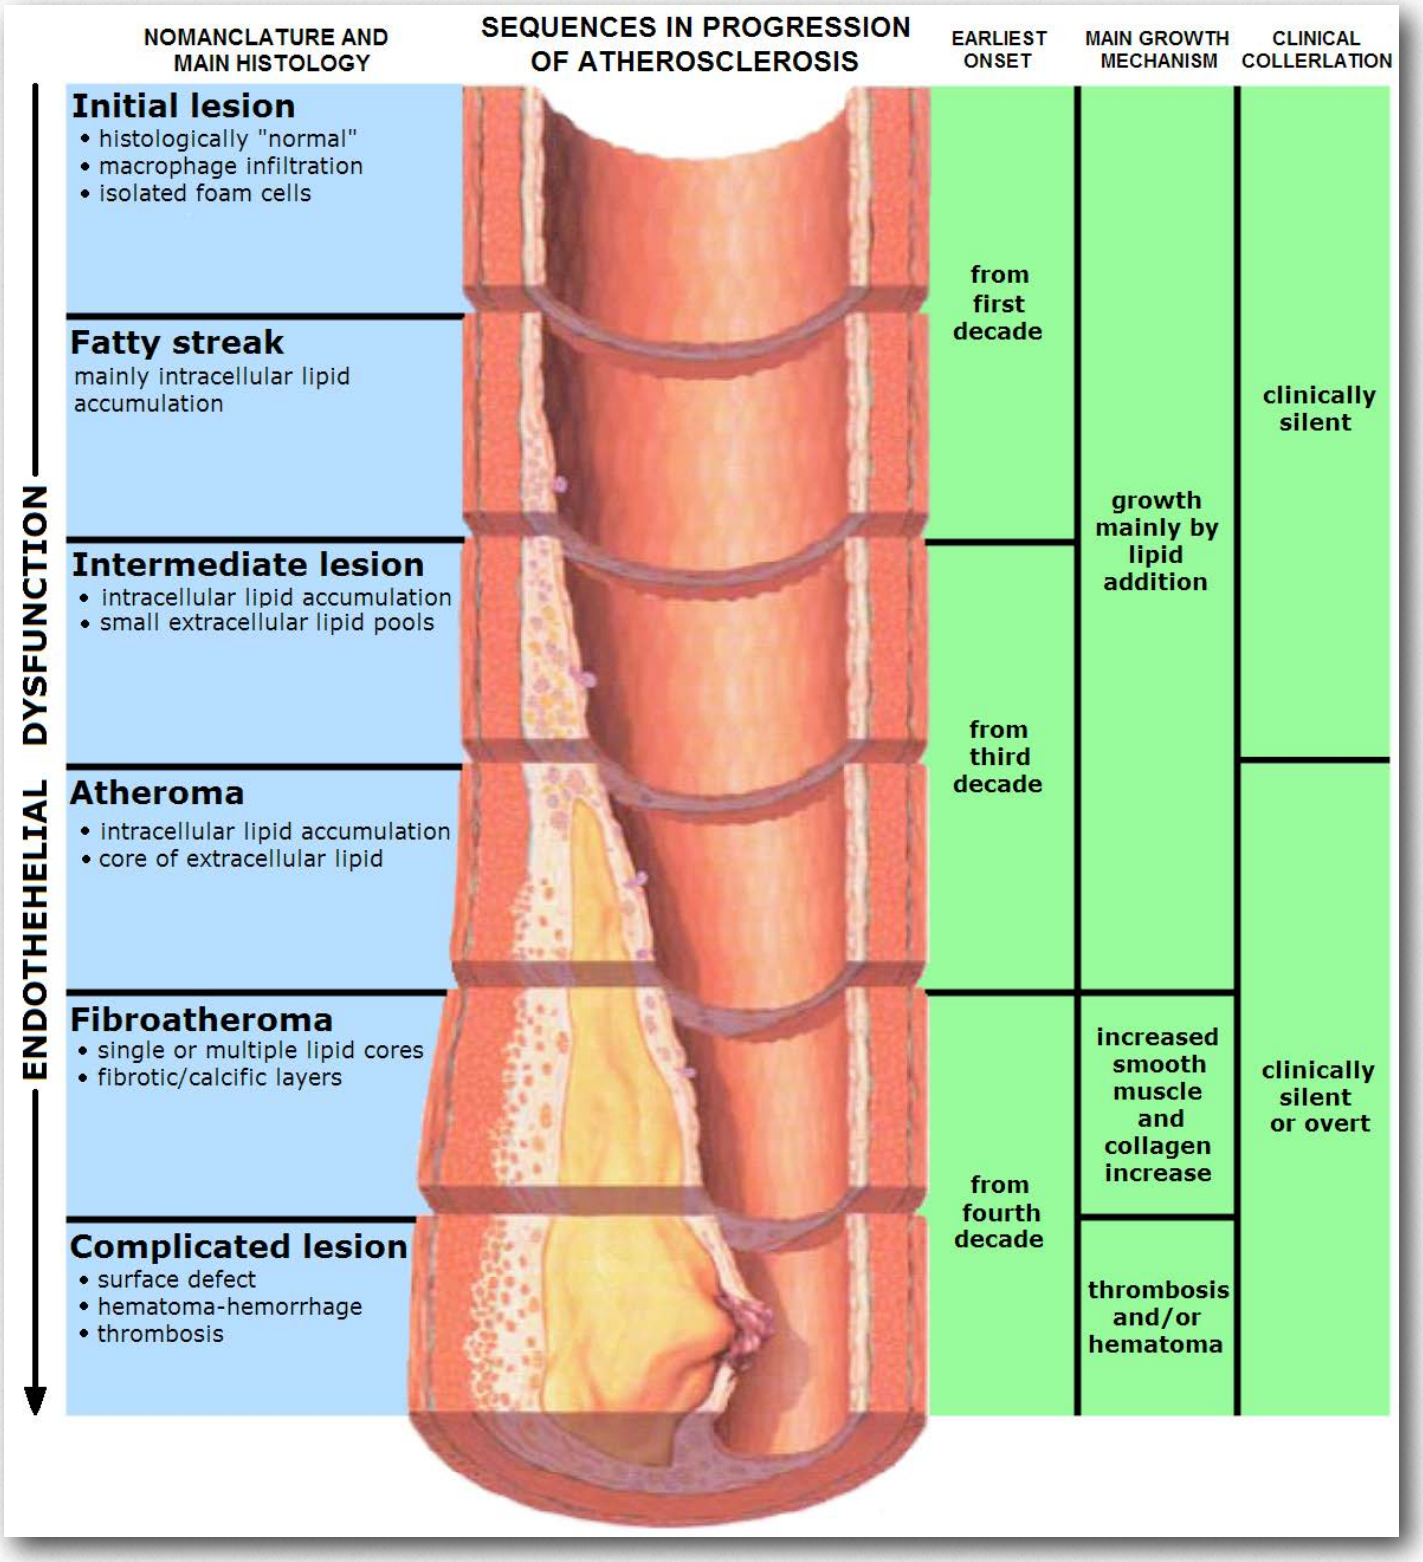

Figure 2.263 - Progression of atherosclerosis

Wikipedia

Good cholesterol / bad cholesterol

It is commonly accepted that “high cholesterol” levels are not healthy. This is due, at least indirectly, to the primary carriers of cholesterol, the LDLs. A primary function of the LDLs is to deliver cholesterol and other lipids directly into cells by receptor mediated endocytosis (Figure 2.237). High levels of LDLs, though, are correlated with formation of atherosclerotic plaques (Figure 2.263 & 2.264) and incidence of atherosclerosis, leading to the description of them as “bad cholesterol.” This is because when LDL levels are very high, plaque formation begins. It is thought that reactive oxygen species (higher in the blood of smokers) causes partial oxidation of fatty acid groups in the LDLs. When levels are high, they tend to accumulate in the extracellular matrix of the epithelial cells on the inside of the arteries. Macrophages of the immune system take up the damaged LDLs (including the cholesterol).

Since macrophages can’t control the amount of cholesterol they take up, cholesterol be-

gins to accumulate in them and they take on appearance that leads to their being described as "foam cells." With too much cholesterol, the foam cells, however, are doomed to die by the process of programmed cell death (apoptosis). Accumulation of these, along with scar tissue from inflammation result in formation of a plaque. Plaques can grow and block the flow of blood or pieces of them can break loose and plug smaller openings in the blood supply, ultimately leading to heart attack or stroke.

YouTube Lectures by Kevin HERE & HERE

Figure 2.264 - Actual carotid artery plaque

Wikipedia

Good cholesterol

On the other hand, high levels of HDL are inversely correlated with atherosclerosis and arterial disease. Depleted HDLs are able to remove cholesterol from foam cells. This occurs as a result of contact between the ApoA-I protein of the HDL and a transport protein on the foam cell (ABC-G1). Another transport protein in the foam cell, ABCA-1 transports extra cholesterol from inside the cell to the plasma membrane where it is taken up into the HDL and returned to the liver or to LDLs by the reverse transport cholesterol pathway.

Deficiency of the ABCA-1 gene leads to Tangier disease. In this condition, HDLs are almost totally absent because they remain empty as a result of not being able to take up cholesterol from foam cells, so they are destroyed by the body.

ApoE and Alzheimer's disease

ApoE is a component of the chylomicrons and is also found in brain, macrophages, kidneys, and the spleen. In humans, it is found in three different alleles, E2, E3, and E4. The E4 allele (present at about 14% of the population) is associated with increased likelihood of contracting Alzheimer's disease. People heterozygous for the allele are 3 times as likely

to contract the disease and those homozygous for it are 15 times as likely to do so. It is not known why this gene or allele is linked to the disease. The three alleles differ only slightly in amino acid sequence, but the changes do cause notable structural differences. The E4 allele is associated with increased calcium ion levels and apoptosis after injury. Alzheimer's disease is associated with accumulation of aggregates of the β-amyloid peptide. ApoE does enhance the proteolytic breakdown of it and the E4 isoform is not as efficient in these reactions as the other isoforms.

Your Poor Veins

To the tune of "*You're So Vain*"

Metabolic Melodies Website HERE

Well I raced off to my doctor
Cause I was feelin' the twinges of pain
I was worried about my heart 'cause I
Was overweight once a-gain
She took one look at my profile and
Just shook her head and complained

"You gotta wake up and change all that junk you've been eating
Junk you've been eating. 'Cause
Your poor veins
Are plugged 'cause you are wolfin' the butter
And LDLs
Are makin' your heart go a-flutter
Flutter, Flutter"

She had warned me several months before
But I just ignored what was said
She told me, "You look like a heart attack"
"It's surprising that you're not dead"
I walked away in disbelief
And ate more bad food instead

I loaded oodles of cream in my tall Macchiatos
Tall Macchiatos and
LDLs
Went up as I was gulping 'em down my
LDLs
Just turned a smile right into a frown
A frown, a frown

I decided to make a change right there
The diet was merely step one
All the *trans* fats were banished from my food
And I started to jog just for fun
I had one foot in the grave when I
Discovered what I had done

I moved away from the edge of the doorstep of death to
Re-gaining my breath when my
HDLs
Increased since I was eating more smartly
HDLs
They lowered my cholesterol partly
Partly, partly

Well you know I'm feeling much better now
And my heart is surely relieved
A factor certainly is the unsaturates
Contained in my sunflower seeds
Yeah the fatty acids were the keys
Essential things that we need

Those fish oil capsules and o-mega threes cleaned
My ar-ter-ies with
HDLs
They're more than just the latest hot crazes
HDLs
They saved me so I'm singing their praises
Praises, Praises

God Rest Ye Merry Dieters

To the tune of "*God Rest Ye Merry Gentlemen*"

Metabolic Melodies Website HERE

God rest ye merry dieters
With high cholesterol
Your chylomicrons all contain
Triacylglycerols
And move from lymph to capillaries
Where their progress stalls
Tha-anks lipo protein li-pase,
Protein lipase
O-oh thank you lipo protein li-pase

And after their fat goodies
Have been hydrolyzed away
The chylomicron remnants
Go along their merry way
The liver grabs them from the blood
And puts them all away
Just as we should do with Kenneth Lay, Kenneth Lay
O-oh just as we should do with Kenneth Lay (Enron scandal guy)

And when the liver gets a message
From the body's cells
It makes up little packages
We call VLDLs
They seem like chylomicrons, but turn
In to something else
Please don't become the LDLs, LDLs

O-oh please don't become the LDLs
For LDLs cause chaos
When their insides oxidize
The macrophages bind to them
And foam cells can arise
You'd better watch your diet
Or your blood flow will downsize
And that would not be very wise, very wise
No-oh that would not be very wise

So if you take some lessons from
This little comic bit
Your diet should be healthy
And you should try to stay fit
Eat greens and drink red wine but try
Not to overdo it
And your heart will never ever quit, want to quit
No, no your heart will never ever quit

Membranes

"The greatest mistake you can make in your life is to be continually fearing you will make one."

-Elbert Hubbard

The membranes and surrounding tissues of cells and their organelles vary immensely in composition, not only in the lipids comprising their bilayers, but also of the protein gatekeepers and in the supporting structures, such as cell walls, which some cells, like our own, don't even have at all. In this chapter, we explore the structure and function of the cell's protective boundary, the membrane.

Membranes: Basic Concepts

Lipid bilayers

The protective membrane around cells contains many components, including cholesterol, proteins, glycolipids, glycerophospholipids, and sphingolipids. The last two of these will, when mixed vigorously with water, spontaneously form what is called a lipid bilayer (Figure 3.1), which serves as a protective boundary for the cell that is largely impermeable to the movement of most materials across it.

YouTube Lectures by Kevin HERE & HERE

With the notable exceptions of water, carbon dioxide, carbon monoxide, and oxygen, most polar/ionic require transport proteins to help them to efficiently navigate across the bilayer. The orderly movement of these compounds is critical for the cell to be able to 1) get food for energy; 2) export materials; 3) maintain osmotic balance; 4) create gradients for secondary transport; 5) provide electromotive force for nerve signaling; and 6) store energy in electrochemical gradients for ATP production (oxidative phos-

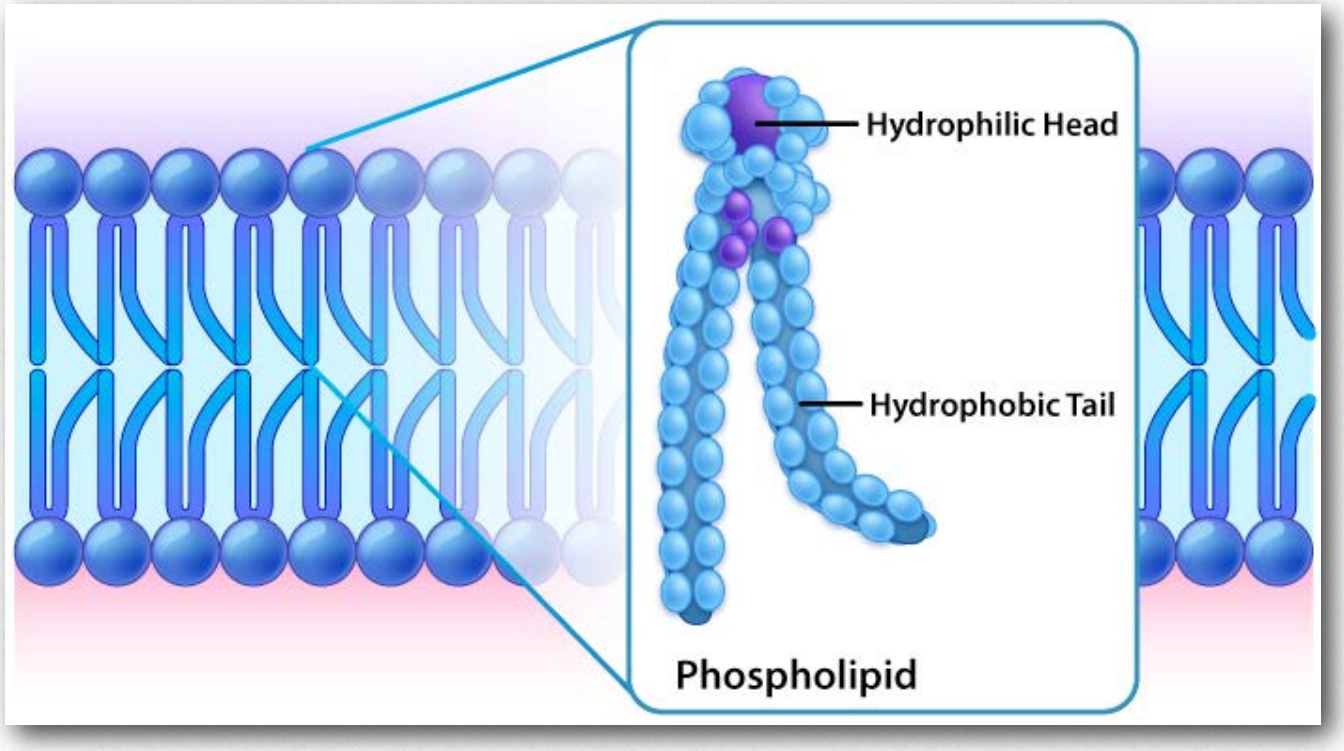

Figure 3.1 - Lipid bilayer closeup

Image by Aleia Kim

phorylation or photosynthesis). In some cases, energy is required to move the substances (active transport).

Facilitated diffusion

In other cases, no external energy is required and they move by diffusion through specific cellular channels. This is referred to as facilitated diffusion. Before we discuss movement of materials across membranes, it is appropriate we discuss the composition of cellular membranes.

Plasma membranes differ from cell walls both in the materials comprising them and in their flexibility. Cell walls will be covered near the end of this chapter (HERE).

Though some cells do not have cell walls (animal cells) and others do (bacteria, fungi, and plants), there is commonality among cells in that they all possess plasma membranes. There is also

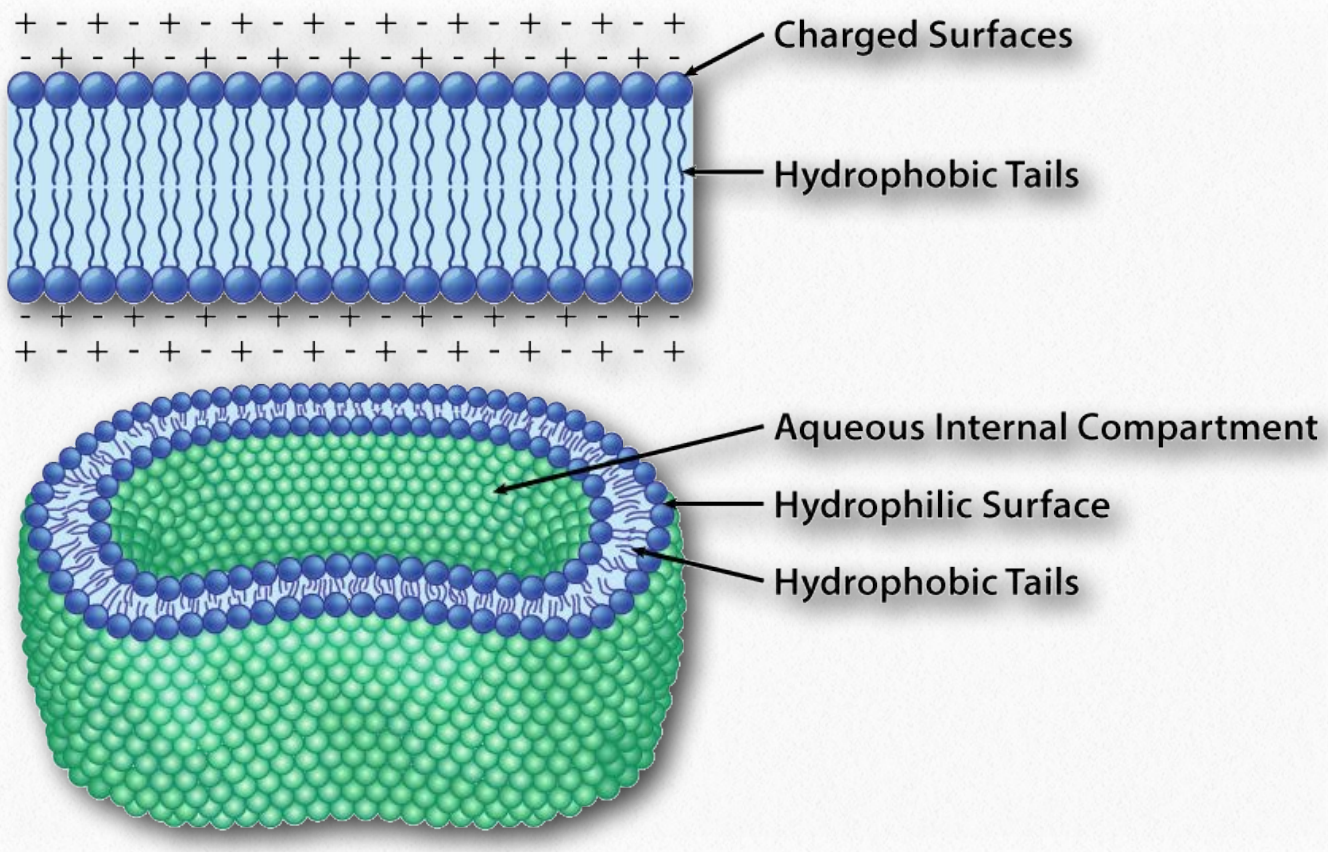

Figure 3.2 - Organization of the lipid bilayer

Image by Aleia Kim

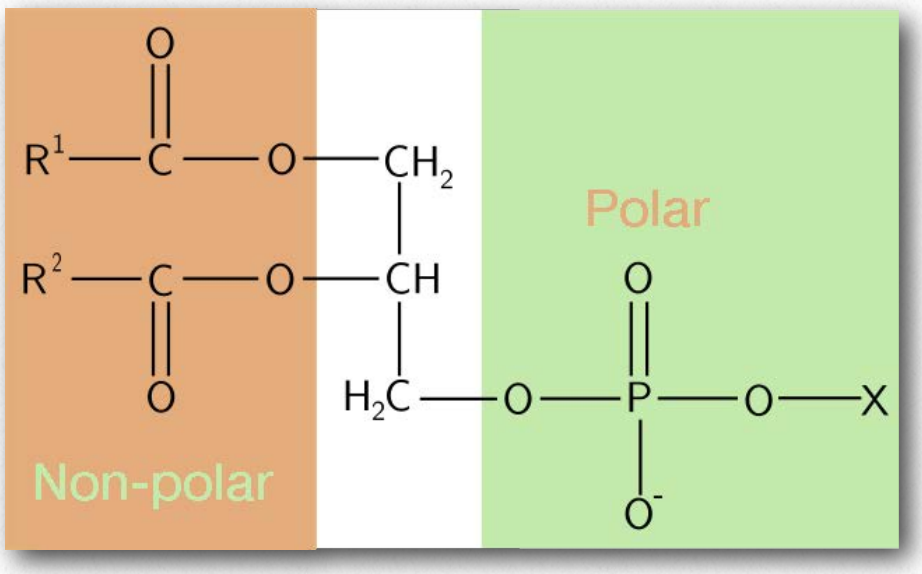

Figure 3.3 - Schematic diagram of a phosphatide

commonality in the components of the membranes, though the relative amount of constituents varies. Figures 3.1 and 3.2 illustrate the structure and environments of plasma membranes. All plasma membranes contain a significant amount of amphiphilic substances linked to fatty acids. These include the glycerophospholipids and the sphingolipids. The fatty acid(s) are labeled as hydrophobic tails in the figures.

Hydrophilic heads

The composition of the hydrophilic heads varies considerably. In glycerophospholipids, a phosphate is always present, of course, and it is often esterified to another substance to make a phosphatide (Figure 3.3). Common compounds linked to the phosphate (at the X position) include serine, ethanolamine, and choline. These vary in the their charges so in this way, the charge on the external or internal surface can be controlled. Cells tend to have more negative charges on the exterior half of the lipid bilayer (called the outer leaflet) and more positive charges on the interior half (inner leaflet).

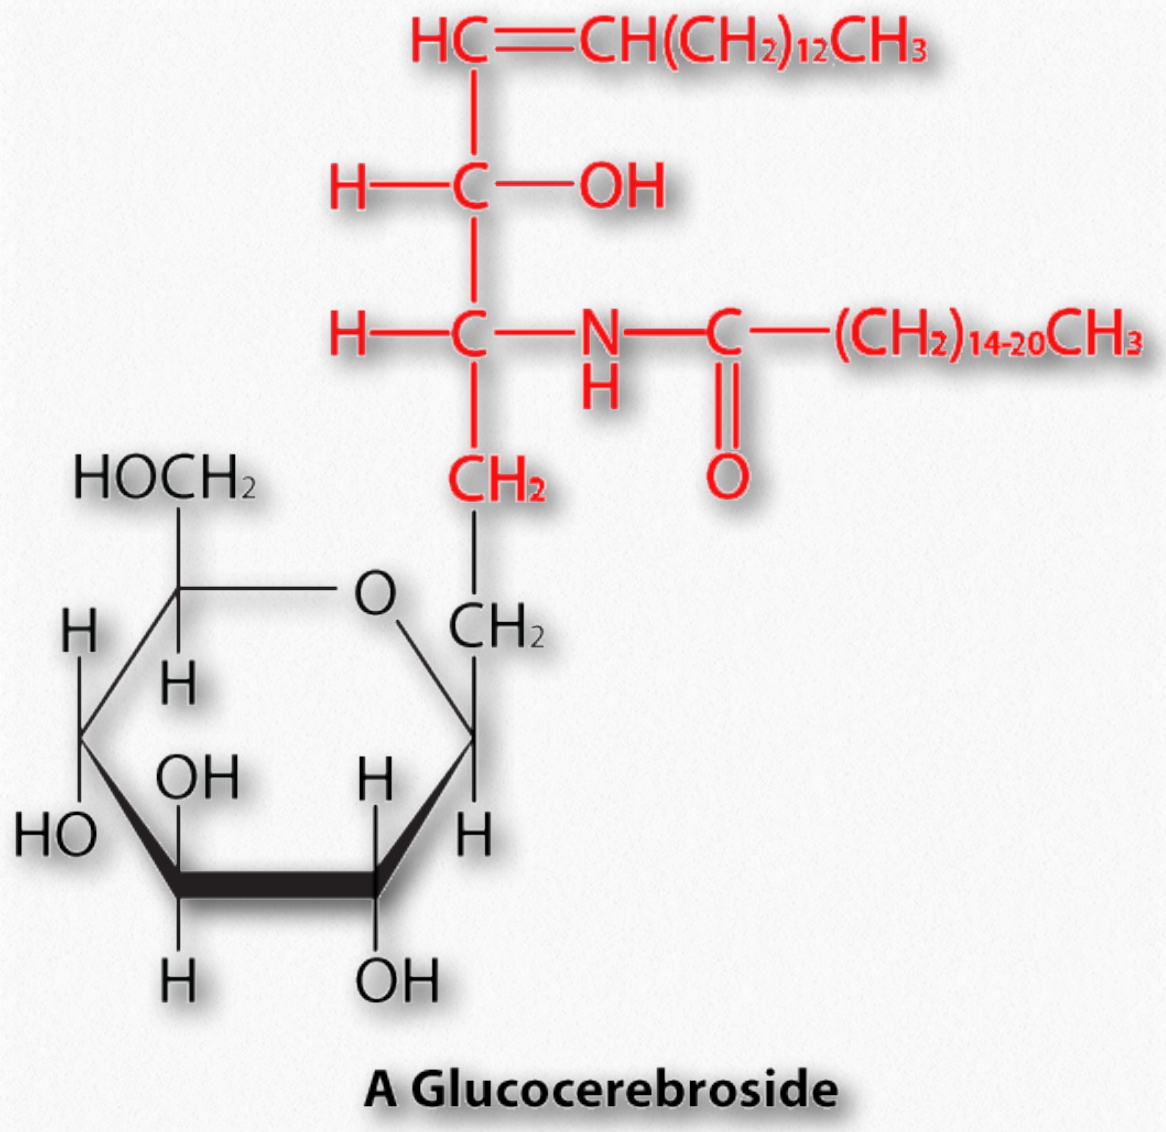

Figure 3.4 - A sphingolipid. Polar head in black. Non-polar tail in red

Image by Aleia Kim

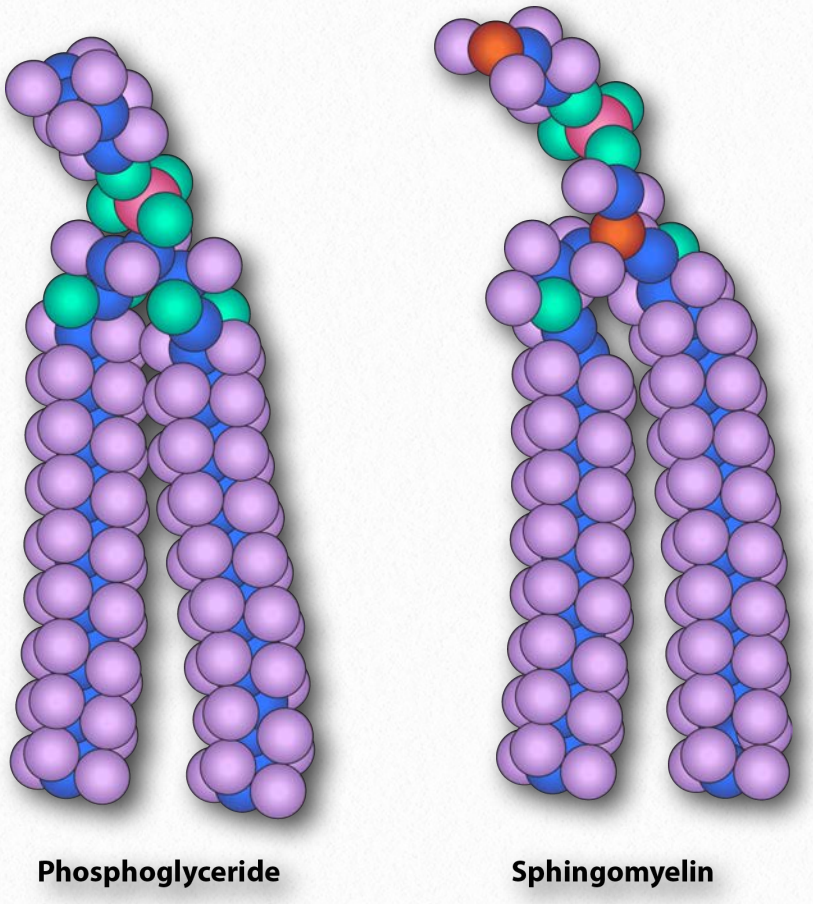

Figure 3.5 - Similarity of form between a phosphoglyceride and sphingomyelin

Image by Aleia Kim

Sphingolipids

In sphingolipids (Figure 3.4), the hydrophilic head can contain a phosphate linked to ethanolamine or choline and this describes the structure of sphingomyelin, an important component of neural membranes. Most sphingolipids lack the phosphate and have instead a hydrophilic head of a single sugar (cerebrosides) or a complex oligosaccharide (gangliosides).

Water exclusion

In each case, the glycerophospholipid or sphingolipid has one end that is polar and one end that is non-polar. As we saw in the organization of amino acids with hydrophobic side chains occurring preferentially on the inside of a folded protein to exclude water, so too do the non-polar portions of these amphiphilic molecules arrange themselves so as to exclude water. Remember that the cytoplasm of a cell is mostly water and the exterior of the cell is usually bathed in an aqueous layer. It therefore makes perfect sense that the polar portions of the membrane molecules arrange themselves as they do - polar parts outside interacting with water and non-polar parts in the middle of the bilayer avoiding/excluding water.

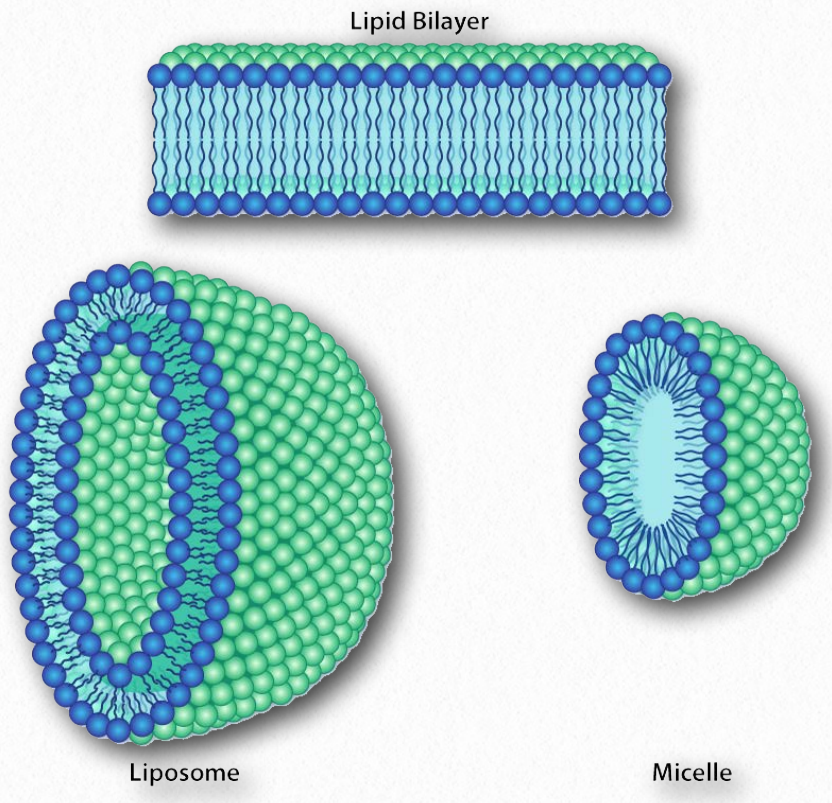

Figure 3.6 - Different lipid bilayer structures

Image by Aleia Kim

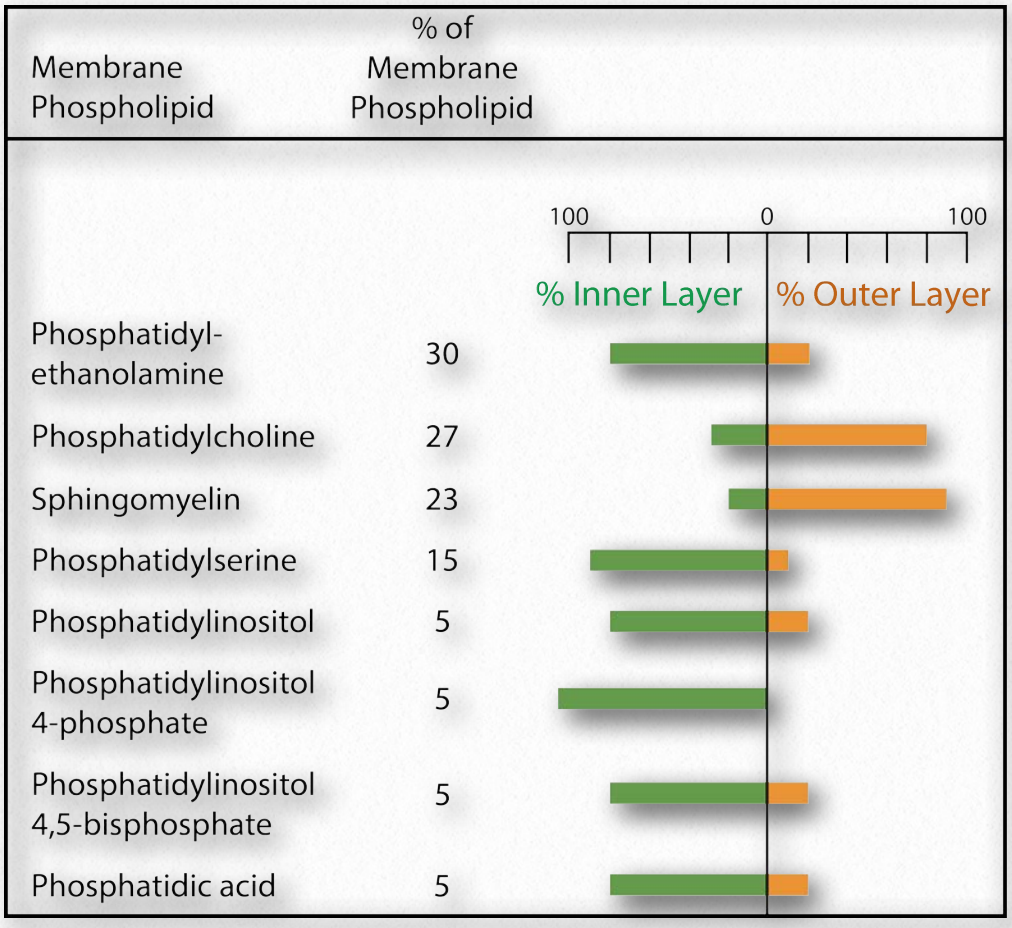

Figure 3.7 - Differential distribution of membrane lipids by inner and outer leaflet

Image by Pehr Jacobson

YouTube Lectures by Kevin HERE & HERE

Composition bias

The plasma membrane has distinct biases of composition relative to its inside and the outside (Figure 3.7). First, glycosylation (of lipids and proteins) has the sugar groups located almost exclusively on the outside of the cell, away from the cytoplasm (Figure 3.8). Among the membrane lipids, sphingolipids are much more commonly glycosylated than glycerophospholipids. In addition,

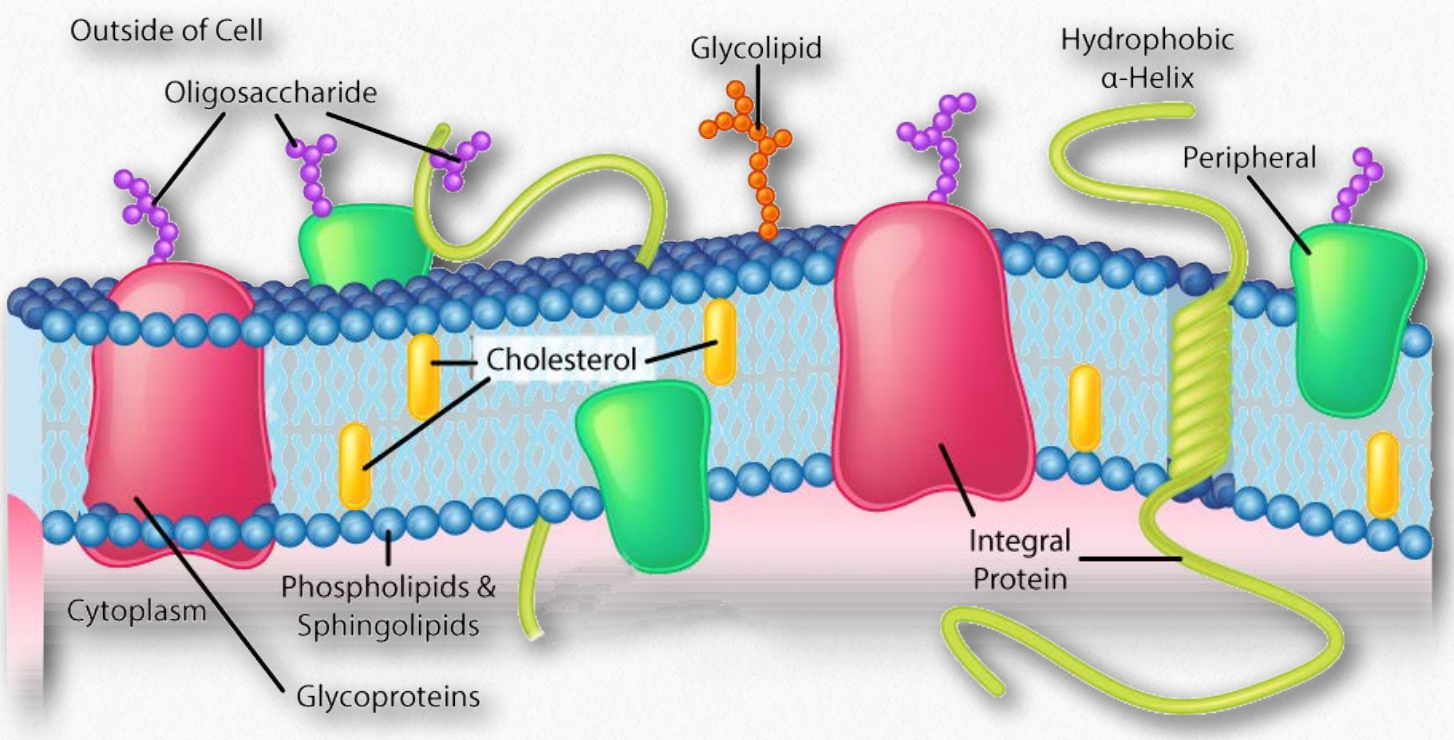

Figure 3.8 - Molecular organization of the lipid bilayer

Image by Aleia Kim

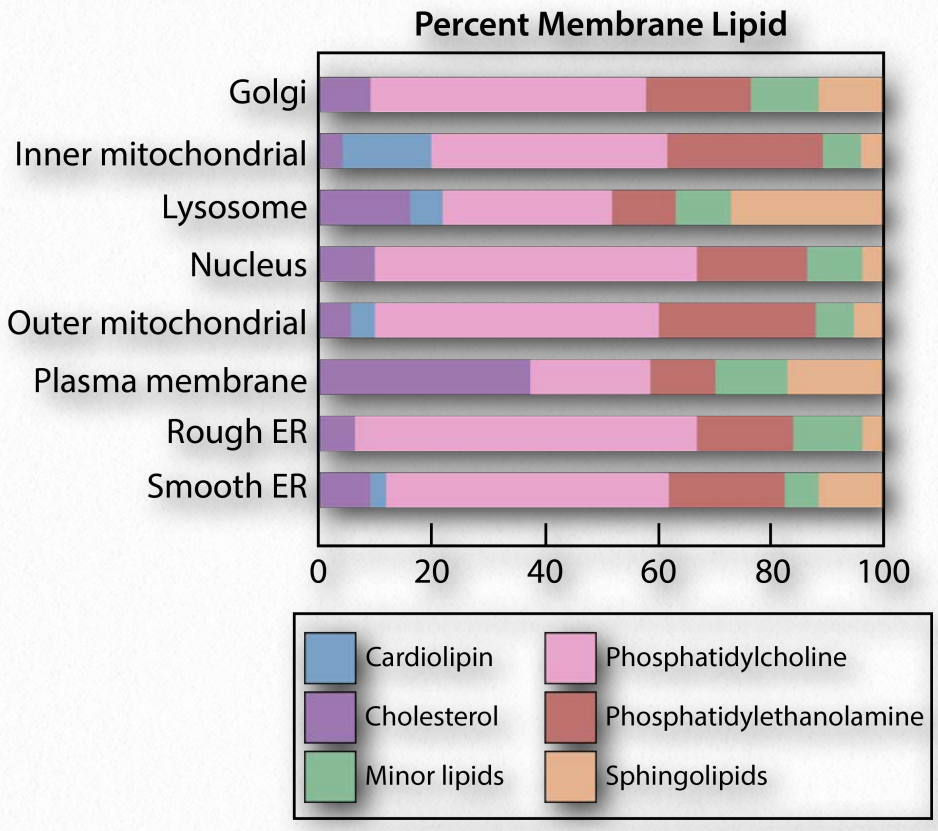

Figure 3.9 - Distribution of lipids in organelle membranes

Image by Pehr Jacobson

some of the glyerophospholipids are found preferentially on one side or the other (Figure 3.7). Phosphatidylserine and phosphatidylethanolamine are found preferentially within the inner leaflet of the plasma membrane, whereas phosphatidylcholine tends to be located on the outer leaflet. In the process of apoptosis, the phosphatidylserines appear on the outer leaflet where they serve as a signal to macrophages to bind and destroy the cell. Sphingolipids are found preferentially in the plasma membrane and are almost completely absent from mitochondrial and endoplasmic reticulum membranes (Figure 3.9).

Organelle membranes

Bias of lipid composition also exists with respect to organelle membranes. The unusual diphosphodiglycerolipid known as cardiolipin, for example, is almost only found in mitochondrial membranes (see HERE) and like phosphatidylserine, its movement is an important step in apoptosis. In signaling, phosphatidylinositols play important roles providing second messengers upon being cleaved (see HERE).

Lateral diffusion

Movement of lipids within each leaflet of the lipid bilayer occurs readily and rapidly due to membrane fluidity. This type of movement is called lateral diffusion and can be measured by the technique called FRAP (Figure 3.10, see HERE also). In this method, a laser strikes and stains a section of the lipid bilayer of a cell, leaving a spot as shown in B. Over time, the stain diffuses out ultimately across the entire lipid bilayer, much like a drop of ink will diffuse throughout when added to a glass of water. A measurement of the rate of diffusion gives an indication of the fluidity of a membrane.

Transverse diffusion

While the movement in lateral diffusion occurs rapidly, movement of molecules from one leaflet over to the other leaflet occurs much more slowly. This type of molecular

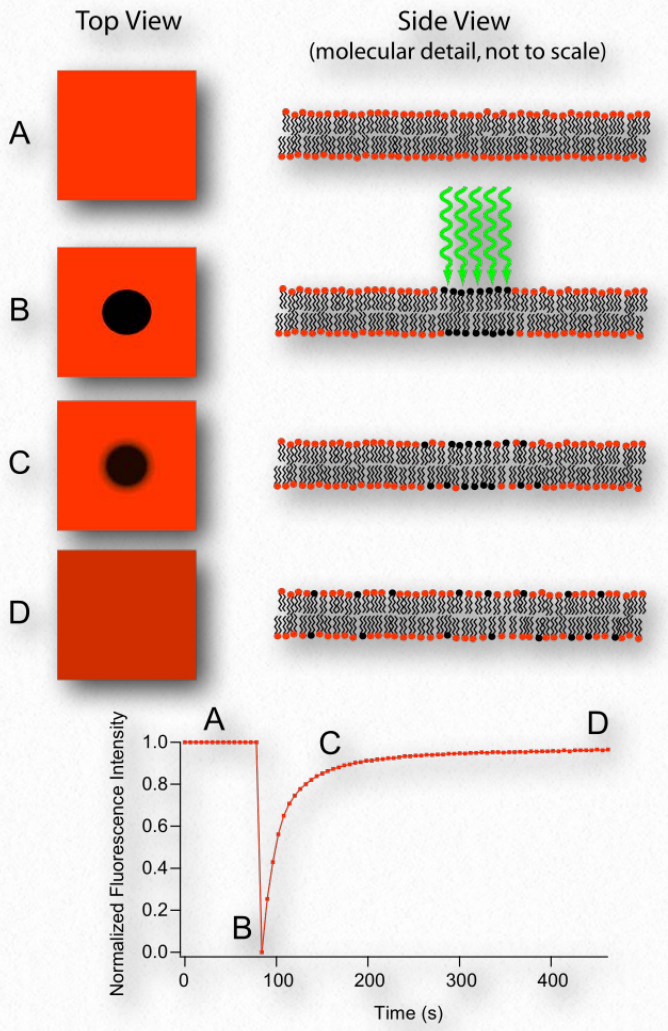

Figure 3.10 - Fluorescence recovery after photobleaching (FRAP)

movement is called transverse diffusion and is almost nonexistent in the absence of enzyme action. Remember that there is a bias of distribution of molecules between leaflets of the membrane, which means that something must be moving them.

There are three enzymes that catalyze movement of compounds in transverse diffusion. Flippases move membrane glycerophospholipids/ sphingolipids from outer leaflet to inner leaflet (cytoplasmic side) of cell. Floppases move membrane lipids in the opposite direction. Scramblases move in either direction.

Other components of lipid bilayer

Besides glycerophospholipids and sphingolipids, there are other materials commonly found in lipid bilayers of cellular membranes. Two important prominent ones are cholesterol (Figure 3.13) and proteins.

Besides serving as a metabolic precursor of steroid hormones and the bile acids, cholesterol's main role in cells is in the membranes. The flatness and hydrophobicity of the sterol rings allow cholesterol to interact with the nonpolar portions of the lipid bilayer while the hydroxyl group on the end can interact with the hydrophilic part.

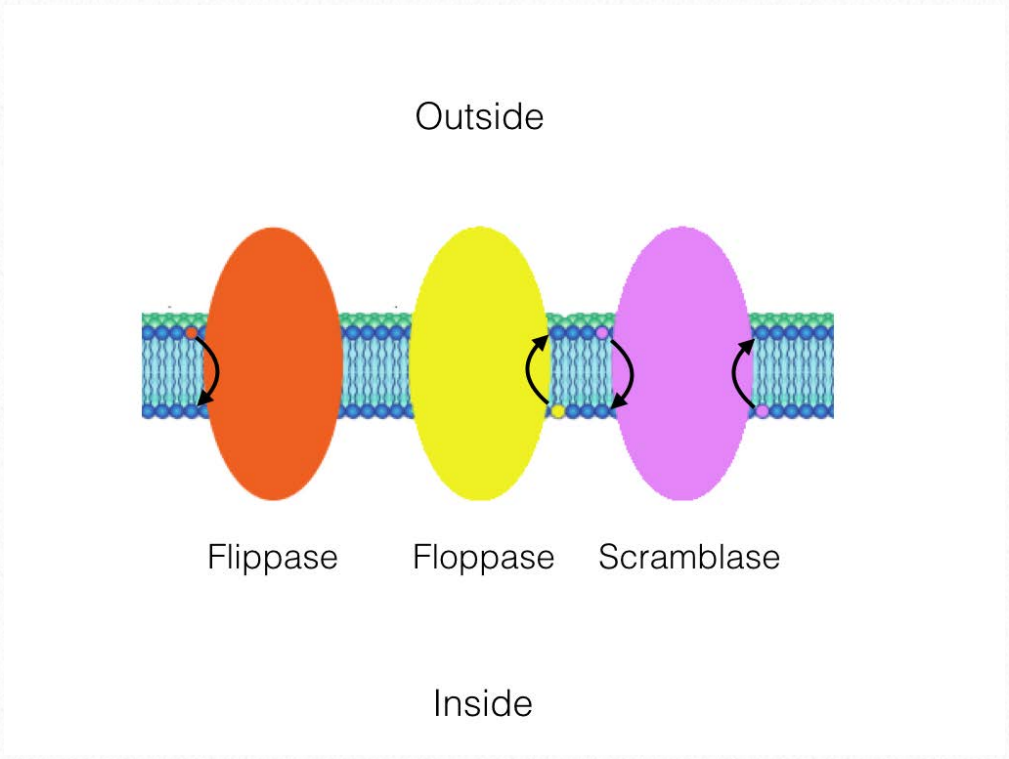

Figure 3.11 - Catalytic action of a flippase, a floppase, and a scramblase

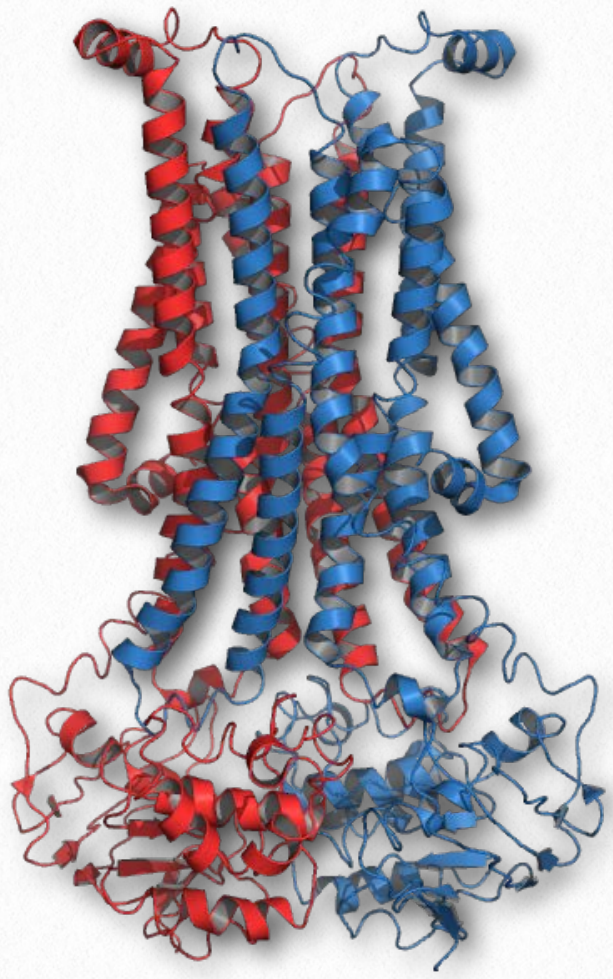

Figure 3.12 - **Structure of a flippase**

Wikipedia

Membrane fluidity

Cholesterol's function in the lipid bilayer is complex (Figure 3.13). It influences membrane fluidity. Figure 3.14 shows the phase transition for a membrane as it is heated, moving from a more "frozen" character to that of a more "fluid" one as the temperature rises. The mid-point of this transition, referred to as the T_m, is influenced by the fatty acid composition of the lipid bilayer compounds. Longer and more saturated fatty acids will favor higher T_m values, whereas unsaturation and short fatty acids will favor lower T_m values. It is for this reason that fish, which live in cool environments,

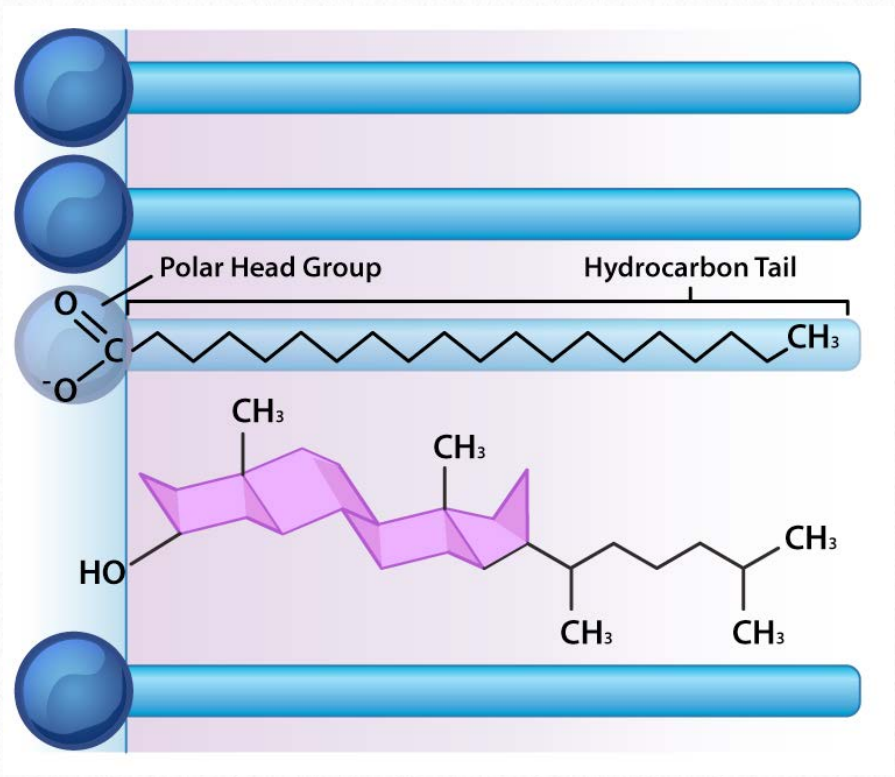

Figure 3.13 - **Cholesterol in the lipid bilayer**

Image by Aleia Kim

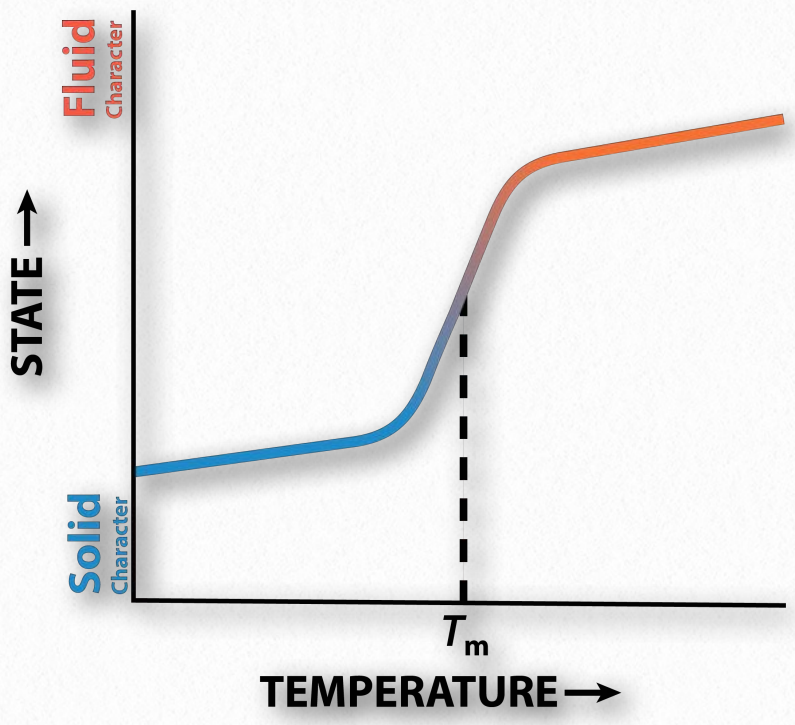

Figure 3.14 - **Membrane transition temperature**

Image by Aleia Kim

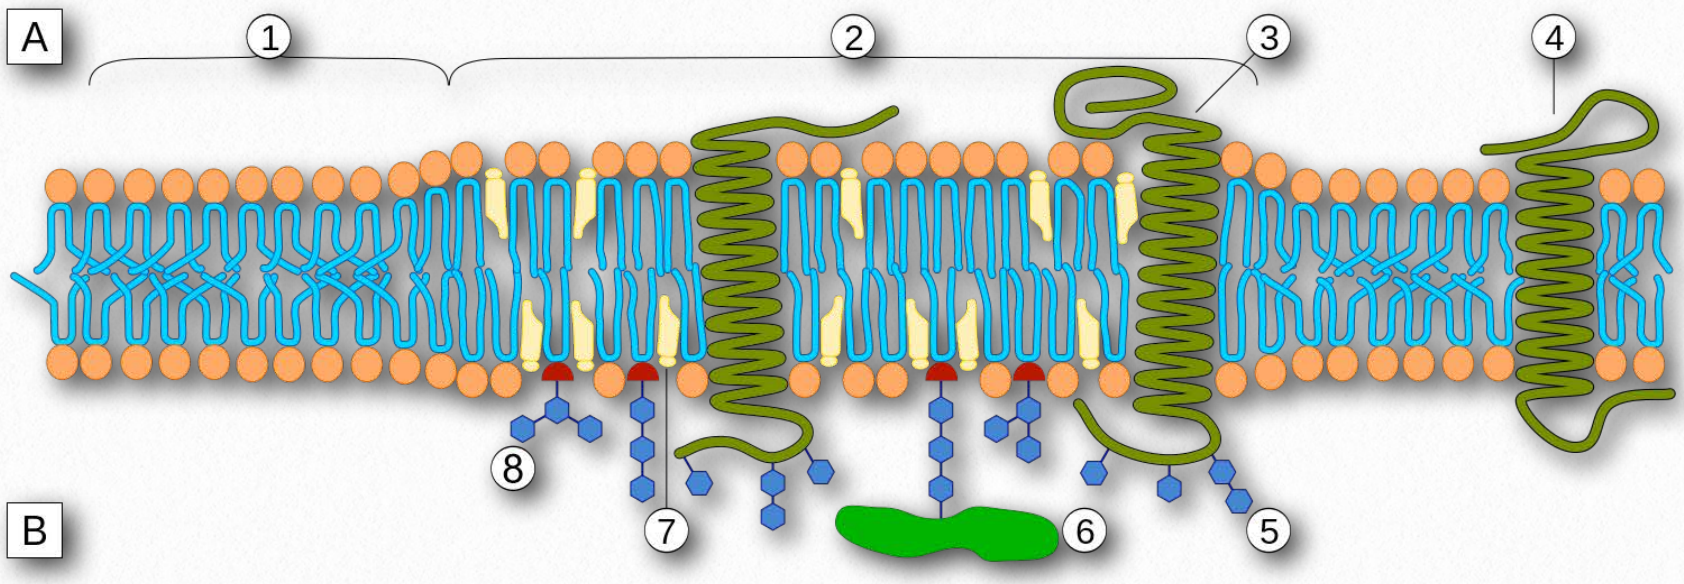

Figure 3.15 - A lipid raft - 1 = Non-raft membrane / 2 = Lipid raft / 3 = Lipid raft associated transmembrane protein / 4 = Non-raft membrane protein / 5 = Glycosylation modifications (on glycoproteins and glycolipids) / 6 = GPI-anchored protein / 7 = Cholesterol / 8 = Glycolipid

have a higher level of unsaturated fatty acids in them - to use to make membrane lipids that will remain fluid at ocean temperatures. Interestingly, cholesterol does not change the T_m value, but instead widens the transition range between frozen and fluid forms of the membrane, allowing it to have a wider range of fluidity.

Lipid rafts

Cholesterol is also abundantly found in membrane structures called lipid rafts. Depicted in Figure 3.15, lipid rafts are organized structures within the membrane typically containing signaling molecules and other integral membrane proteins. Lipid rafts affect membrane fluidity, neurotransmission, and trafficking of receptors and membrane proteins.

YouTube Lectures by Kevin HERE & HERE

Features

Distinguishing features of the rafts is that they are more ordered than the bilayers surrounding them, containing more saturated fatty acids (tighter packing and less disorganization, as a result) and up to 5 times as much cholesterol. They also are relatively rich in sphingolipids, with as much as 50% greater quantities of sphingomyelin than surrounding areas of the bilayer. The higher concentration of cholesterol in the rafts may be due to its greater ability to associate with sphingolipids (Figure 3.16). Some groups, such as prenylated proteins, like RAS, may be excluded from lipid rafts.

Lipid rafts may provide concentrating platforms after individual protein receptors bind to ligands in signaling. After receptor activation takes place at a lipid raft, the signaling

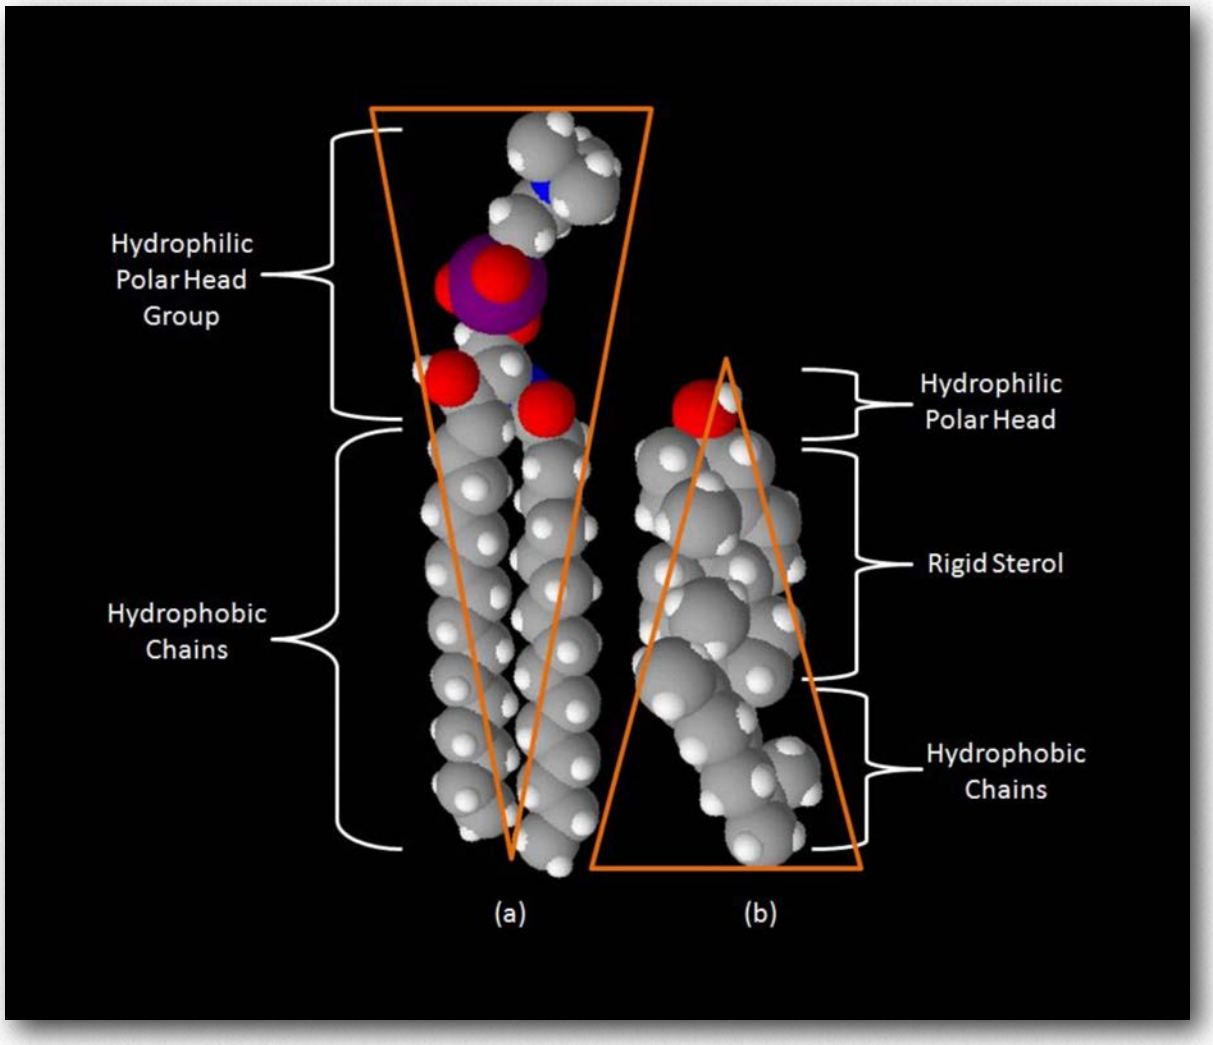

Figure 3.16 - A sphingolipid (left) associating with cholesterol (right)

complex would provide protection from non-raft enzymes that could inactivate the signal. For example, a common feature of signaling systems is phosphorylation, so lipid rafts might provide protection against dephosphorylation by enzymes called phosphatases. Lipid rafts appear to be involved in many signal transduction processes, such as T cell antigen receptor signaling, B cell antigen receptor signaling, EGF receptor signaling, immunoglobulin E signaling, insulin receptor signaling and others. For more on signaling, see HERE.

Barrier

Transport of materials across membranes is essential for a cell to exist. The lipid bilayer is an effective barrier to the entry of most molecules and without a means of allowing food molecules to enter a cell, it would die. The primary molecules that move freely across the lipid bilayer are small, uncharged ones, such as H_2O, CO_2, CO, and O_2, so larger molecules, like glucose, that the cell needs for energy, would be effectively excluded if there were not proteins to facilitate its movement across the membrane.

Figure 3.17 depicts the barrier that the lipid bilayer provides to movement across it and the pressures (ionic attraction, in this case) that can affect movement. Potential energy from charge and concentration differences are harvested by cells for purposes that include synthesis of ATP, and moving materials against a concentration gradient in a process called active transport.

Membrane proteins

Proteins in a lipid bilayer can vary in quantity enormously, depending on the mem-

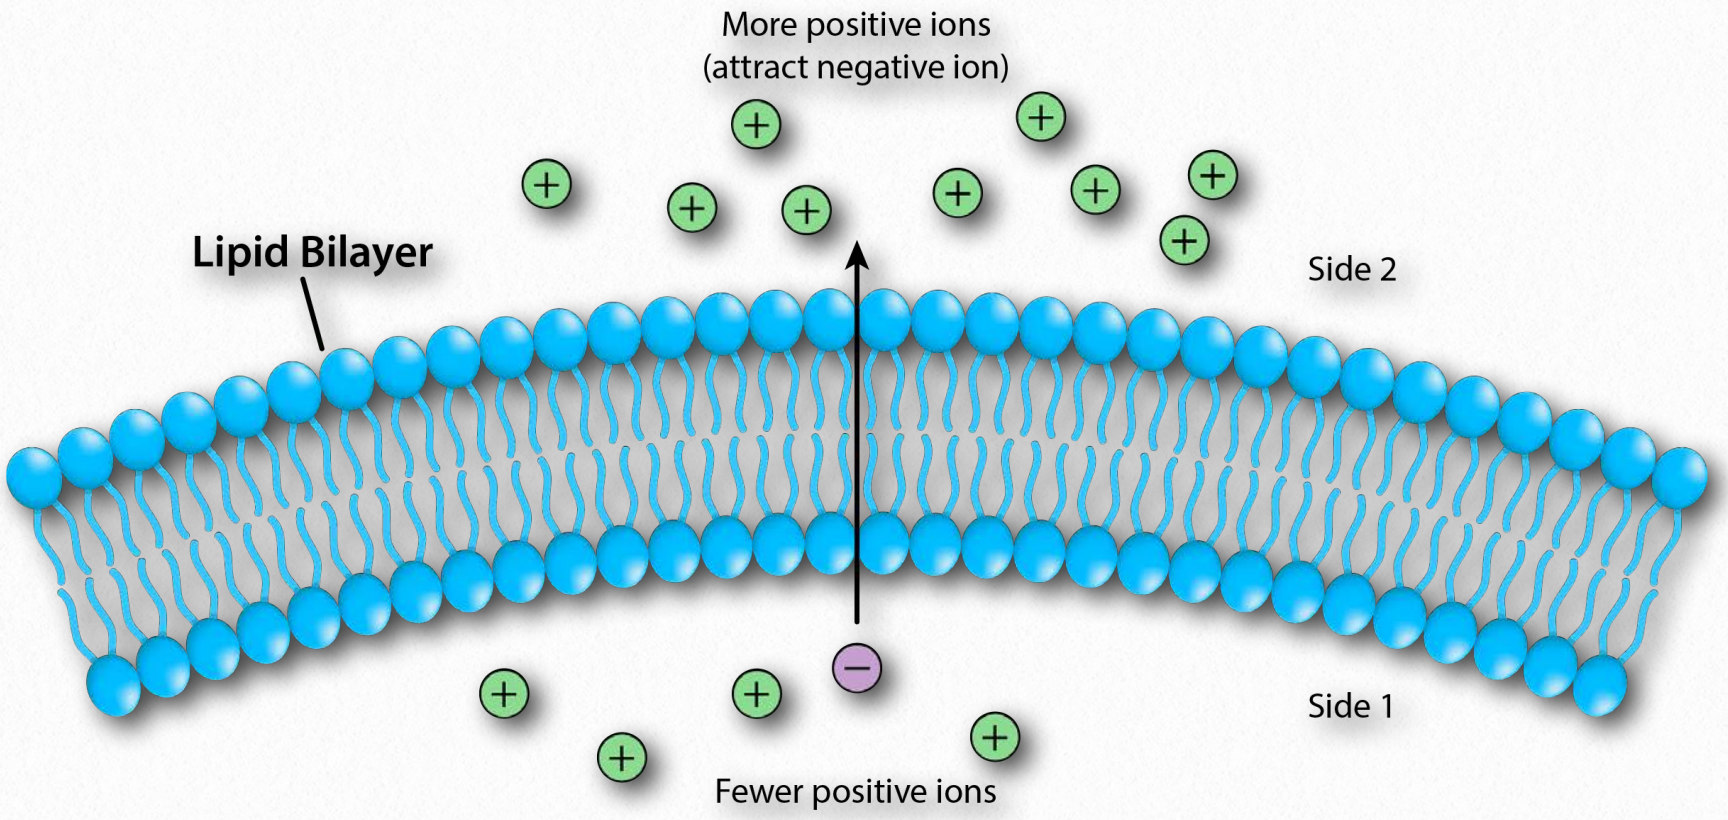

Figure 3.17 - The lipid bilayer as a barrier

Image by Pehr Jacobson

brane. Protein content by weight of various membranes typically ranges between 30 and 75% by weight. Some mitochondrial membranes can have up to 90% protein. Proteins linked to and associated with membranes come in several types.

Transmembrane proteins

Transmembrane proteins are integral membrane proteins that completely span from one side of a biological membrane to the other and are firmly embedded in the membrane (Figure 3.18). Transmembrane proteins can function as docking sites for attachment (to the extracellular matrix, for example), as receptors in the cellular signaling system, or facilitate the specific

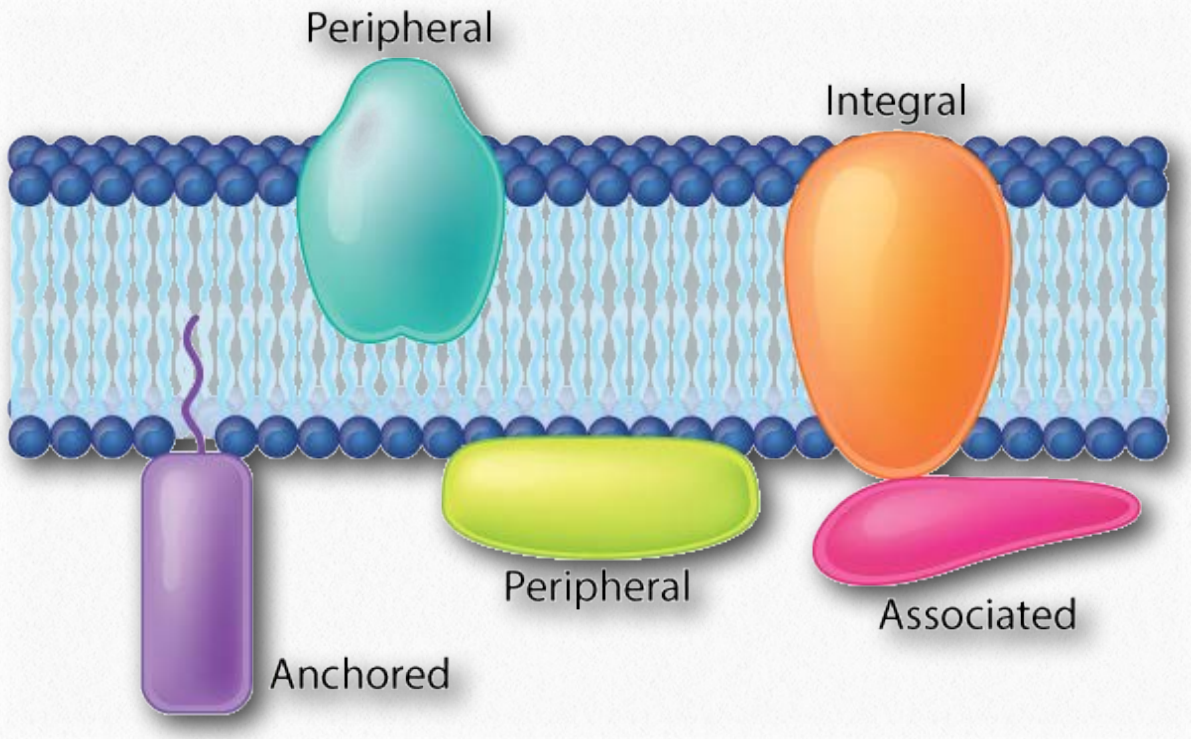

Figure 3.18 - Membrane protein types

Image by Aleia Kim

transport of molecules into or out of the cell.

Example of integrated/transmembrane proteins include those involved in transport (e.g., Na+/K+ ATPase), ion channels (e.g., potassium channel of nerve cells) and signal transduction across the lipid bilayer (e.g., G-Protein Coupled Receptors).

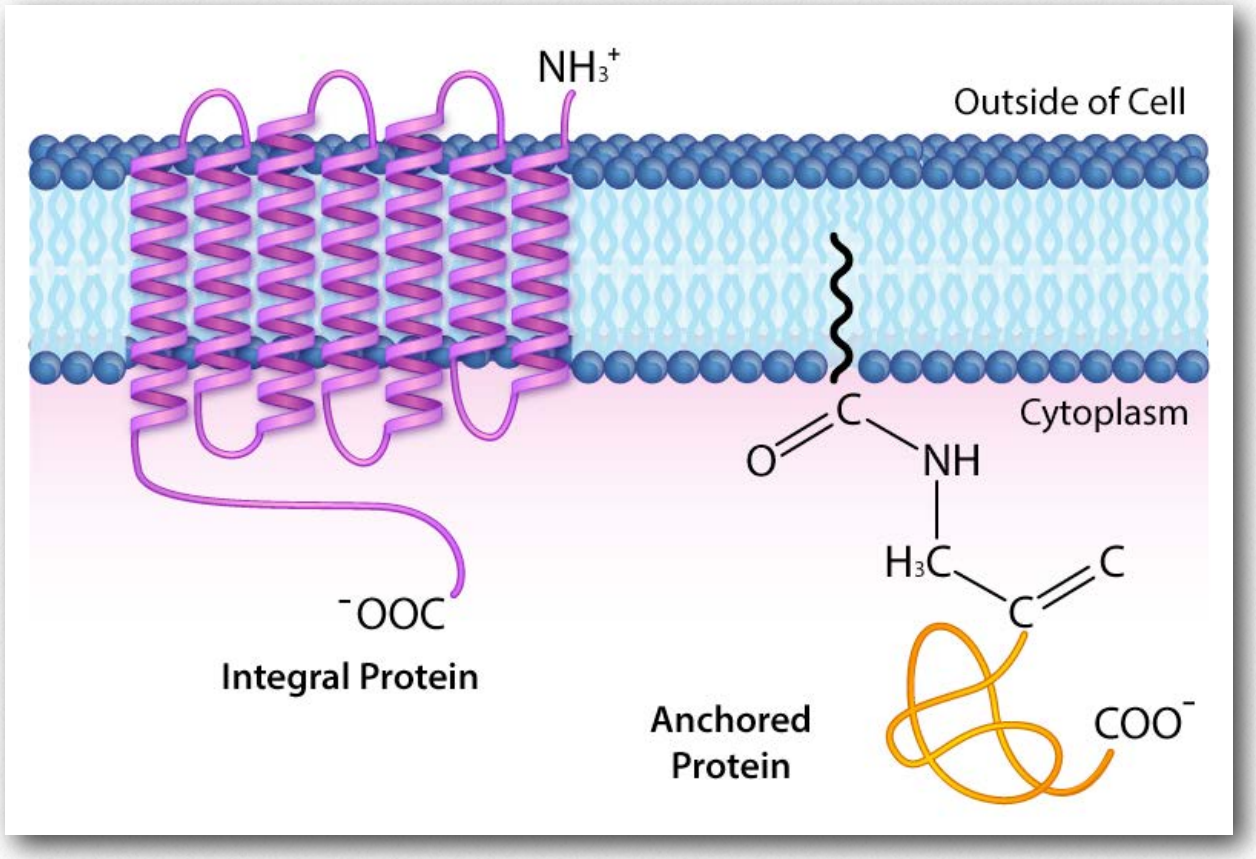

Figure 3.19 - Integral and anchored proteins

Image by Aleia Kim

Peripheral membrane proteins interact with part of the bilayer (usually does not involve hydrophobic interactions), but do not project through it. A good example is phospholipase A_2, which cleaves fatty acids from glycerophospholipids in membranes. Associated membrane proteins typically do not have external hydrophobic regions, so they cannot embed in a portion of the lipid bilayer, but are found near them. Such association may arise as a result of interaction with other proteins or molecules in the lipid bilayer. A good example is ribonuclease.

Anchored membrane proteins

Anchored membrane proteins are not themselves embedded in the lipid bilayer, but instead are attached to a molecule (typically a fatty acid) that is embedded in the membrane (Figure 3.19). The oncogene family of proteins known as ras are good examples. These proteins are anchored to the lipid bilayer by attachment to non-polar farnesyl groups catalyzed by the enzyme farnesyltransferase.

Finer classification

A more detailed classification scheme further categorizes the integral and anchored proteins into six different types (Figure 3.20). Type I and Type II have only one portion of the protein pass through the membrane. They differ in the orientation of the amine and carboxyl end with respect to inside/outside. Type I transmembrane proteins have the amino terminus on the outside and carboxy terminus on the inside, whereas Type II pro-

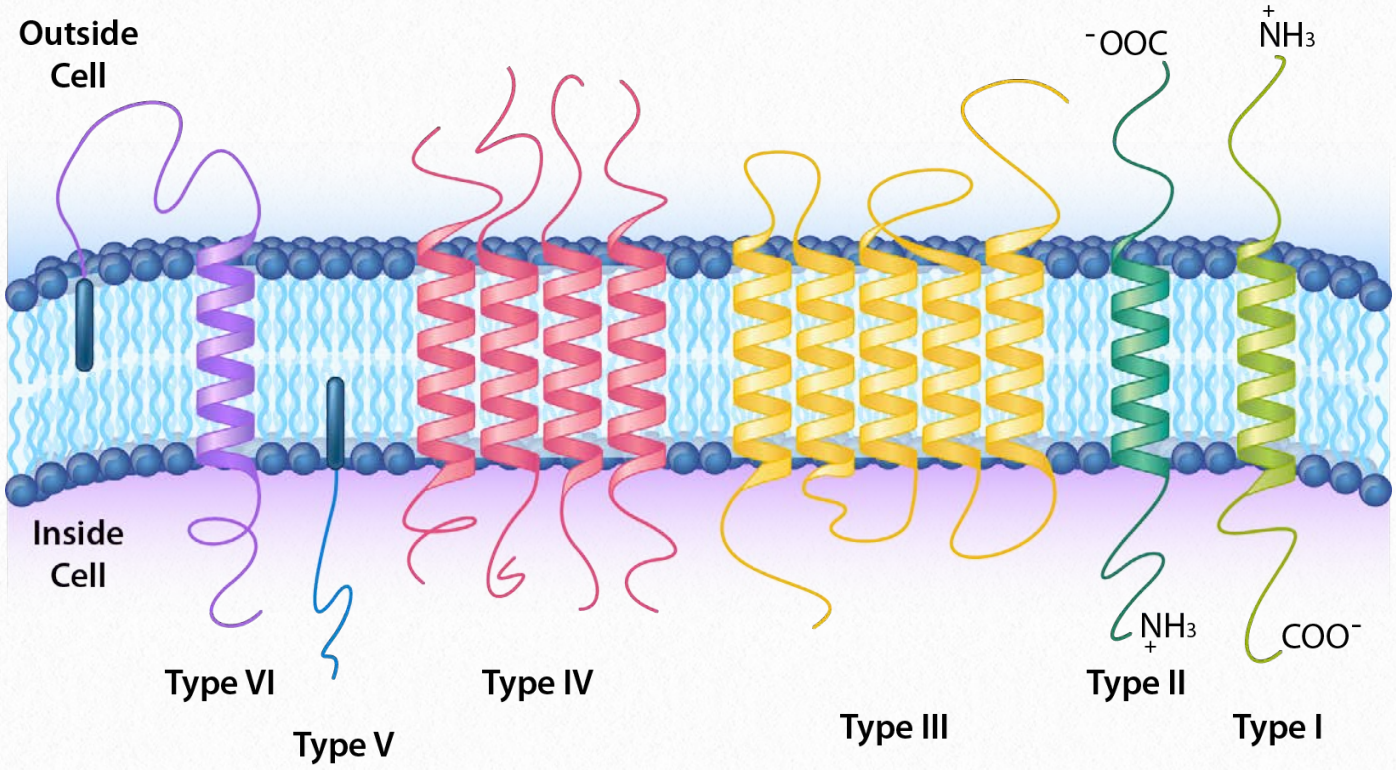

Figure 3.20 Types of integral and anchored membrane proteins

Image by Aleia Kim

teins have this reversed. Type III proteins are a single polypeptide chain that has multiple regions of it cross back and forth across the membrane, often to form a channel. Type IV is a multi-polypeptide protein which has multiple crossings of the membrane. Type V transmembrane proteins do not have a part of them that crosses the membrane, but they are anchored to the membrane by a lipid (such as a fatty acid) embedded in the lipid bilayer. Type VI transmembrane proteins both have a portion of them that crosses the membrane and they are attached to a lipid embedded in the lipid bilayer.

Blood types

Cells have hundreds-thousands of membrane proteins and the protein composition of a membrane varies with its function and location. Glycoproteins embedded in membranes play important roles in cellular identification. Blood types, for example, differ from each other in the structure of the carbohydrate chains projecting out from the surface of the glycoprotein in their membranes (Figure 3.21).

YouTube Lectures by Kevin HERE & HERE

Osmotic pressure

Membranes provide barriers/boundaries for most molecules, but the permeability of water across a lipid bilayer creates a variable that must be considered. The variable here is osmotic pressure. Osmotic pressure (loosely) refers to the tendency of a solution to take in water by the process of osmosis. In Figure 3.22, one can see a visual representation of the concept of the pressure.

A U-shaped tube has at its bottom a semi-permeable membrane. Water can pass through the membrane, but sugar molecules ($C_6H_{12}O_6$) cannot. On the left side, sugar is added creating a concentration difference be-

	Group A	Group B	Group AB	Group O
Red blood cell type	A	B	AB	O
Antibodies in Plasma	Anti-B	Anti-A	None	Anti-A and Anti-B
Antigens in Red Blood Cell	A antigen	B antigen	A and B antigens	None

Figure 3.21 - Blood types arise from cell surface glycoproteins

tween the right and left chambers. Water diffuses across the membrane from right to left in an attempt to equalize the concentrations, causing the level of the right side to decrease and the left side to increase. The pressure resulting from the differences in height is felt at the membrane.

Equalizing concentrations

The liquid on the right does not completely move to the left, though, as might be expected if the only force involved is equalizing the concentration of sugar across the membrane (no sugar on right = no water). Instead, an equilibrium of sorts of water levels is reached even though the concentrations don't equal out. The pressure existing at the membrane then from the differences in level corresponds to the osmotic pressure of the mixture. The osmotic pressure of a solution is the pressure difference needed to halt the flow of solvent across a semipermeable membrane. Osmotic pressure can also be thought of as the pressure required to counter osmosis. The osmotic pres-

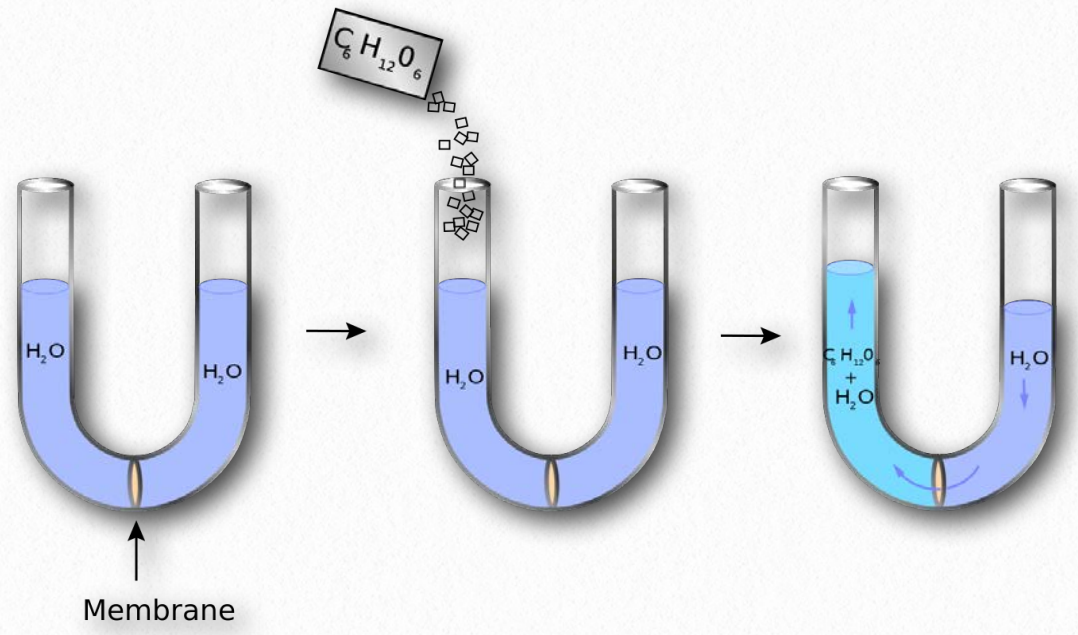

Figure 3.22 - Osmotic pressure. Water diffuses leftwards to try to equalize the solute concentration. The pressure realized at the membrane in the right figure is the osmotic pressure

sure of a dilute solution mathematically behaves like the ideal gas law

$$P_{osmotic} = nRT/V$$

where n is the number of moles, R is the gas constant, T is the temperature in Kelvin, and V is the volume.

It is more convenient in solutions to work with molarity, so

$$P_{osmotic} = MR^*T$$

where M is the molarity of the dissolved molecules, R* is the gas constant expressed in (L atm)/(K mol), and T is the temperature.

The Greek letter Π is used to refer to the $P_{osmotic}$ term, so

$$\Pi = MR^*T$$

Remember when calculating the molarity to include the molarity of each particle. For example, when one dissolves sucrose in solution, it does not split into smaller particles, so $Molarity_{Particles} = Molarity_{Sucrose}$.

However, for salts, like KOH, which forms two ions in solution (K^+ and OH^-),

$Molarity_{Particles} = 2^* Molarity_{KOH}$.

Significant consideration

Osmotic pressure is a significant consideration for cells. Consider the fact that water can move freely across cellular membranes, but most of the contents of the cell, such as proteins, DNA, ions, sugars, etc., cannot. Second, the concentration of these compounds inside the cell is different than the concentration of them outside of the cell. Third, since water can move through the lipid bilayer, it will tend to move in the direction that will tend to equalize solute

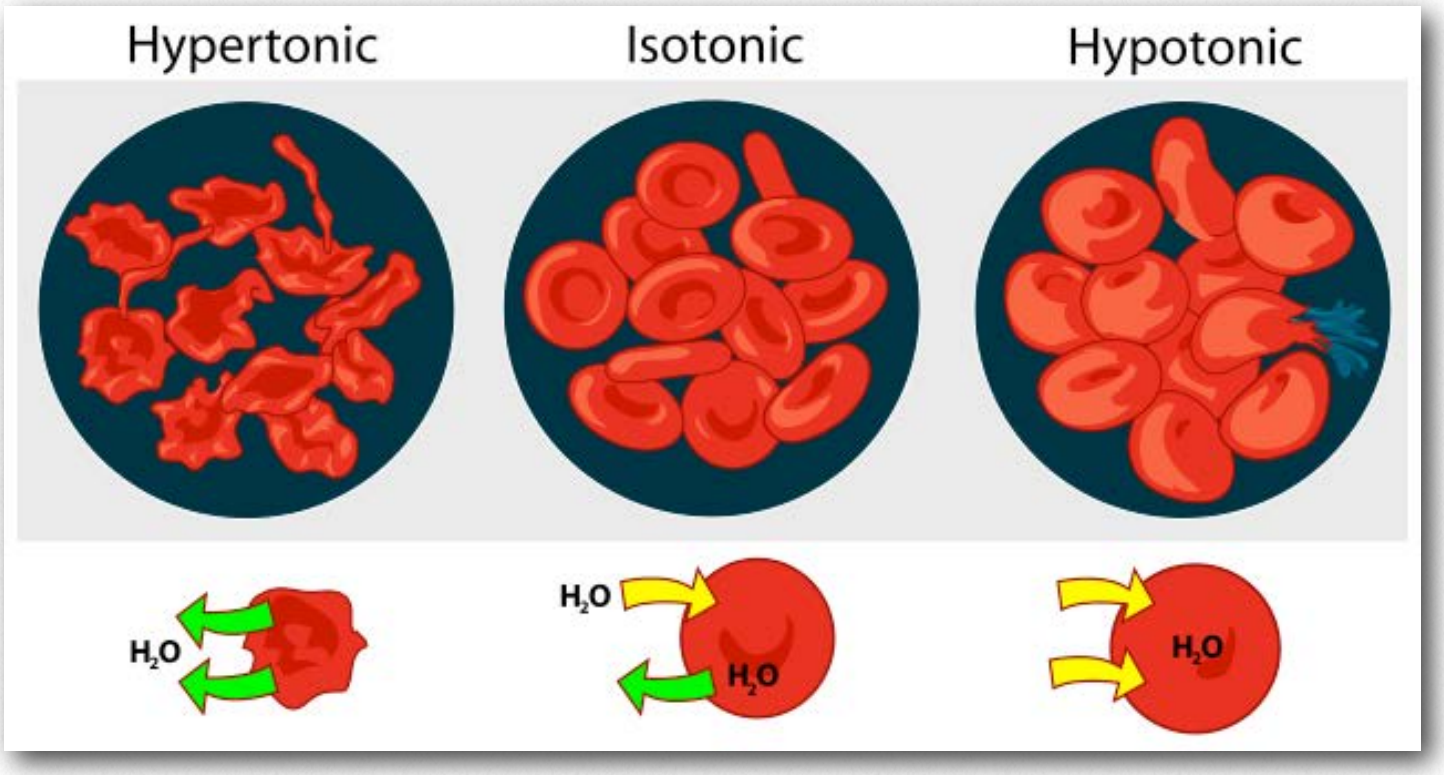

Figure 3.23 - The effect of three different osmotic conditions on red blood cells

concentrations on either side of the membrane.

Hypotonic, hypertonic, isotonic

YouTube Lectures by Kevin HERE & HERE

We consider three situations (Figure 3.23). First, if the concentration of solutes is greater inside the cell than outside, water will tend to move into the cell, causing the cell to swell. This circumstance is called hypotonic. Conversely, if the solute concentration is greater outside the cell than inside of it, water will exit the cell and the cell with shrink. This is a hypertonic situation. Last, if the concentrations of solutes into and outside of the cell is equal, this is called an isotonic solution. Here, no movement of water occurs across the cell membrane and the cell retains its size.

If the osmotic pressure is greater than the forces holding together a cellular membrane, the cell will rupture. Because of this, some cells have built in defenses to prevent problems. Plant cells, for example have a fairly rigid cell wall that resists expansion in hypotonic solutions (Figure 3.24). Bacteria also have a cell wall that provides protection.

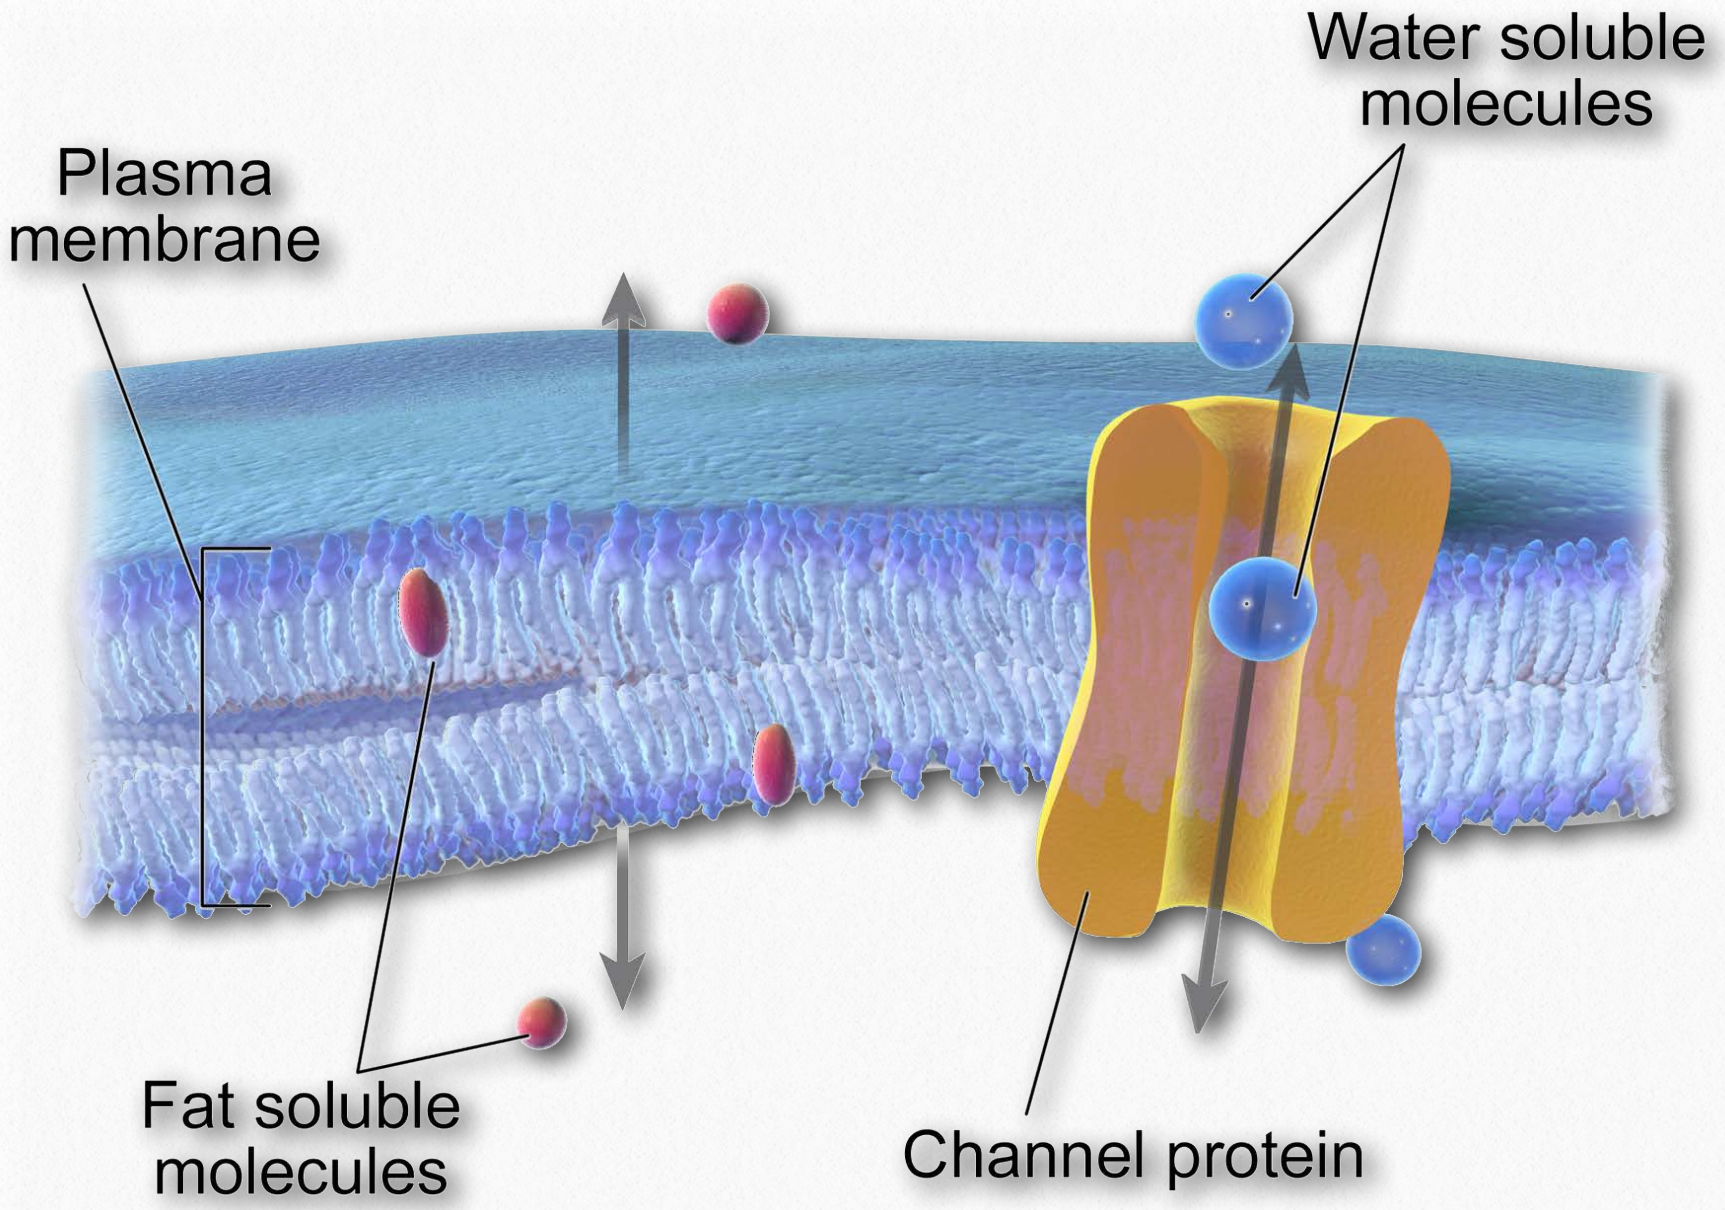
Membranes: Transport



Wikipedia

Movement of materials across membranes

As noted earlier, it is essential for cells to be able to uptake nutrients. This function along with movement of ions and other substances is provided by proteins/protein complexes that are highly specific for the compounds they move.

Selective movement of ions by membrane proteins and the ions' extremely low permeability across the lipid bilayer are important for helping to maintain the osmotic balance of the cell and also for providing for the most important mechanism for it to make ATP - the process of oxidative phosphorylation.

YouTube Lectures by Kevin
HERE & HERE

Terminology

A protein involved in moving only one molecule across a membrane is called a uniport (Figure 3.25). Proteins that move two molecules in the same direction across the membrane are called symports (also called syn-

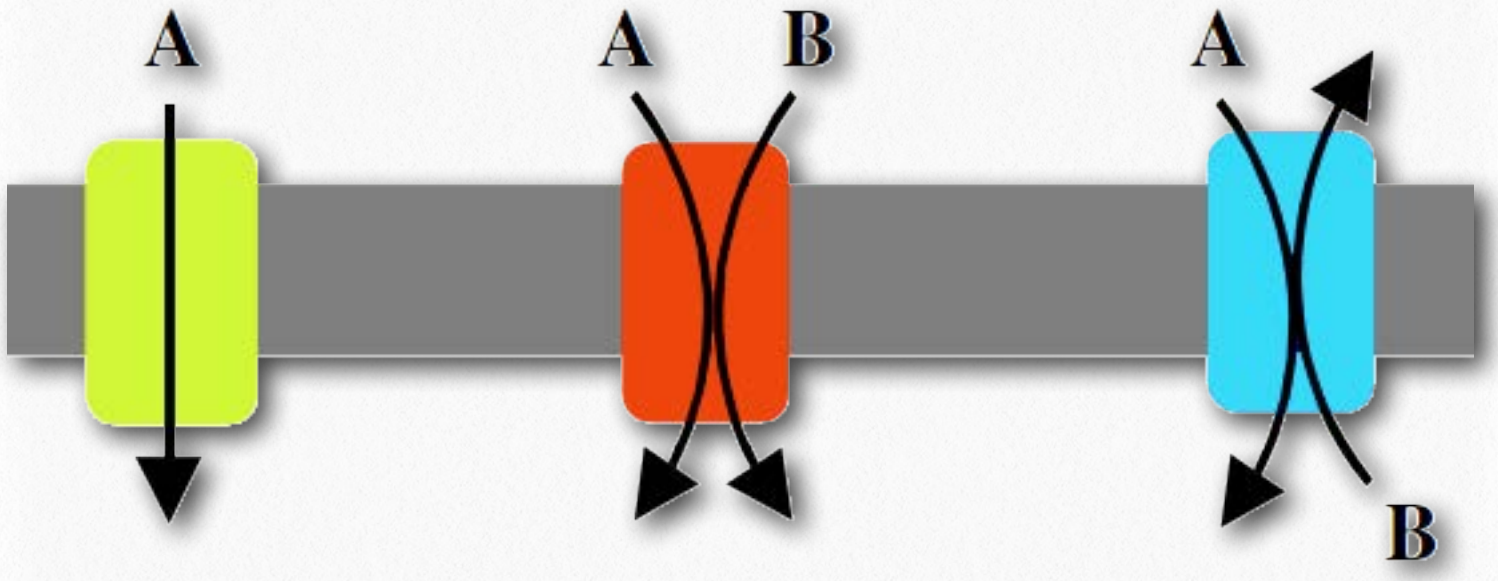


Figure 3.25 - A uniport, a symport, and an antiport

porters, synports, or symporters). If two molecules are moved in opposite directions across the bilayer, the protein is called an antiport. Proteins involved in moving ions are called ionophores.

If the action of a protein in moving ions across a membrane results in a net change in charge, the protein is described as electrogenic and if there is no change in charge the protein is described as electroneutral (Figure 3.26). When the driving force for movement through the membrane protein is simply diffusion, the process is called facilitated diffusion or passive transport and when the process requires other energy input, the process is called active transport.

Channels and transporters

With respect to movement of materials through membrane proteins, there is a difference between channels (sometimes called

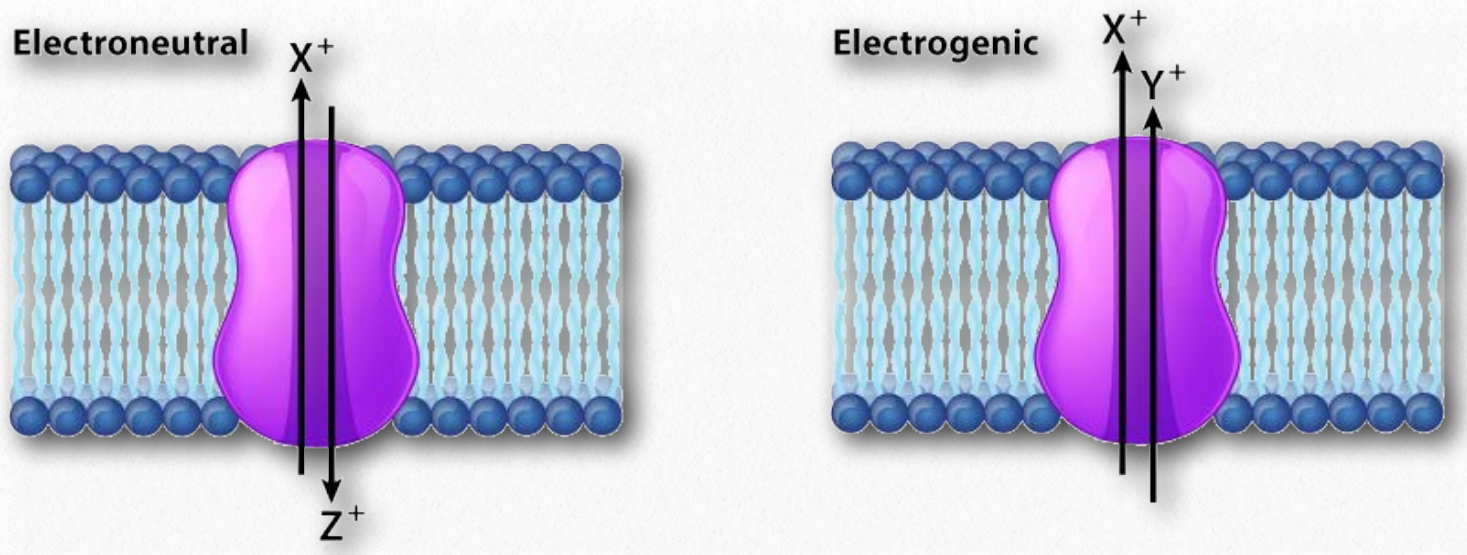

Figure 3.26 - Electroneutral and electrogenic transporters

Image by Aleia Kim

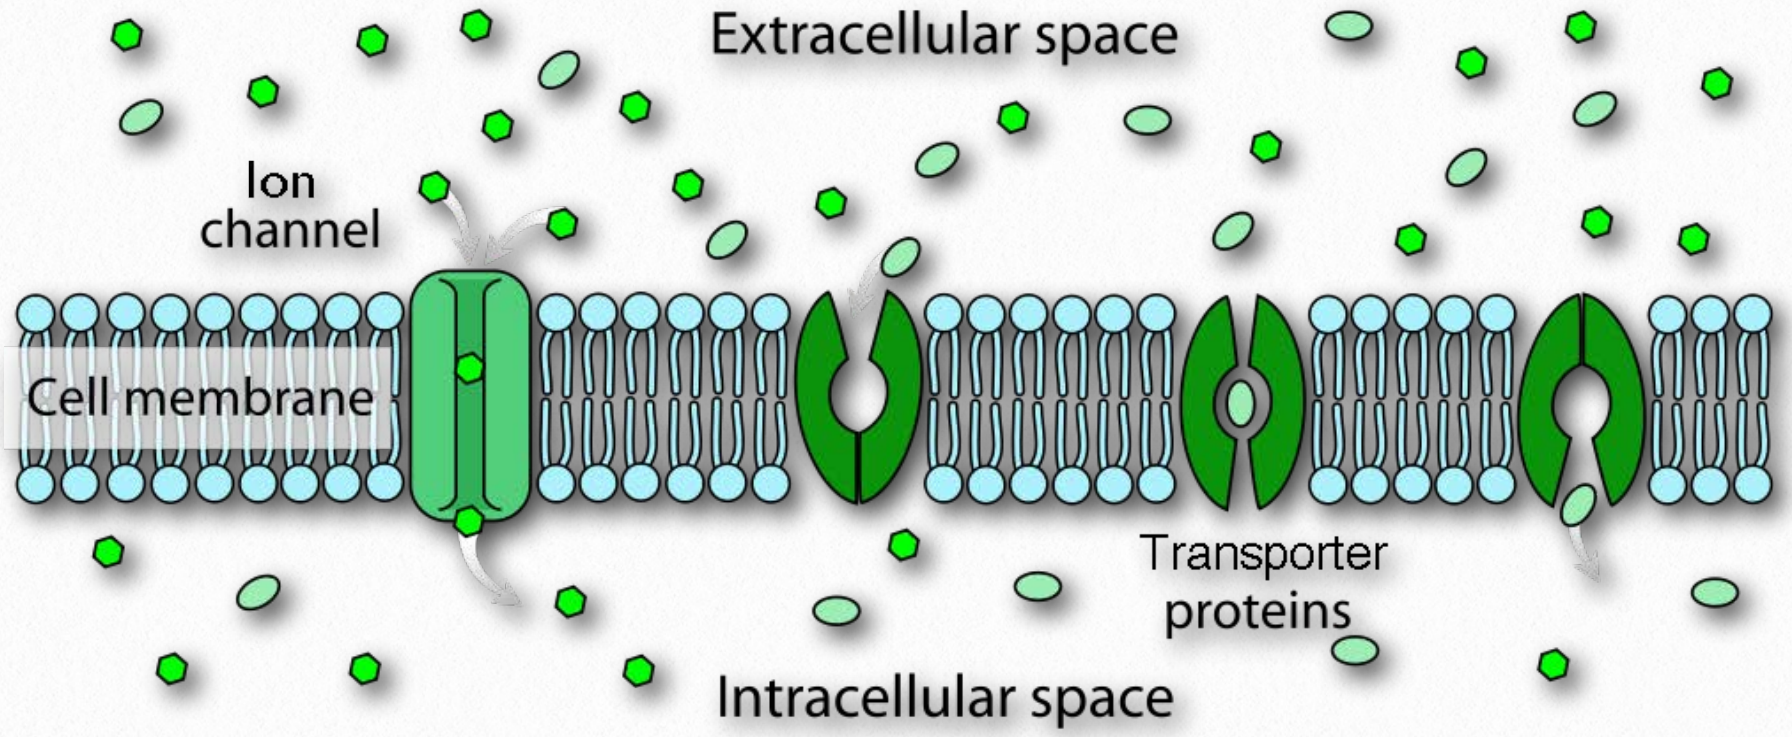

Figure 3.27 - Ion channel and transporter proteins

pores) and transporters. Channels largely provide openings with some specificity and molecules pass through them at close to the rate of diffusion. They usually involve movement of water or ions. Examples would be the sodium or potassium channels of nerve cells. Transporters have high specificity and transfer rates that are orders of magnitude slower. Transport proteins include the sodium-potassium pump, the sodium-calcium exchanger, and lactose permease, amongst many others).

Facilitated diffusion

As noted, the driving force for facilitated diffusion is concentration, meaning that in facilitated diffusion, materials will only move from a higher concentration to a lower concentration and that at the end of the process, the concentration of materials on each side of a bilayer will be equal (Figure 3.28). This may work well in many cases.

For example, the blood concentration of glucose is sufficiently high that red blood cells can use facilitated diffusion as a means of

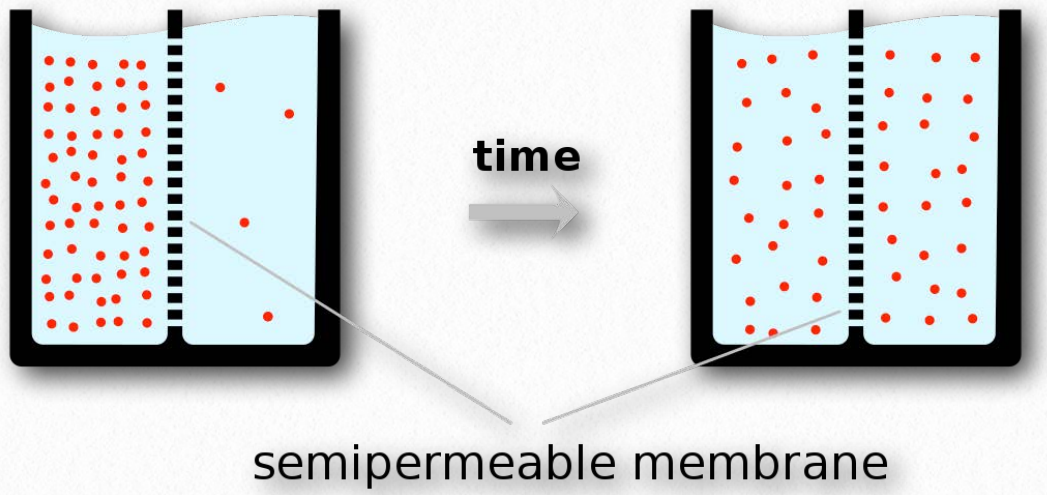

Figure 3.28 - In diffusion, solutes move from high concentration to lower concentration and eventually equalize

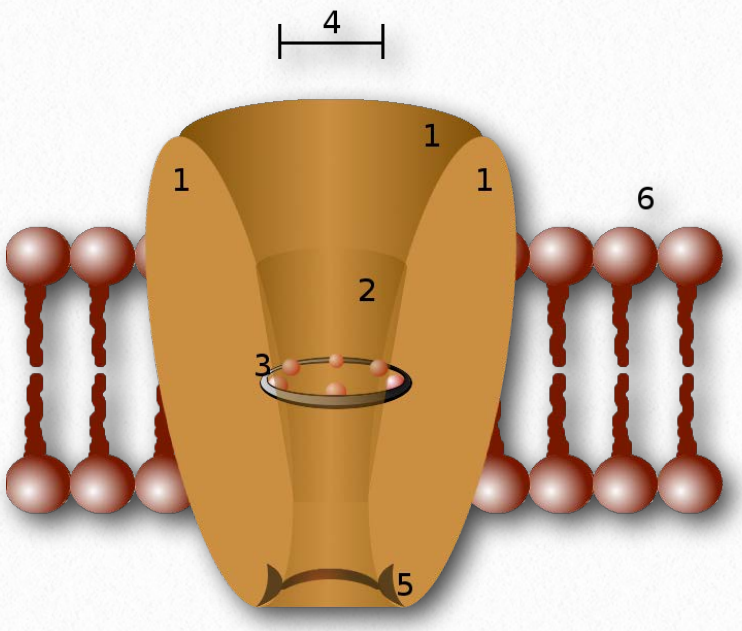

Figure 3.29 - Schematic structure of an ion channel protein - 1 = General structure / 2 = Entrance / 3 = Selectivity filter / 4 = Effective diameter / 5 = Controllable opening

acquiring glucose. Other cells, further removed from the blood supply where the glucose concentration is lower, must use active transport mechanisms because there is not a sufficient concentration of glucose to provide cells with the glucose they need.

Ion channels

Ion channels are pore-forming membrane proteins in the membranes of all cells that regulate movement of selected ions across a membrane (Figures 3.29 & 3.30). They help to establish the resting membrane potential and to affect action potentials and other electrical signals. They are very important in the process of nerve transmission. Ion channels control the flow of ions across secretory and epithelial cells, and consequently help to regulate cell volume by affecting osmotic pressure.

Ion channels are essential features of almost all cells, functioning as selective "tunnels" that restrict movement through them to ions with specific characteristics (typically size). The size of the opening is very narrow (usually one or two atoms wide) and is able to select even against ions that are too small.

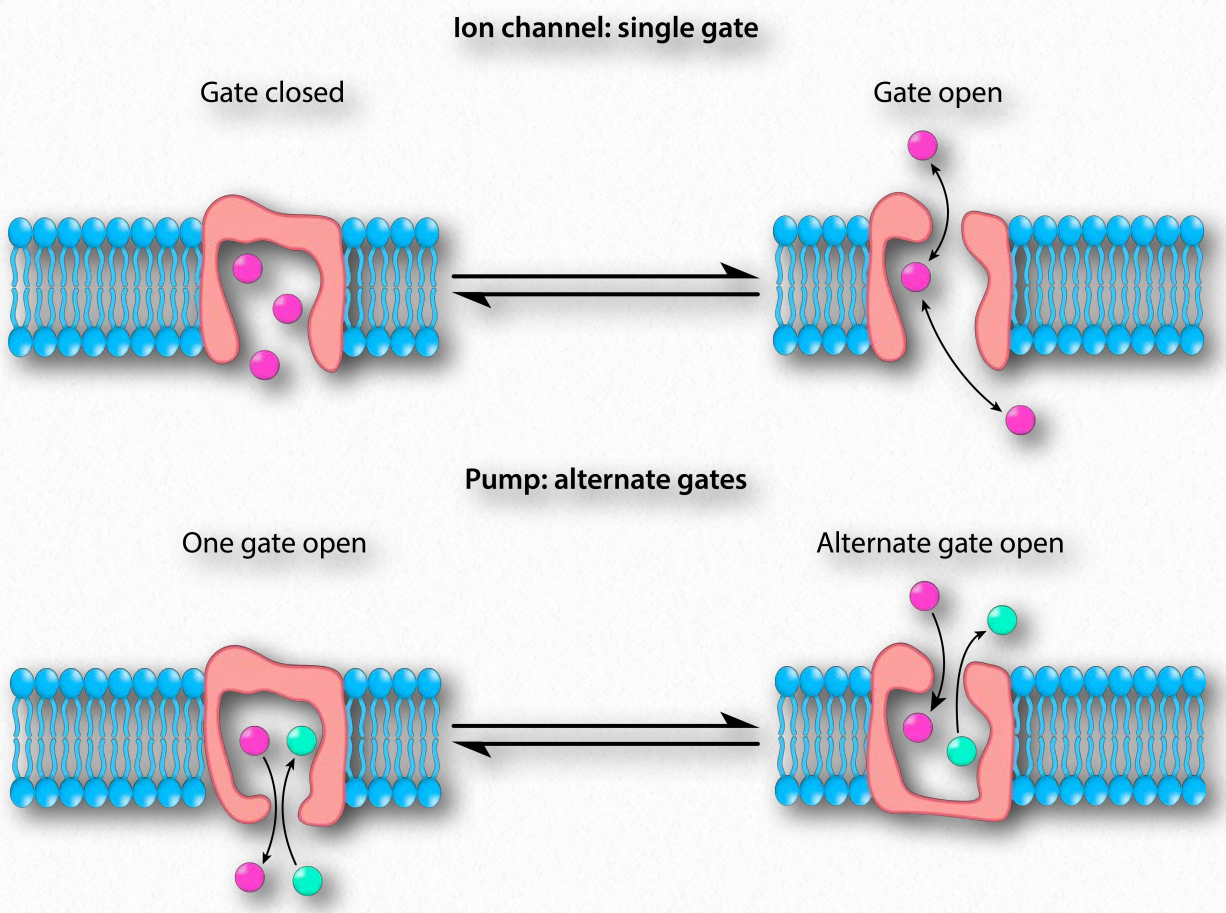

Figure 3.30 - Two types of ion channel - single and double gates

Image by Pehr Jacobson

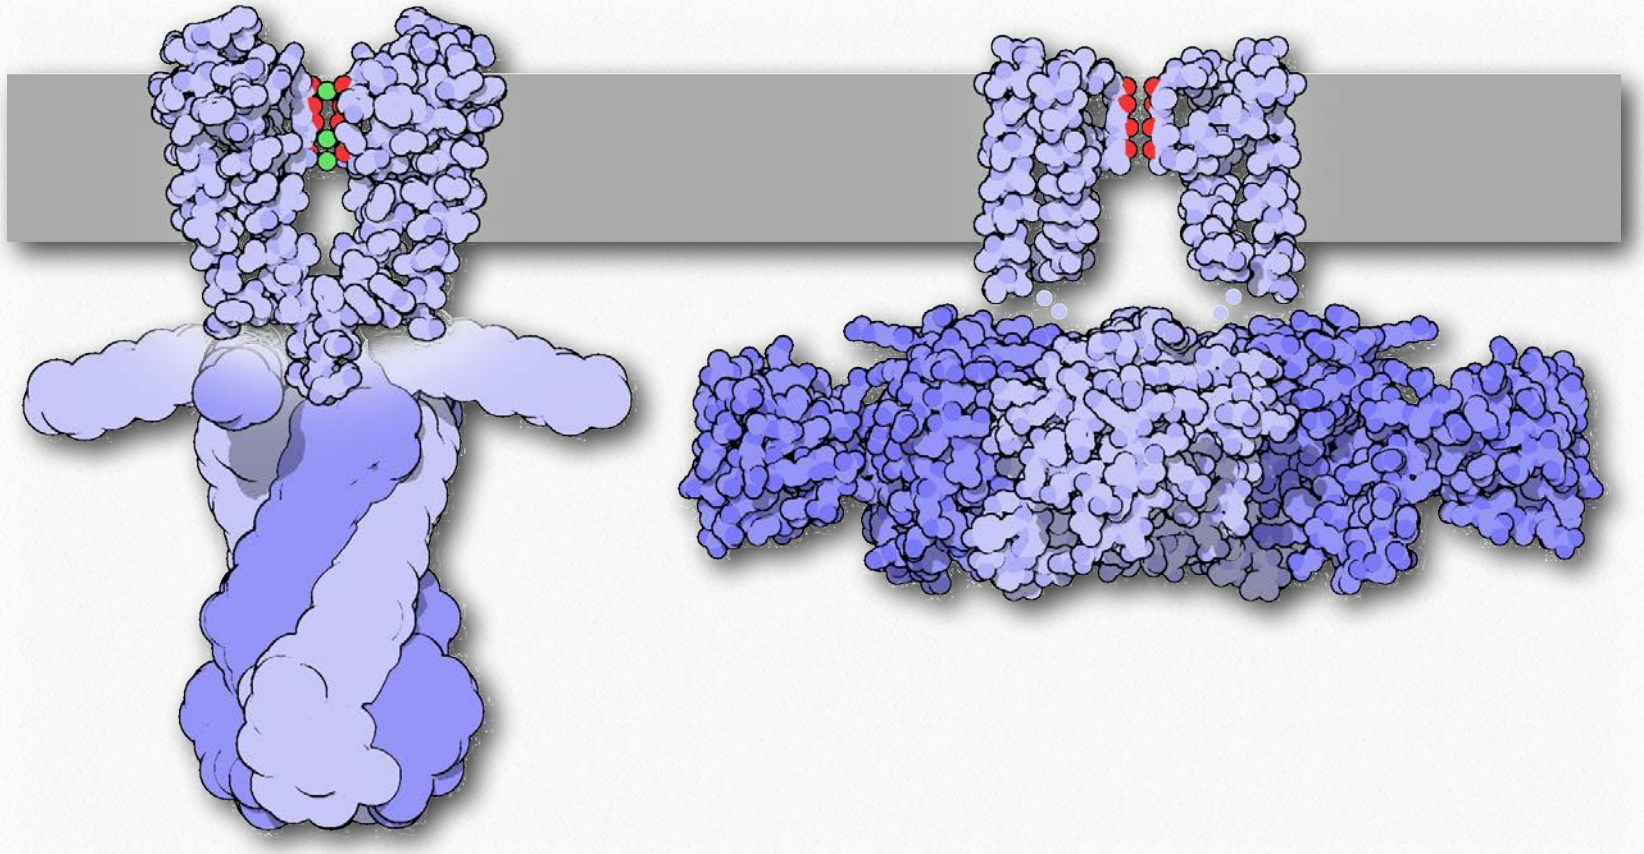

Figure 3.31 - **A potassium channel closed (left) and open (right)**

Wikipedia

Control mechanisms

Ion channels are controlled by mechanisms that include voltage, ligands, light, temperature, and mechanical deformation (stretch activated). Ligand-gated ion channels (LGICs) are transmembrane proteins which open to selectively allow ions such as Na^+, K^+, Ca^{++}, or Cl^- to pass through the membrane in response to the binding of a ligand messenger.

Sound waves cause mechanical deformation of hair cells in the ear. This results in the opening of ion channels and initiation of a nerve signal to the brain.

YouTube Lectures by Kevin HERE & HERE

Sodium ion channels in the tongue for sugar receptors open in response to binding of sucrose, allowing sodium concentration in the nerve cell to increase and initiate a nerve signal to the brain. In this case, the default for the gate is to be closed and it opens in response to binding of a ligand (sucrose).

In light sensing cells of the eye, calcium gates are open by default, but stimulation by light causes them to close, triggering a series of events that result in a signal being sent the brain about the perception of light. Thus, in this case, the stimulus (light) causes an open channel to close.

Moving the other direction, nerve signals originating in the brain travel to muscle tissue and through a complicated set of exchanges, result in the opening of calcium gates of muscle cells, increasing the concentration of calcium and stimulating muscular contraction (see HERE).

Voltage gated channels are essential for transmission of nerve signals, a process discussed in more depth HERE.

Ion movement through channels

The ability of ion channels to select against ions too large is intuitive - the size of the opening in the ion channel simply isn't big enough for a larger ion to fit through the opening. Potassium, for example, passes through sodium channels rarely because the opening is too small.

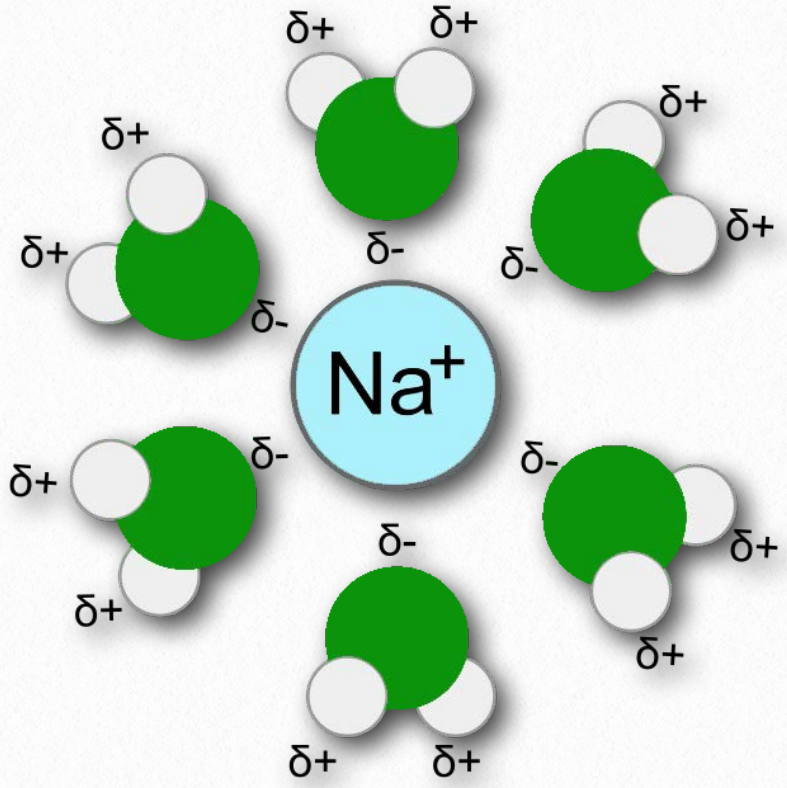

Figure 3.32 - Sodium surrounded by water molecules in a hydration shell

Potassium channels that are selective for potassium ions must be big enough to allow potassium to enter, but if size were the only selection means, then sodium ions would also readily pass through potassium channels, since sodium ions (0.95 Å) are smaller than potassium ions (1.33 Å). In order for potassium channels to select against sodium ions and favor potassium ions, other considerations come into play.

Hydration shell

To understand this unique selectivity, it is important to understand how ions move through channels. Before an ion can pass through a channel, it must first be dissociated from (stripped of) the water molecules in its hydration shell - water molecules surrounding ions in aqueous solutions (Figure 3.32). This process requires an input of energy. The initial energy required to strip the water molecules from the hydration shell has been compared to the activation energy of an enzymatic reaction.

Comparable to enzymes

Just as enzymes lower the activation energy of enzymatic reactions and thus allow them to more readily occur, so too do channel proteins

lower the energy requirements for a molecule to traverse a lipid bilayer. In the absence of the channel protein, the dehydration energy is mostly prohibitive for most polar molecules to occur, so very few make it across the lipid bilayer without the channel protein. This is why ion channel/transport proteins are so important to the cell.

After the water has been stripped, the ion can pass through the channel and when it arrives at the other side of the channel, the diffusing ion becomes rehydrated, thus regaining the energy that was required initially to strip away the water molecules from the ion.

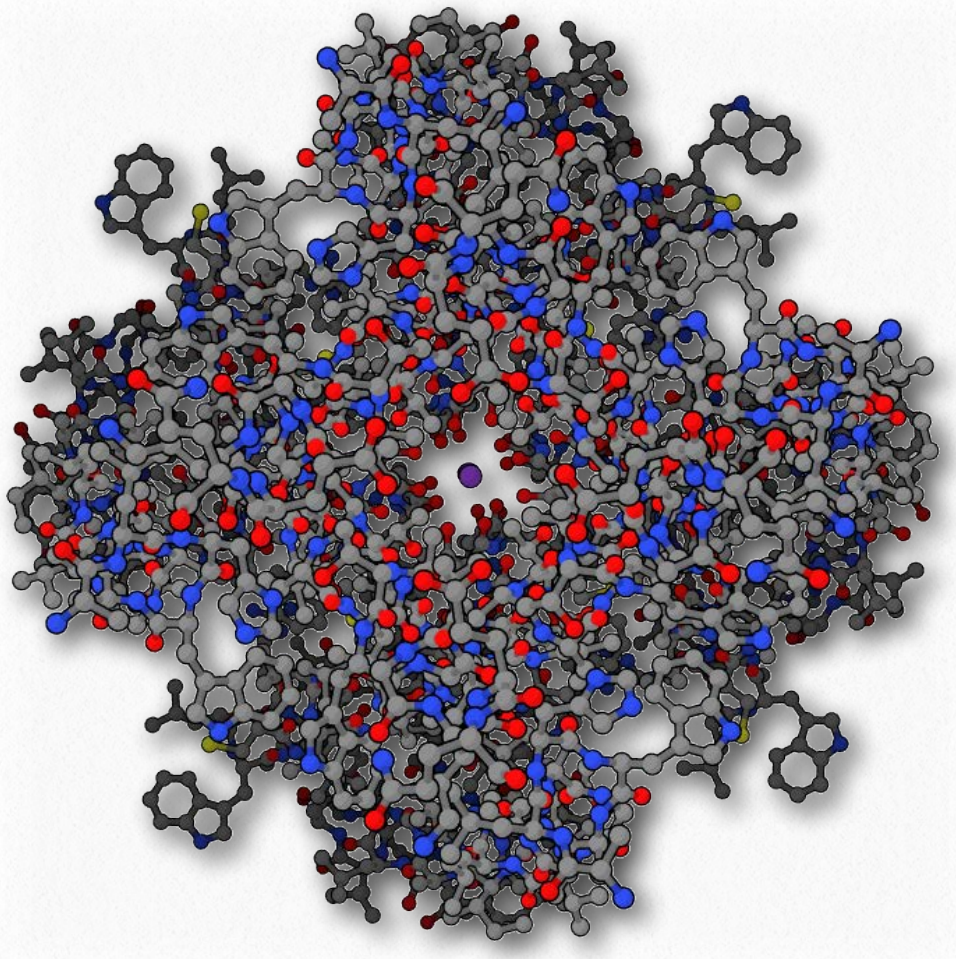

Figure 3.33 - A potassium ion (center) transiting the potassium channel

Selectivity of the potassium channel

The potassium channel (Figure 3.33) uses the dimensions of the potassium ion precisely to shepherd it through the channel. The sodium ion, which has different dimensions has a more difficult time making it through the channel despite its smaller size. The reason this is rooted in the energy required for dehydration.

For potassium ions, after the water has been stripped off, precisely positioned carbonyl groups along the channel help to stabilize the ion as it moves. The sodium ion, on the other hand is too small and does not make efficient connections with carbonyl groups and thus has a more difficult path. Because of this, the energy difference between dehydration and rehydration of a sodium ion in a potassium channel is energetically unfavorable (requires net input of energy) but the same process for a potassium ion is energetically favorable (results in a net gain of energy).

Energy factor

Thus the selection in favor of potassium and against sodium ions in a potassium channel is based on energy, not physical size, whereas in

Movie 3.1 - Gramicidin A

Wikipedia

Gramicidin

Gramicidins (Movie 3.1) are antibiotic polypeptides synthesized by the soil bacterium known as *Bacillus brevis.* These small pentadecapeptides (15 amino acids) are synthesized by the bacterium to kill other bacteria.

When released by the *Bacillus brevis*, the gramicidins insert themselves in the membranes of Gram positive bacteria and allow the movement of sodium ions into the target cells, ultimately killing them. Gramicidins can also cause hemolysis in humans so they cannot be used internally, but instead are used topically.

the selection of sodium ions over potassium ions in a sodium channel, size is the primary consideration.

Ion balance

The movement of ions across a lipid bilayer is tightly regulated, and with good reason. Maintaining a proper balance of ions inside and outside of cells is important for maintaining osmotic balance. It is also important inside and outside of organelles like the mitochondria and chloroplasts for energy generation. If the ionic balance of a cell is sufficiently disturbed by an uncontrolled ionophore, a cell may die.

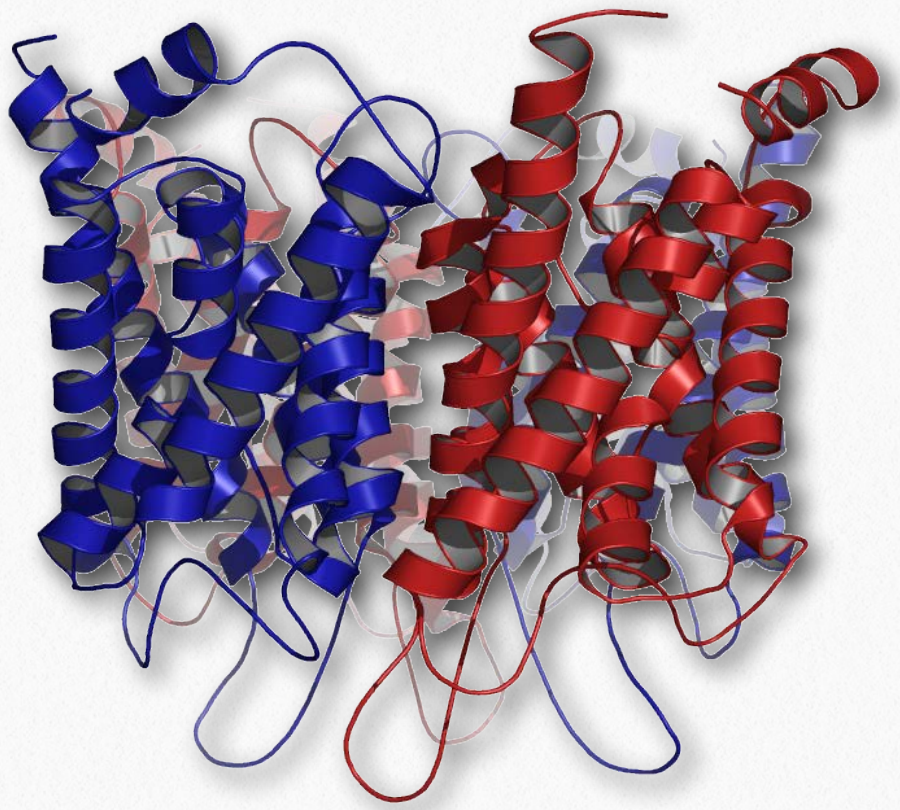

Figure 3.34 - View of aquaporin from the side

Wikipedia

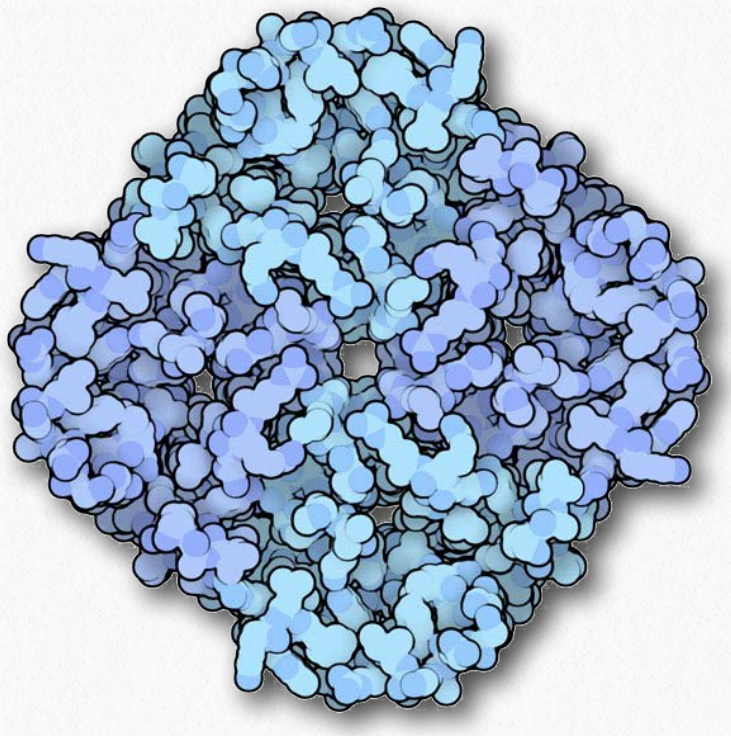

Figure 3.35 - View of aquaporin from the top

Wikipedia

Aquaporins

Aquaporins are pore-containing integral membrane proteins that selectively permit passage of water molecules in and out of the cell, while preventing ions and other solutes from moving (Figures 3.34 & 3.35). Some aquaporins called aquaglyceroporins, also transport other small uncharged entities, such as glycerol, ammonia, urea, and CO_2, across the membrane,. The water pores are completely impermeable to charged molecules, such as protons, which is important for the preserving the membrane's electrochemical potential difference.

Porins

Porins are proteins containing a β-barrel structure that crosses the cell membrane/ wall and acts as a pore/channel through which specific molecules diffuse. Porins are found in the outer membrane of Gram-negative bacteria and some Gram-positive bacteria, mitochondria, and chloroplasts.

Porins typically transport only one group of molecules or, in some cases, one specific molecule. Antibiotics, such as β-lactam and fluoroquinolone pass through porins to reach the cytosol of Gram negative bacteria. Bacteria may develop resistance to these antibiotics when a mutation occurs to the porin involved that results in exclusion of the antibiotics that would otherwise pass through.

Transporter proteins

Not all facilitated transport occurs through ion channel proteins. Transporter proteins, as noted earlier (HERE and Figure 3.27) facilitate movement of materials across a lipid bilayer, but are slower than ion channels. Figure 3.36 illustrates a transporter protein in action. As can be seen, transporter proteins rely on a specific receptor site for proper recognition of the molecule to be moved.

Binding of the proper molecule causes a conformational change in the shape of the protein (an eversion) which results in a flipping of the open side of the protein to the other side of the lipid bilayer. In this way, the molecule is moved. Like ion channels, transporter proteins facilitate movement of materials in ei-

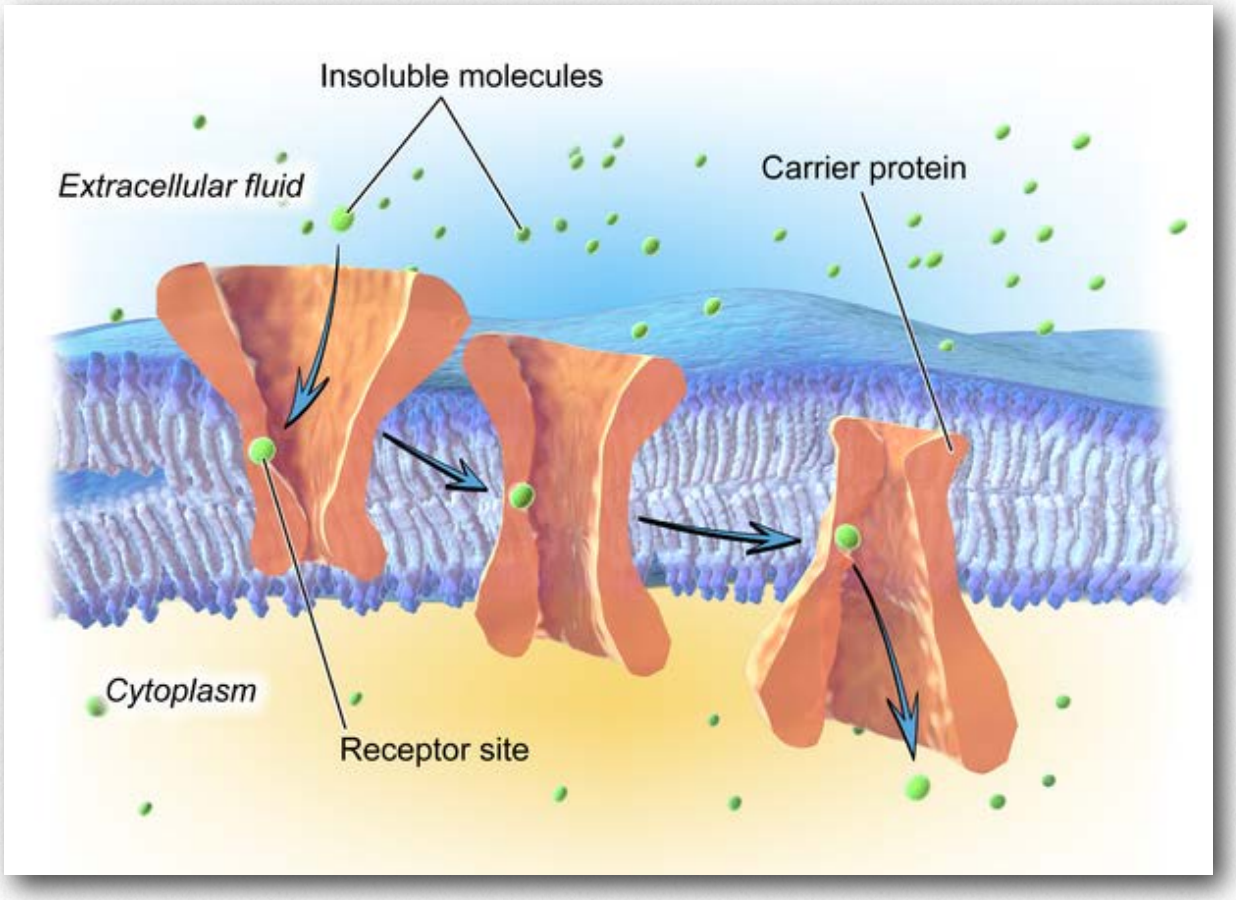

Figure 3.36 - Facilitated diffusion with a transporter protein
Wikipedia

ther direction, driven only by the concentration difference between one side and the other.

Active transport

All of the transport mechanisms described so far are driven solely by a concentration gradient - moving from higher concentrations in the direction of lower concentrations. These movements can occur in either direction and, as noted, result in equal concentrations on either side of the bilayer, if allowed to go to completion. Many times, however, cells must move materials against a concentration gradient and when this occurs, another source of energy is required. This process is known as active transport.

YouTube Lectures by Kevin HERE & HERE

A good definition of active transport is that in active transport, at least one molecule is being moved against a concentration gradient. A common, but not exclusive, energy source is ATP (see Na^+/K^+ ATPase), but other energy sources are also employed. For example, the sodium-glucose transporter uses a sodium gradient as a force for actively transporting glucose into a cell. Thus, it is important to know that not all active transport uses ATP energy.

Na^+/K^+ ATPase

An important integral membrane transport protein is the Na^+/K^+ ATPase antiport (Figures 3.37 and 3.38), which moves three sodium ions out of the cell and two potassium ions into the cell with each cycle of action. In each case, the movement of ions is against the concentration gradient. Since three positive charges are moved out for each two positive charges moved in, the system is electrogenic.

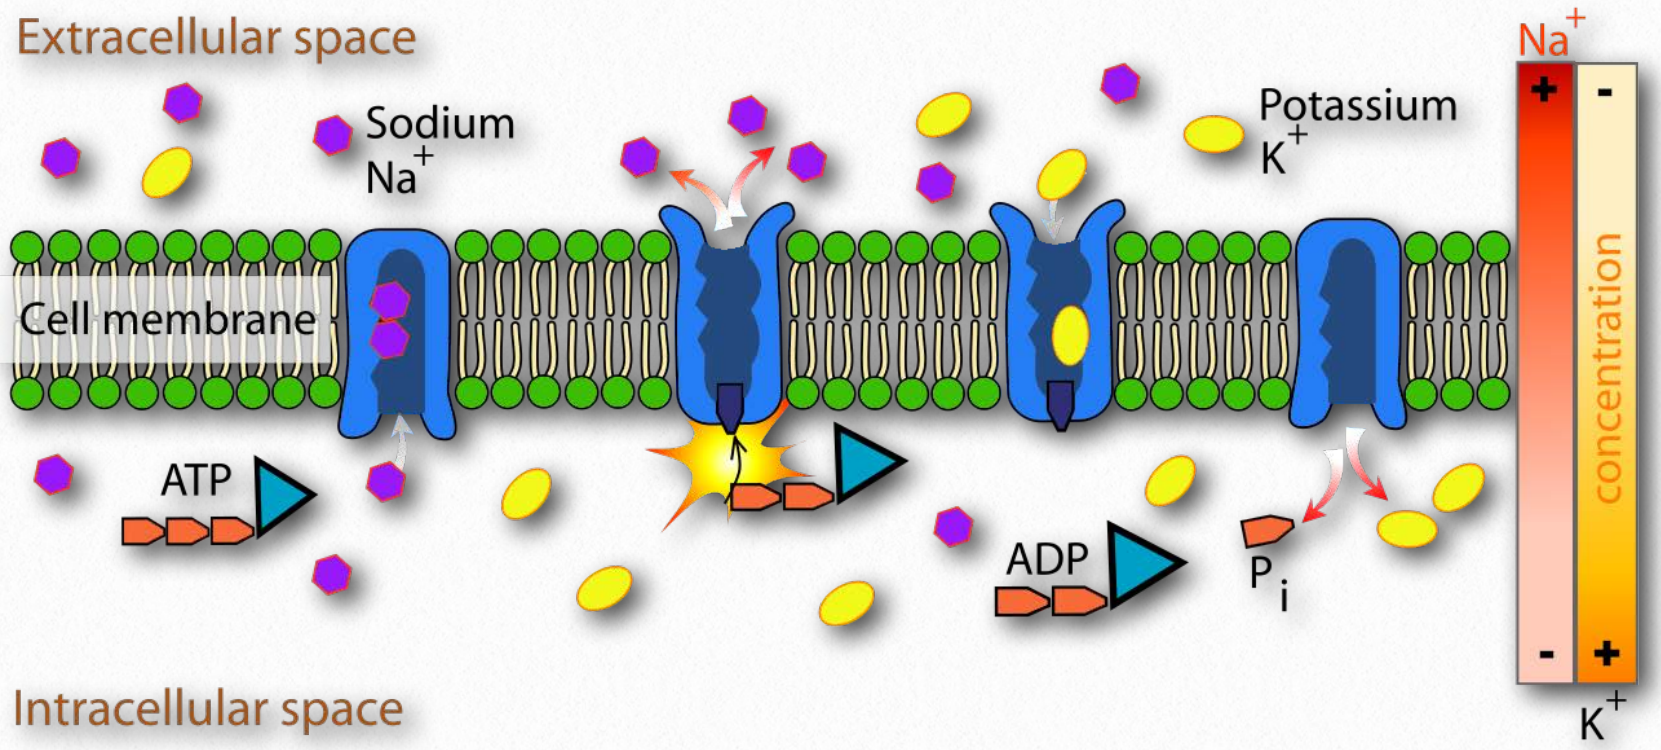

Figure 3.37 - An overview of active transport by the Na^+K^+ ATPase

The protein uses the energy of ATP to create ion gradients that are important both in maintaining cellular osmotic pressure and (in nerve cells) for creating the sodium and potassium gradients necessary for signal transmission. Failure of the system to function results in swelling of the cell due to movement of water into the cell through osmotic pressure. The transporter expends about one fifth of the ATP energy of animal cells. The cycle of action occurs as follows:

1. Pump binds ATP followed by binding of 3 Na^+ ions from cytoplasm of cell

2. ATP hydrolysis results in phosphorylation of aspartate residue of pump. ADP is released

3. Phosphorylated pump undergoes conformational change to expose Na^+ ions to exterior of cell. Na^+ ions are released.

4. Pump binds 2 extracellular K^+ ions.

5. Pump dephosphorylates causing it to expose K^+ ions to cytoplasm as pump returns to original shape.

6. Pump binds 3 Na^+ ions, binds ATP and releases 2 K^+ ions to restart process

The Na^+/K^+ ATPase is classified as a P-type ATPase. This category of pump is notable for having a phosphorylated aspartate intermediate and is present across the biological kingdoms - bacteria, archaeans, and eukaryotes.

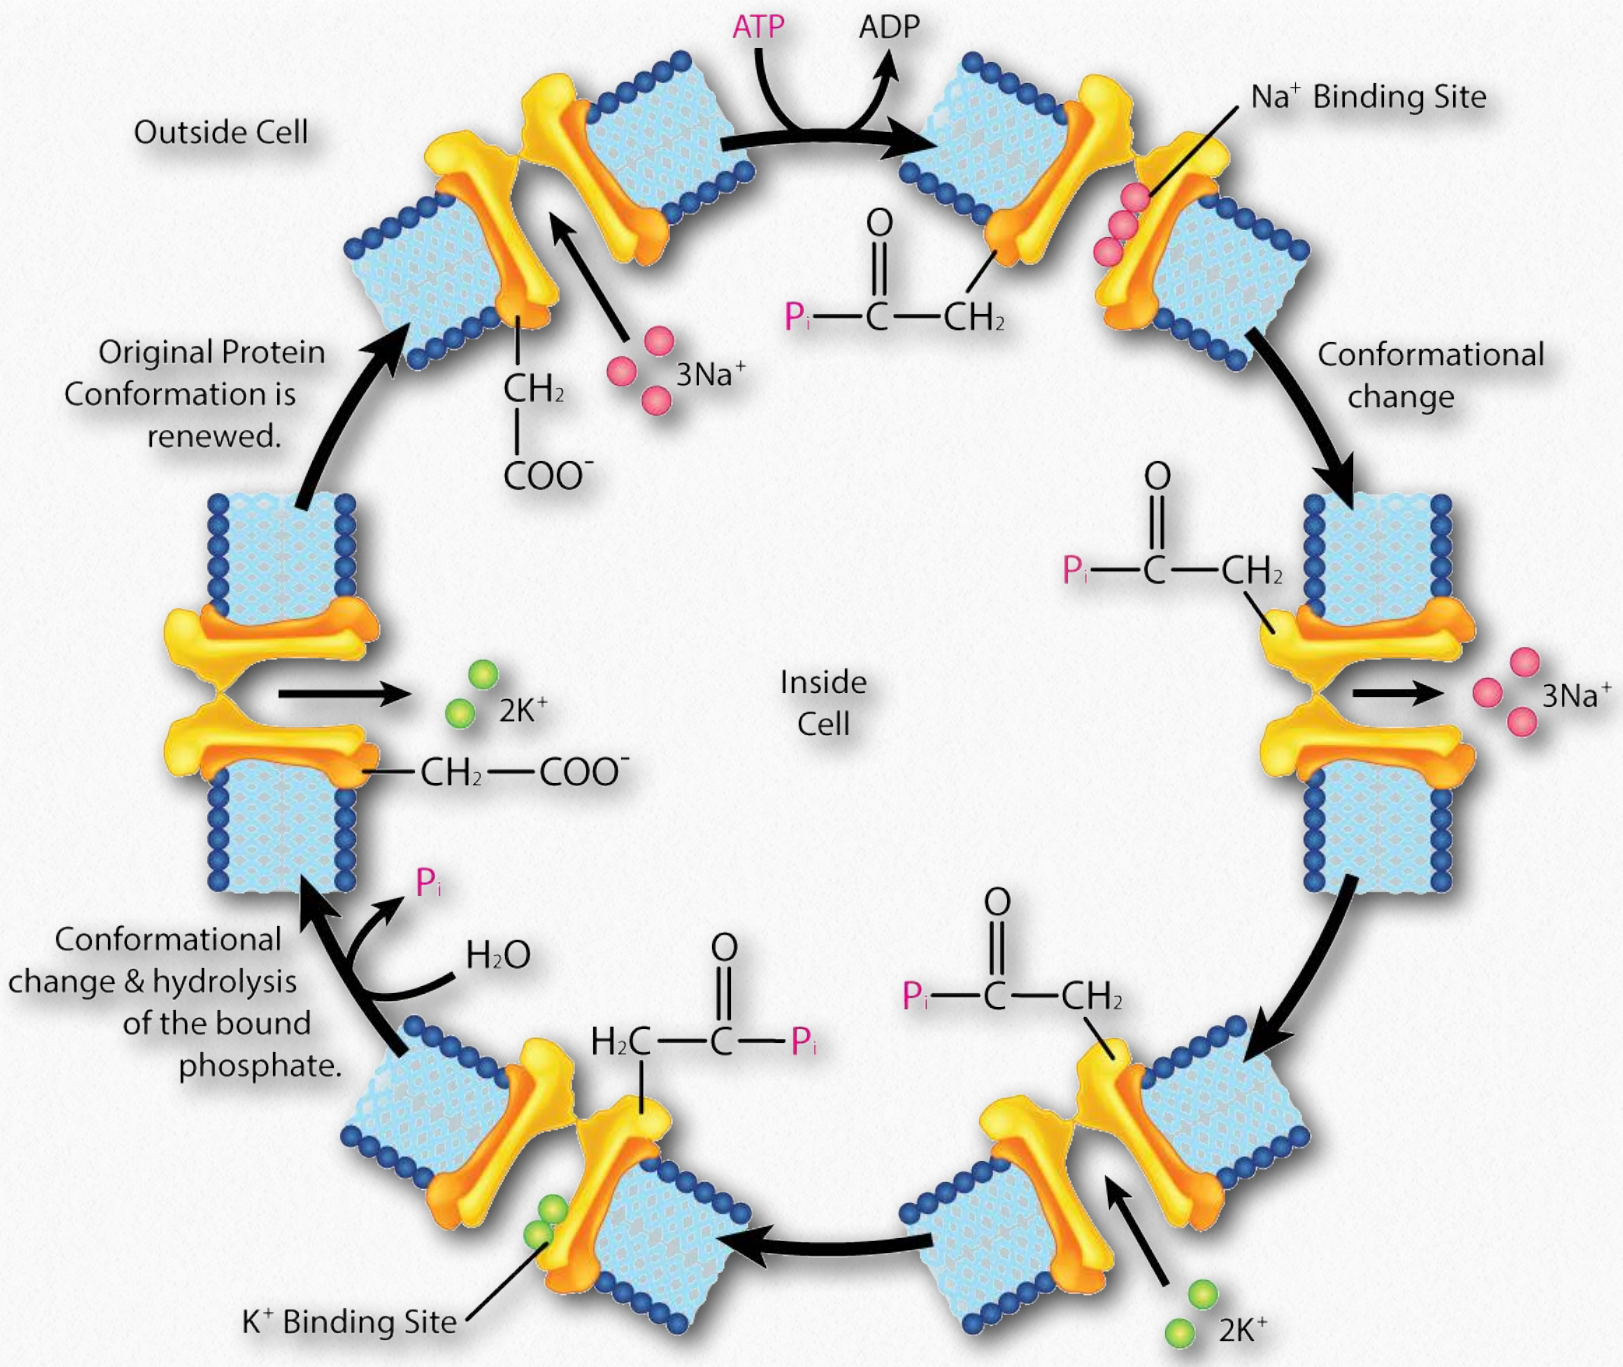

Figure 3.38 - Sequential steps in the active transport of ions by the Na^+K^+ ATPase

Wikipedia

ATPase types

ATPases have roles in either the synthesis or hydrolysis of ATP and come in several different forms.

• F-ATPases (F_1F_O-ATPases) are present in mitochondria, chloroplasts and bacterial plasma membranes and are the prime ATP synthesizers for these systems. Each uses a proton gradient as its energy source for ATP production. Complex V of the mitochondrion is an F-type ATPase.

• V-ATPases (V_1V_O-ATPases) are mostly found in vacuoles of eukaryotes. They utilize energy from ATP hydrolysis to transport solutes and protons into vacuoles and lysosomes, thus lowering their pH values.

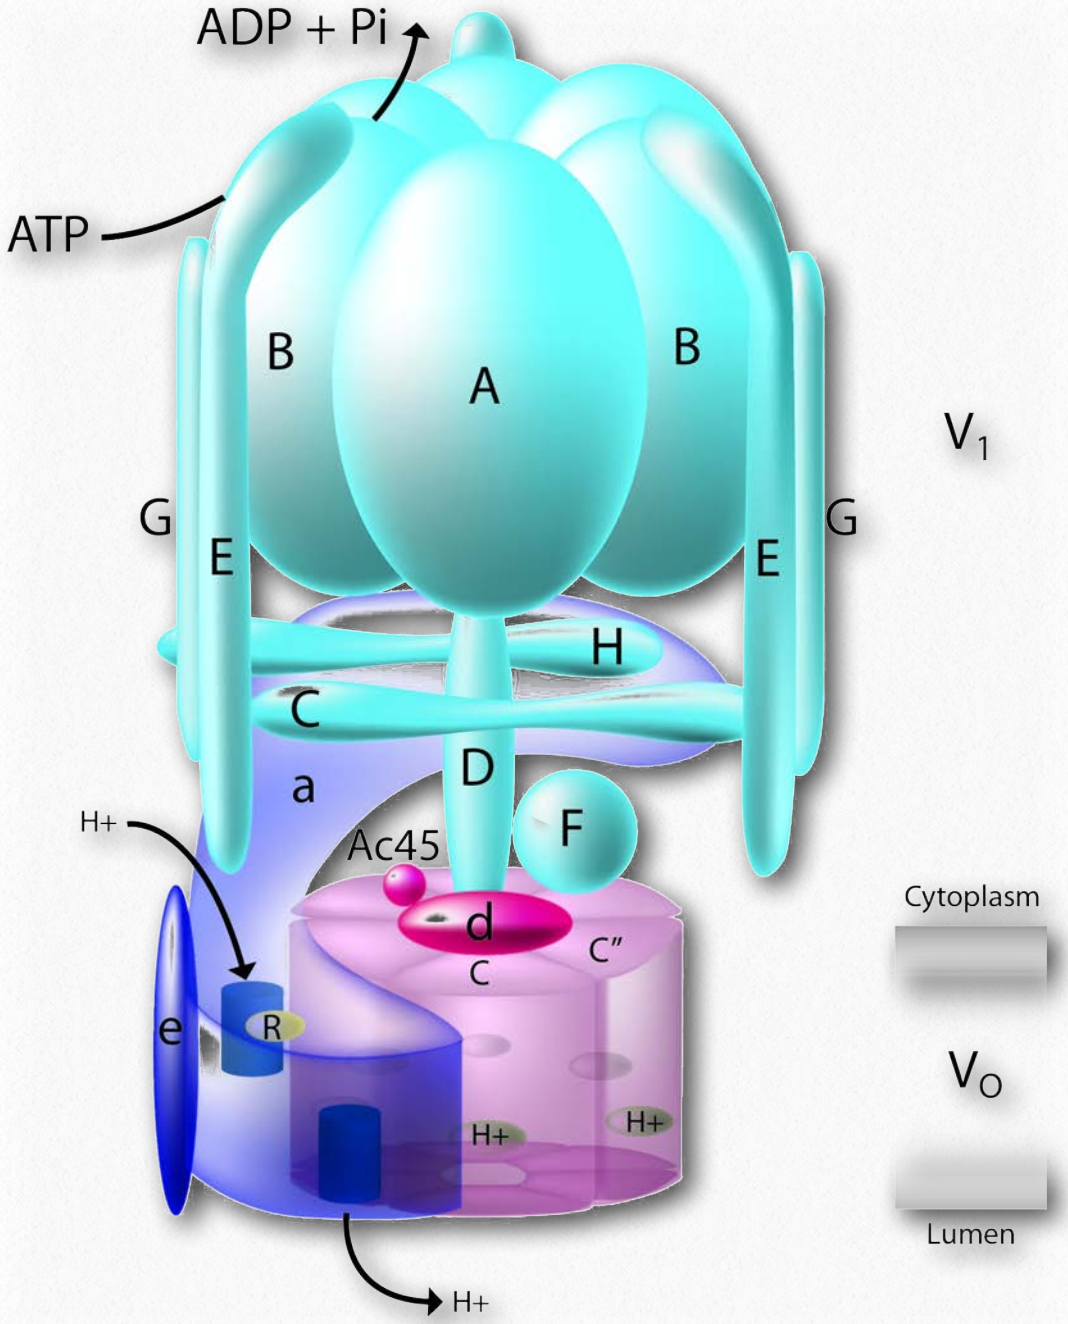

Figure 3.39 - Schematic structure of V-ATPases
Wikipedia

The V-type and F-type ATPases are very similar in structure. The V-type (Figure 3.39) uses ATP to pump protons into vacuoles and lysosomes, whereas F-types use proton gradients of the mitochondria and chloroplasts to make ATP.

• A-ATPases (A_1A_O-ATPases) are found in archaeans and are similar to F-ATPases in function.

• P-ATPases (E_1E_2-ATPases) are in bacteria, fungi and in eukaryotic plasma membranes and organelles. They transport a diversity of ions across membranes. Each has a common mechanism of action which include autophosphorylation of a conserved aspartic acid side chain within it. Examples of P-type ATPases include the Na+/K+ ATPase and the calcium pump.

• E-ATPases are enzymes found on the cell surface. They hydrolyze a range of extracellular nucleoside triphosphates, including ATP.

Nerve transmission

Now that you have seen how the Na^+/K^+ ATPase functions, it is appropriate to discuss how nerve cells use ion gradients created with it to generate and transmit nerve signals. Neurons are cells of the nervous system that use chemical and electrical signals to rapidly transmit information across the body (Figure 3.40). The sensory nerve system links receptors for vision, hearing, touch, taste, and smell to the brain for perception. Motor neurons run from the spinal cord to muscle cells. These neurons have a cell body and a very long, thin extension called an axon, that stretches from the cell body in the spinal cord all the way to the muscles they control. Nerve impulses travel down the axon to

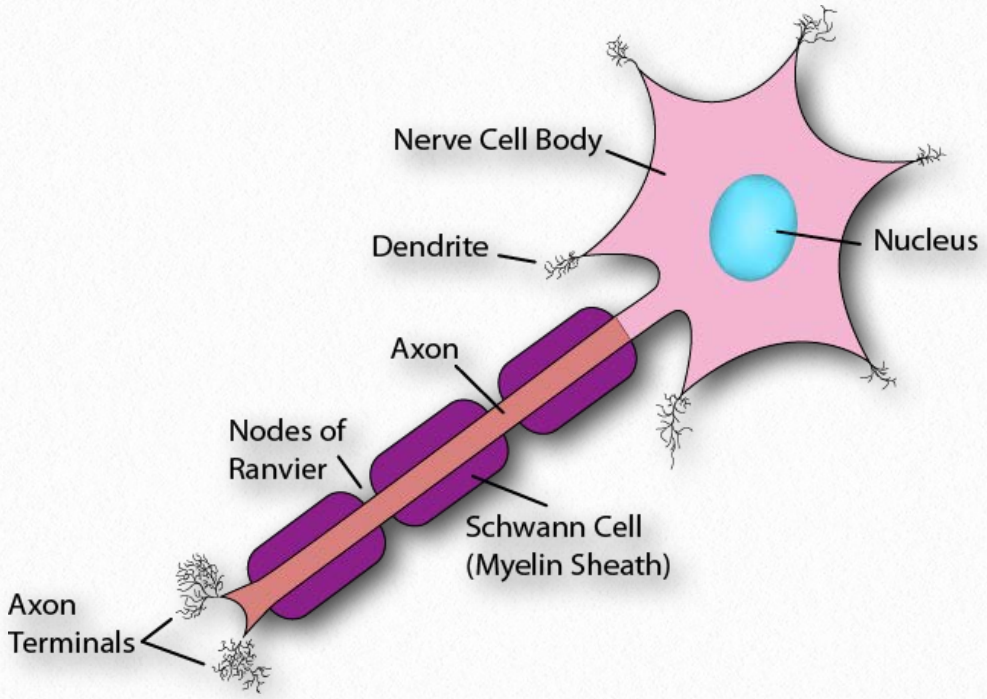

Figure 3.40 - Anatomy of a nerve cell

Image by Pehr Jacobson

the neuron releases neurotransmitters that exit the nerve cell and travel across the junction to a recipient cell where a response is generated. That response may be creating another nerve signal, if the adjacent cell is a nerve cell or it may be a muscular contraction if the recipient is a muscle cell (Figure 3.41).

stimulate muscle contraction.

Signals travel through neurons, ultimately arriving at junctions with other nerve cells or target cells such as muscle cells. Note that neurons do not make physical contact with each other or with muscle cells. The tiny space between two neurons or between a neuron and a muscle cell is called the synaptic cleft. At the synaptic cleft,

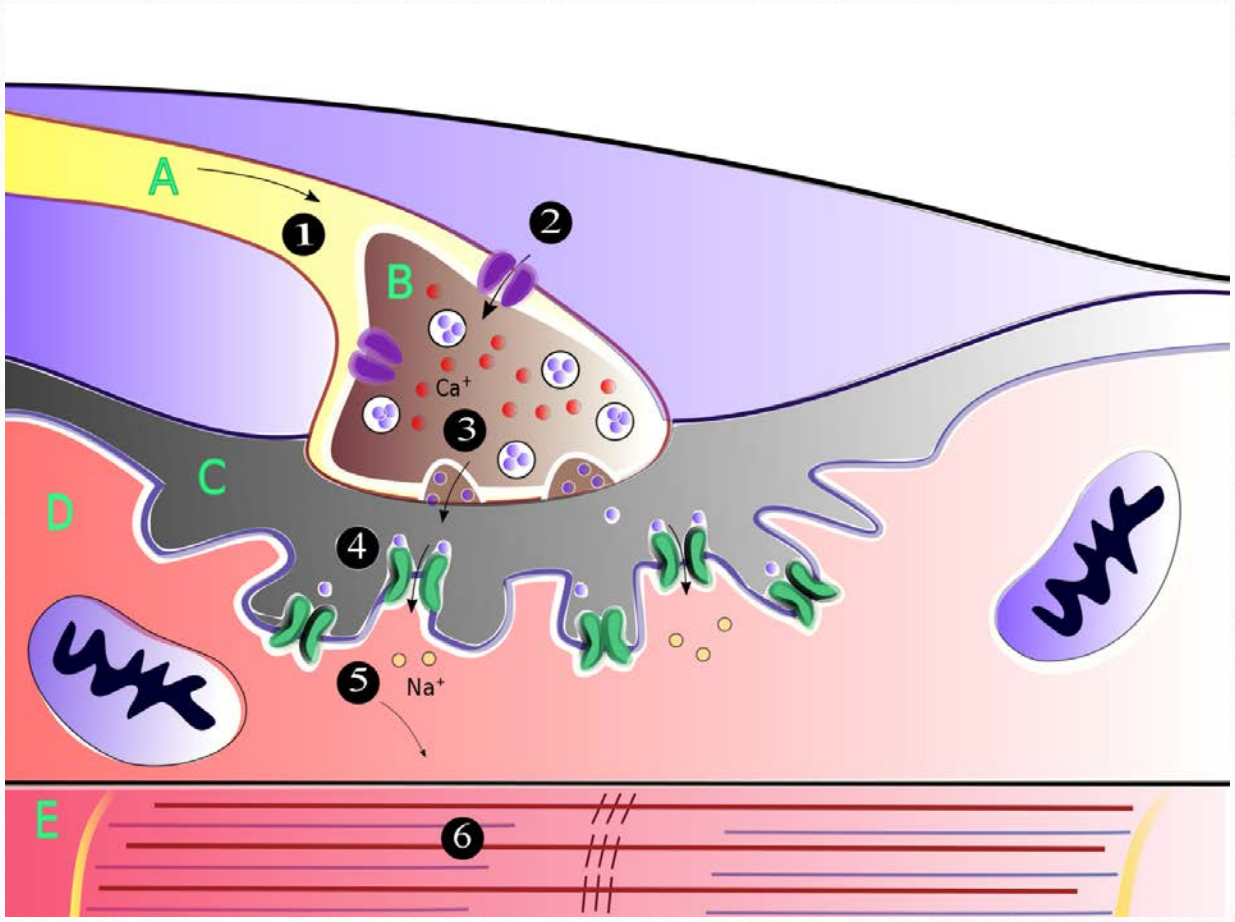

Figure 3.41 - (1) The action potential reaches the axon terminal; (2) voltage-dependent calcium gates open - calcium enters the axon terminal; (3) neurotransmitter vesicles fuse with the presynaptic membrane and release acetylcholine (ACh); (4) ACh binds to postsynaptic receptors on the sarcolemma; (5) ion channels open in response and allow sodium ions to flow into the muscle cell; (6) The flow of sodium ions into the muscle cell generates an action potential which travels to the myofibril and results in muscle contraction.

Wikipedia

In considering information movement via nerve cells, then, we will discuss two steps - 1) creation and propagation of a signal in a nerve cell and 2) action of neurotransmitters exiting a nerve cell and transiting a synaptic junction.

Signal source

Creation of a nerve signal begins with a stimulus to the nerve cell. In the case of muscle contraction, the motor cortex of the brain sends signals to the appropriate motor neurons, stimulating them to generate a nerve impulse. How is such an impulse generated?

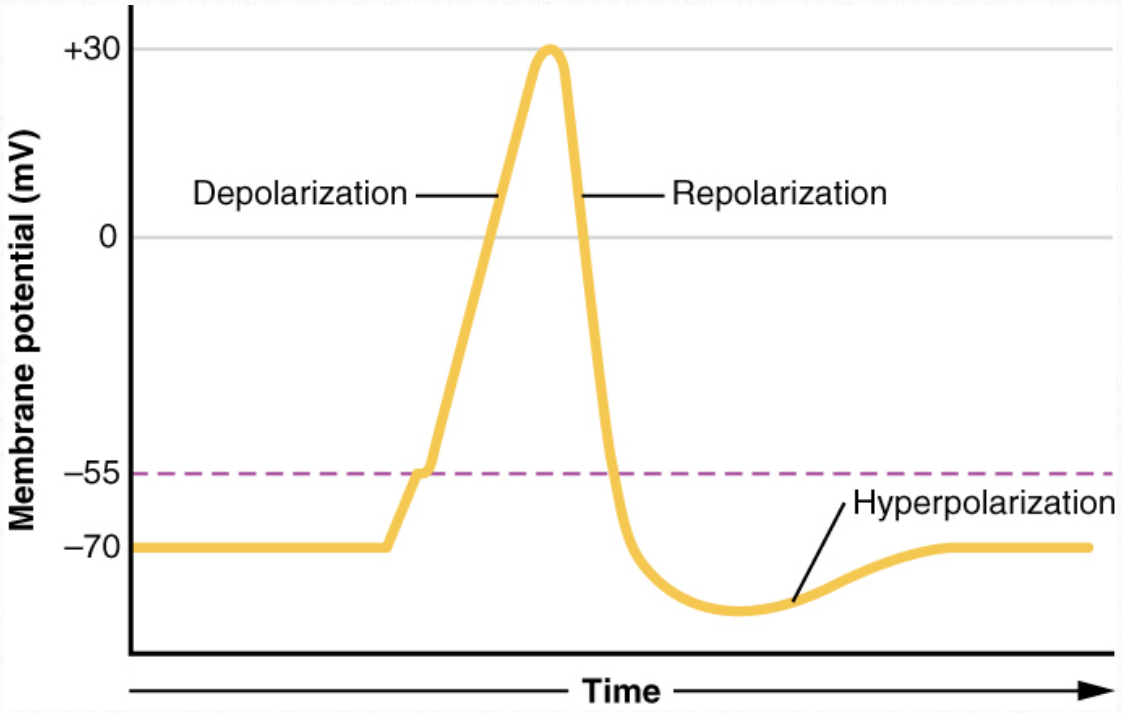

Figure 3.42 - Depolarization and repolarization of a nerve cell

Wikipedia

YouTube Lectures by Kevin HERE & HERE

Resting potential

In the unstimulated state, all cells, including nerve cells, have a small voltage difference (called the resting potential) across the plasma membrane, arising from unequal pumping of ions across the membrane. The Na^+/K^+ ATPase, for example, pumps sodium ions out of the cell and potassium ions into cells. Since three sodium ions get pumped out for every two potassium ions pumped in, a charge and chemical gradient is created. It is the charge gradient that gives rise to the resting potential.

Altering the gradients of ions across membranes provide the driving force for nerve signals. This happens as a result of opening and closing of gated ion channels. Opening of gates to allow ions to pass through the membrane swiftly changes the ionic balance across the membrane resulting in a new voltage difference called the action potential. It is the action potential that is the impetus of nerve transmission.

Initiation of signal

The signal generated by a motor neuron begins with opening of sodium channels in the membrane of the nerve cell body causing a rapid influx of sodium ions into the nerve cell. This step, called depolarization (Figure 3.42), triggers an electrochemical

signal - the action potential. Remember that the Na^+/K^+ ATPase has created a large sodium gradient, so sodium ions rush into the cell when sodium channels open. After the initial depolarization, potassium channel gates, responding to the depolarization, open, allowing potassium ions to rapidly diffuse out of the cell (remember K^+ ions are more abundant inside of the cell). This phase is called the repolarization phase and during it, the sodium gates close.

The rapid exit of potassium ions causes the voltage difference to "overshoot" the resting potential and potassium gates close. This followed by the so-called refractory period, when the Na^+/K^+ ATPase begins its work to re-establish the original conditions by pumping sodium ions out and potassium ions into the nerve cell. Eventually, the system recovers and the resting potential is re-established. The initiating end of the nerve cell is then ready for another signal.

Propagation of action potential

What we have described here is only the initiation of the nerve signal in one part of the nerve cell. For the signal to be received, the action potential must travel the entirety of the length of the nerve cell (the axon) and cause a chemical signal to be released into the synaptic cleft to get to its target. Propagating the nerve signal (action potential) in the original nerve cell is the function of all of the rest of the gated ion channels (Figure 3.43) positioned on the sides of the nerve cell. The sodium and potassium gates involved in propagation of the signal all act in response to voltage changes created by the electrochemical gradient moving down

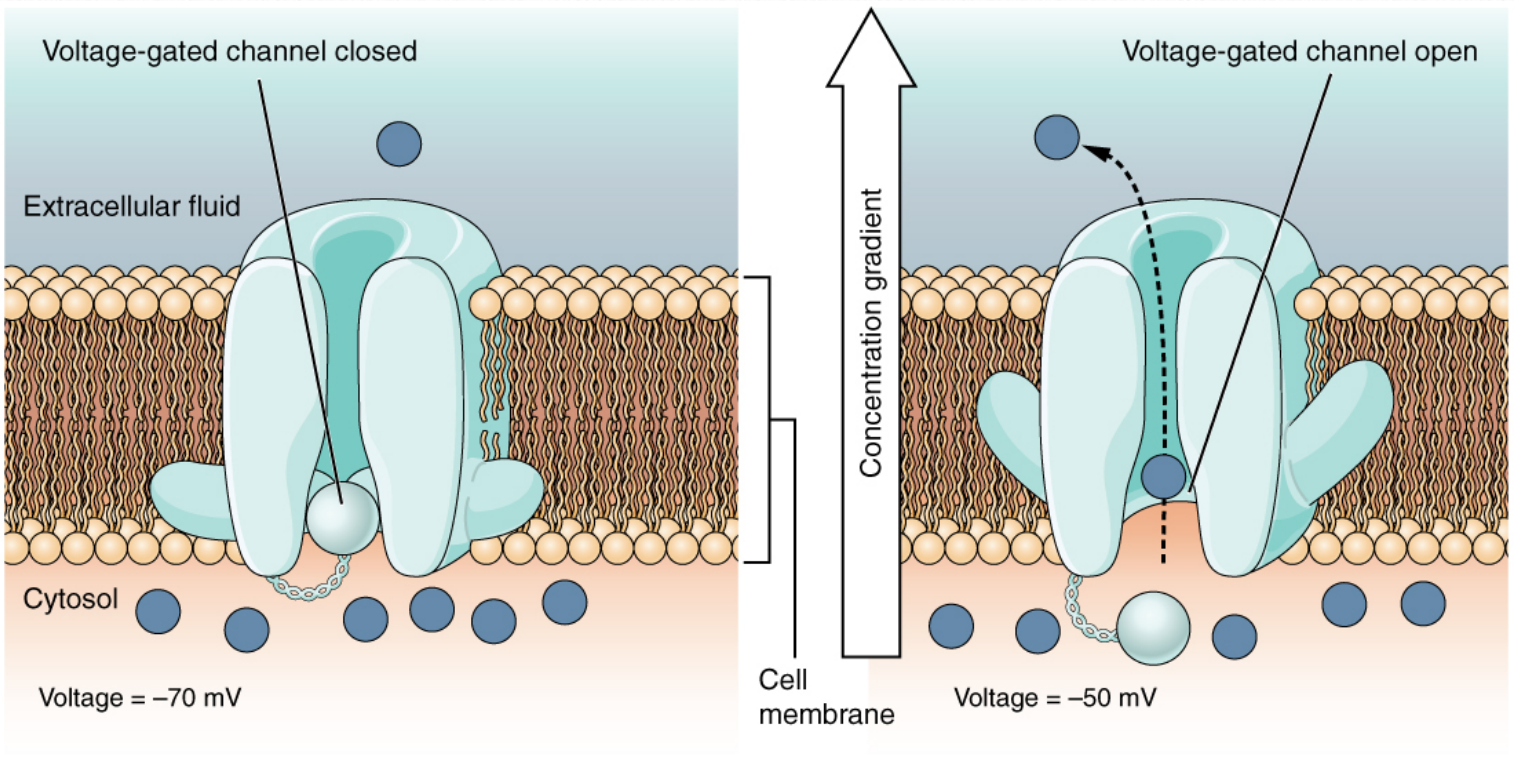

Figure 3.43 - Voltage gated ion channels

Wikipedia

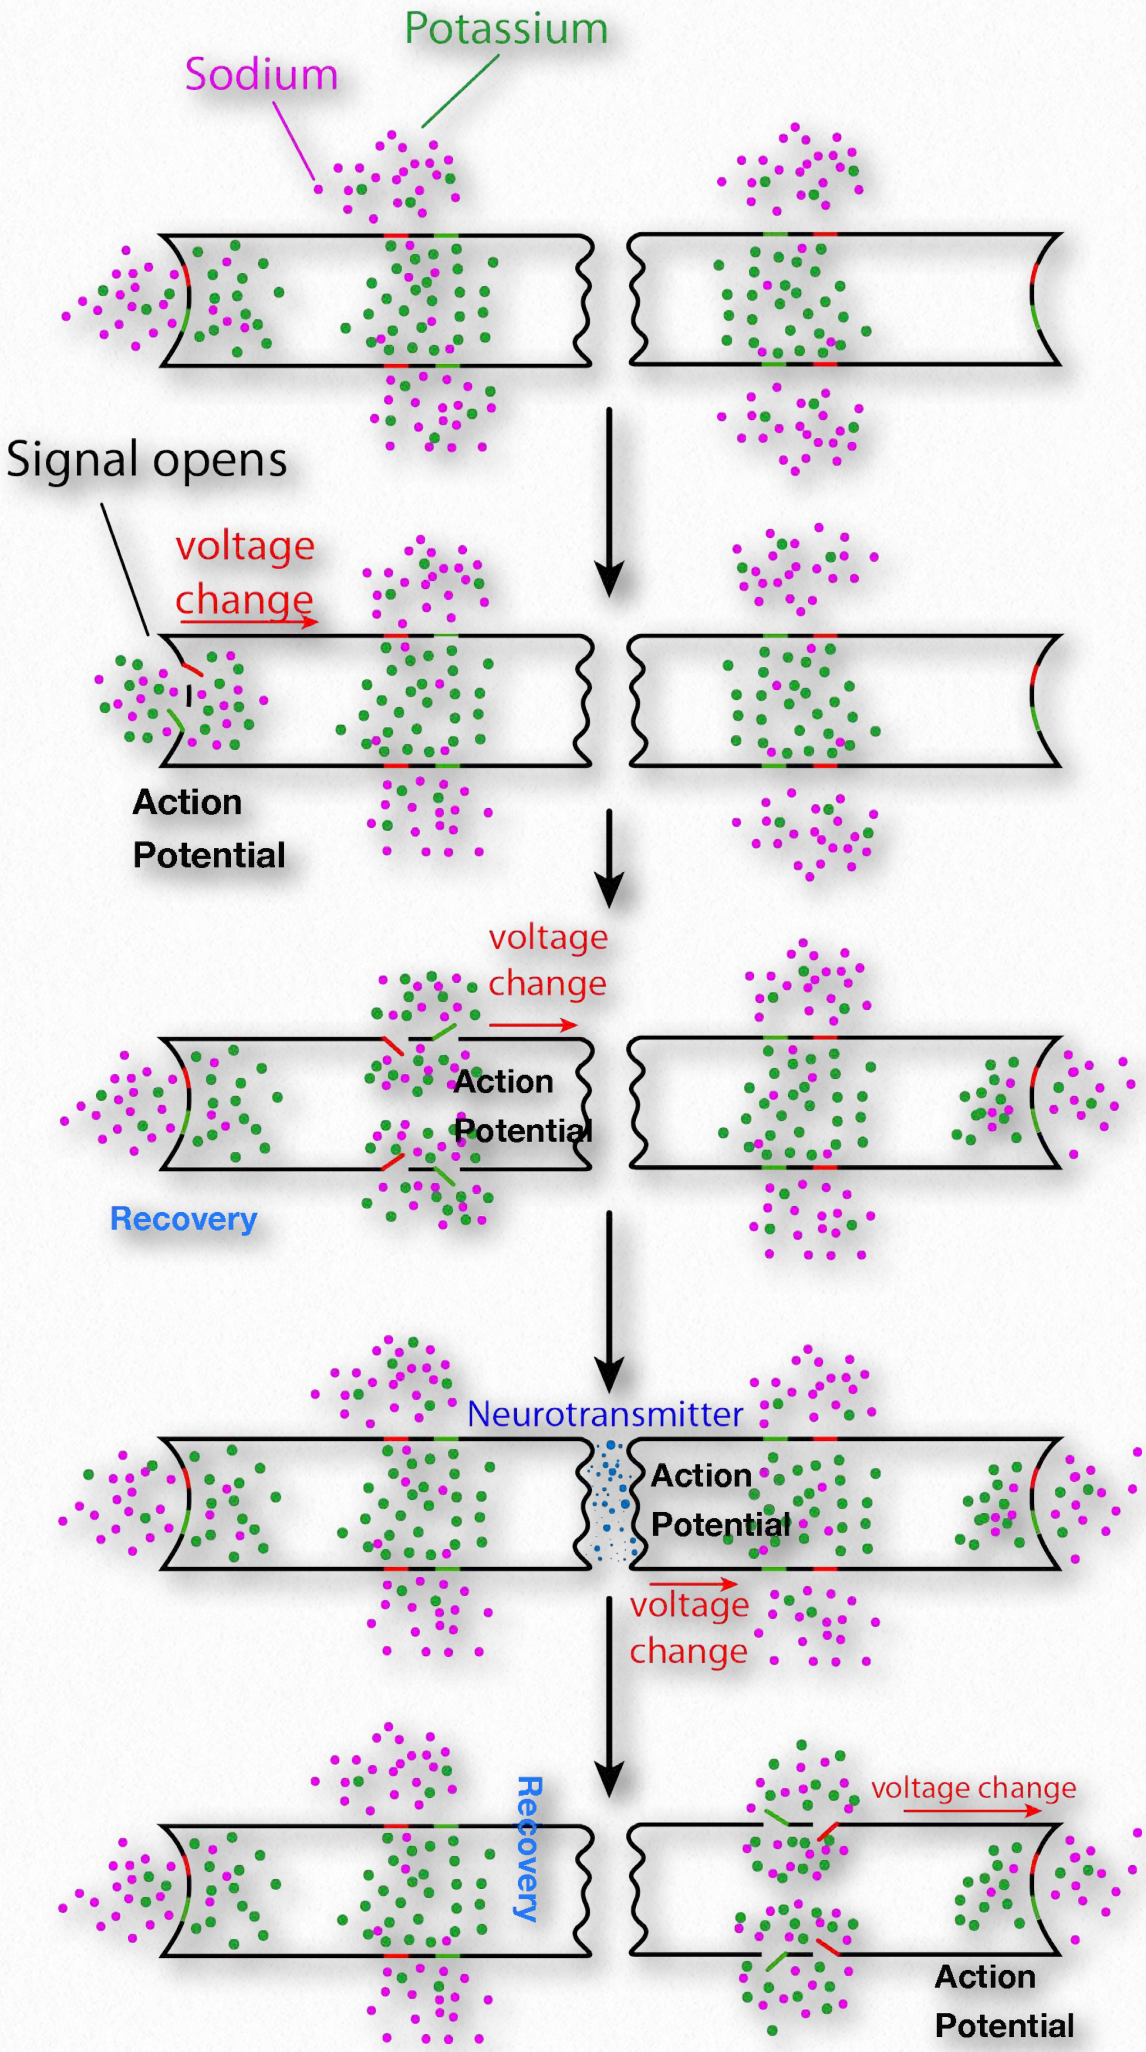

Figure 3.44 - Action potential moving across a synaptic junction of two nerve cells

Image by Pehr Jacobson

the nerve cell (Figure 3.44). Remember that opening of the initial gates at initiation of the signal created an influx of sodium ions and an efflux of potassium ions.

Moving signal

This chemical and electrical change that creates the ac-

Wikipedia

tion potential leaves the end of the nerve cell where it started and travels down the axon towards the other end of the nerve cell. Along the way, it encounters more sodium and potassium gated channels. In each case, these respond simply to the voltage change of the action potential and open and close, exactly in the same way the gates opened to start the signal. Thus, a rapid wave of increasing sodium ions and decreasing potassium ions moves along the nerve cell, propagated (and amplified) by gates opening and closing as the ions and charges move down the nerve cell. Eventually, the ionic tidal wave reaches the end of the nerve cell (axon terminal) facing the synaptic cleft.

Crossing the synaptic cleft

For the signal to be received by the intended target (postsynaptic cell) from the originating neuron (presynaptic neuron), it must cross the synaptic cleft and stimulate the neighboring cell (Figure 3.45). Communicating information across a synaptic cleft is the job of neurotransmitters. These are small molecules synthesized in nerve cells that are packaged in membrane vesicles called synaptic vesicles in the nerve cell. Neurotransmitters come in all shapes and chemical forms, from small chemicals like acetylcholine to peptides like neuropeptide Y. The most abundant neurotransmitter is glutamate, which acts at over 90% of the synapses in the human brain.

Into the cleft

As the action potential in the presynaptic neuron approaches the axon terminus, synaptic vesicles begin to fuse with the membrane and their neurotransmitter contents spill into the synaptic cleft. Once in the cleft, the neurotransmitters diffuse, some of them reaching receptors on the postsynaptic cell. Binding of the neurotransmitter to the receptors on the membrane of the postsynaptic cell stimulates a response.

For motor neurons, the postsynaptic cell will be a muscle cell, and the response will be

muscle contraction/relaxation. At this point, the originating nerve cell has done its job and communicated its information to its immediate target. If the postsynaptic cell is a nerve cell, the process repeats in that cell until it gets to its destination.

YouTube Lectures by Kevin HERE & HERE

Na^+/glucose transporter

Absorbing nutrients from the digestive system is necessary for animal life. The sodium/glucose transport protein is an electrogenic symporter that moves glucose into intestinal cells. It is found in the intestinal mucosa and the proximal tubule of the nephron of the kidney. The sodium/glucose transport system functions in the latter to promote reabsorption of glucose. The pump works in conjunction with the Na^+/K^+ transport system. The gradient of sodium ions built up by the Na^+/K^+ pump is used as an energy source to drive movement of glucose into cells (see Figure 3.38). Use of an ion gradient established by a separate pump is known as secondary active transport. For intestinal mucosa, the pump transports glucose out of the gut and into gut cells. Later, the glucose is exported out the other side of the gut cells to the interstitial space for use in the body.

Calcium pumps

Calcium ions are necessary for muscular contraction and play important roles as signaling molecules within cells. In addition, when calcium concentrations rise too high, DNA in chromosomes can precipitate. Calcium concentration in cells is therefore managed carefully. It is kept very low in the cytoplasm as a result of action of pumps, both in the plasma membrane, which pump calcium outwards from the cytoplasm and in organelles, such as the endoplasmic reticulum (sarcoplasmic reticulum of muscle cells), which pump calcium out of the cytoplasm and into these organelles.

Opening of calcium channels, then, increases calcium concentration quickly in the cytoplasm resulting in a quick response, whether the intention is signaling or contraction of a muscle. After the response is generated, the calcium is pumped back out of the cytoplasm by the respective calcium pumps.

Some calcium pumps use ATP as an energy source to move calcium and others use ion gradients, such as sodium for the same purpose.

Na^+/Ca^{++} transporter

One calcium pump of interest uses the sodium gradient as an energy source. It is the sodium/calcium pump. This electrogenic antiport system uses sodium's movement into the cell as a driving force to move calcium out of the cell, although its direction can reverse in some circumstances. The pump is a high capacity system to move a lot of calcium quickly, moving up to 5000 calcium ions per second and is found in many tissues with many functions.

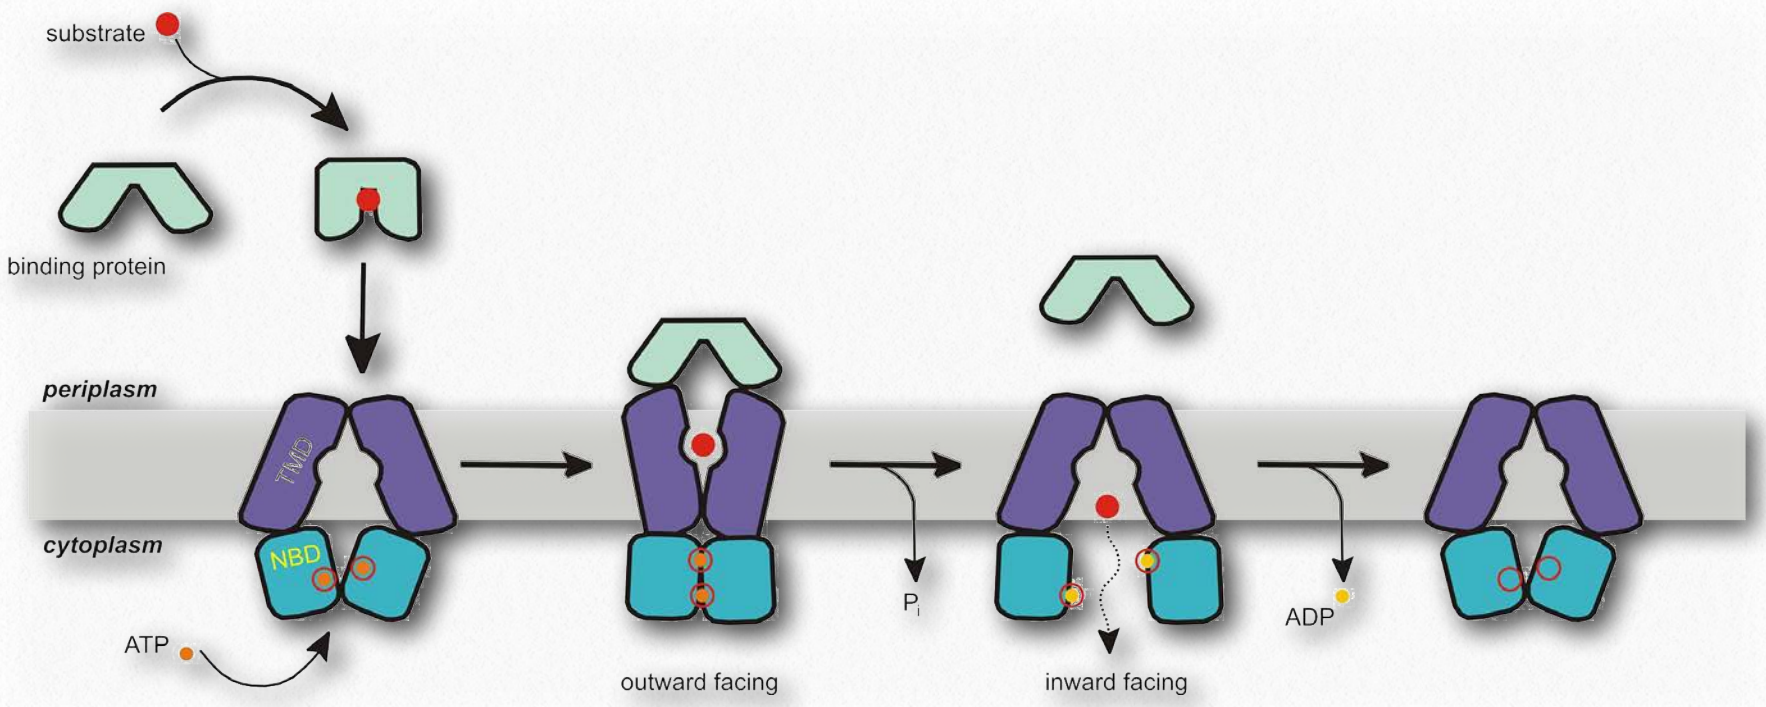

Figure 3.47 - Mechanism of an ABC importer

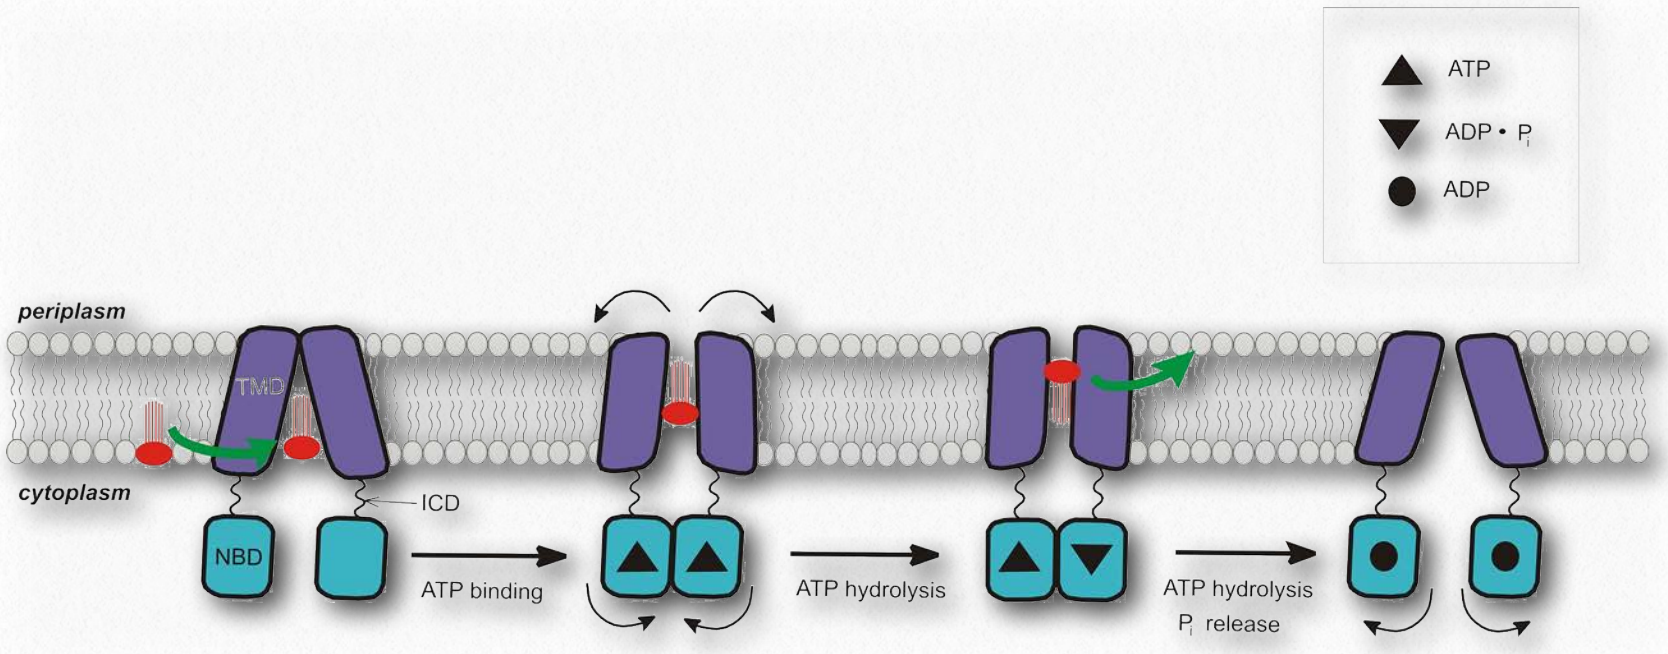

Figure 3.48 - Another view of an ABC exporter. NBD = Nucleotide Binding Domain

Digitalis

One important function of the Na^+/Ca^{++} pump occurs in heart cells. Ca^{++} is important for contraction of heart muscle. Calcium efflux from the cells is the normal operation of the pump, however, during the upstroke of the cycle, there is a large movement of sodium ions into the heart cell. When this occurs, the pump reverses and pumps Na^+ out and Ca^{++} in briefly. Since calcium helps stimulate contraction of cardiac muscle, this can help make the heart beat stronger and is the focus of the use of digitalis to treat congestive heart failure.

Digitalis blocks the sodium-potassium ATPase and interferes with the sodium ion gradient. As noted above, when the Na^+ gradient is oriented in the wrong direction, calcium is pumped in. Digitalis is therefore used to treat congestive heart failure because it increases the concentration of calcium in the heart cells, favoring more forceful beats.

ABC transporters

ABC transporters are another class of transmembrane proteins that use ATP energy to transport things against concentration gradients (Figures 3.47 & 3.48). This protein superfamily includes hundreds of proteins (48 in humans alone) and spans all extant phyla from prokaryotes to humans. These proteins function not only in membrane transport, but also in processes that include DNA repair and the process of translation.

Transport

Substances that ABC transporters move across membranes include metabolic prod-

ucts, lipids, sterols, and drugs. ABC transporters function in multi-drug resistance of many cells, and provide resistance to antibiotics in bacteria as well as resistance to chemotherapy in higher cells by exporting drugs used to treat both of these types of cells.

ABC transporters are divided into three main groups - 1) importers (prokaryotes only); 2) exporters (prokaryotes and eukaryotes), and 3) non-transporters with roles in DNA repair and translation. All ABC transport proteins have four protein domains - two that are cytoplasmic and two that are membrane bound. They are alternately open to the cytoplasmic or extracellular (or periplasmic) regions and this is controlled by hydrolysis of ATP.

Disease

ABC transporters have roles in cystic fibrosis and other inherited human diseases. They are very involved in development of resistance to multiple drugs by a diverse group of cells. ABC transporters provide multi-drug resistance by expelling drug(s) from cells. $ABCB_1$ protein, for example, pumps tumor suppression drugs out of the cell. Another ABC transporter known as

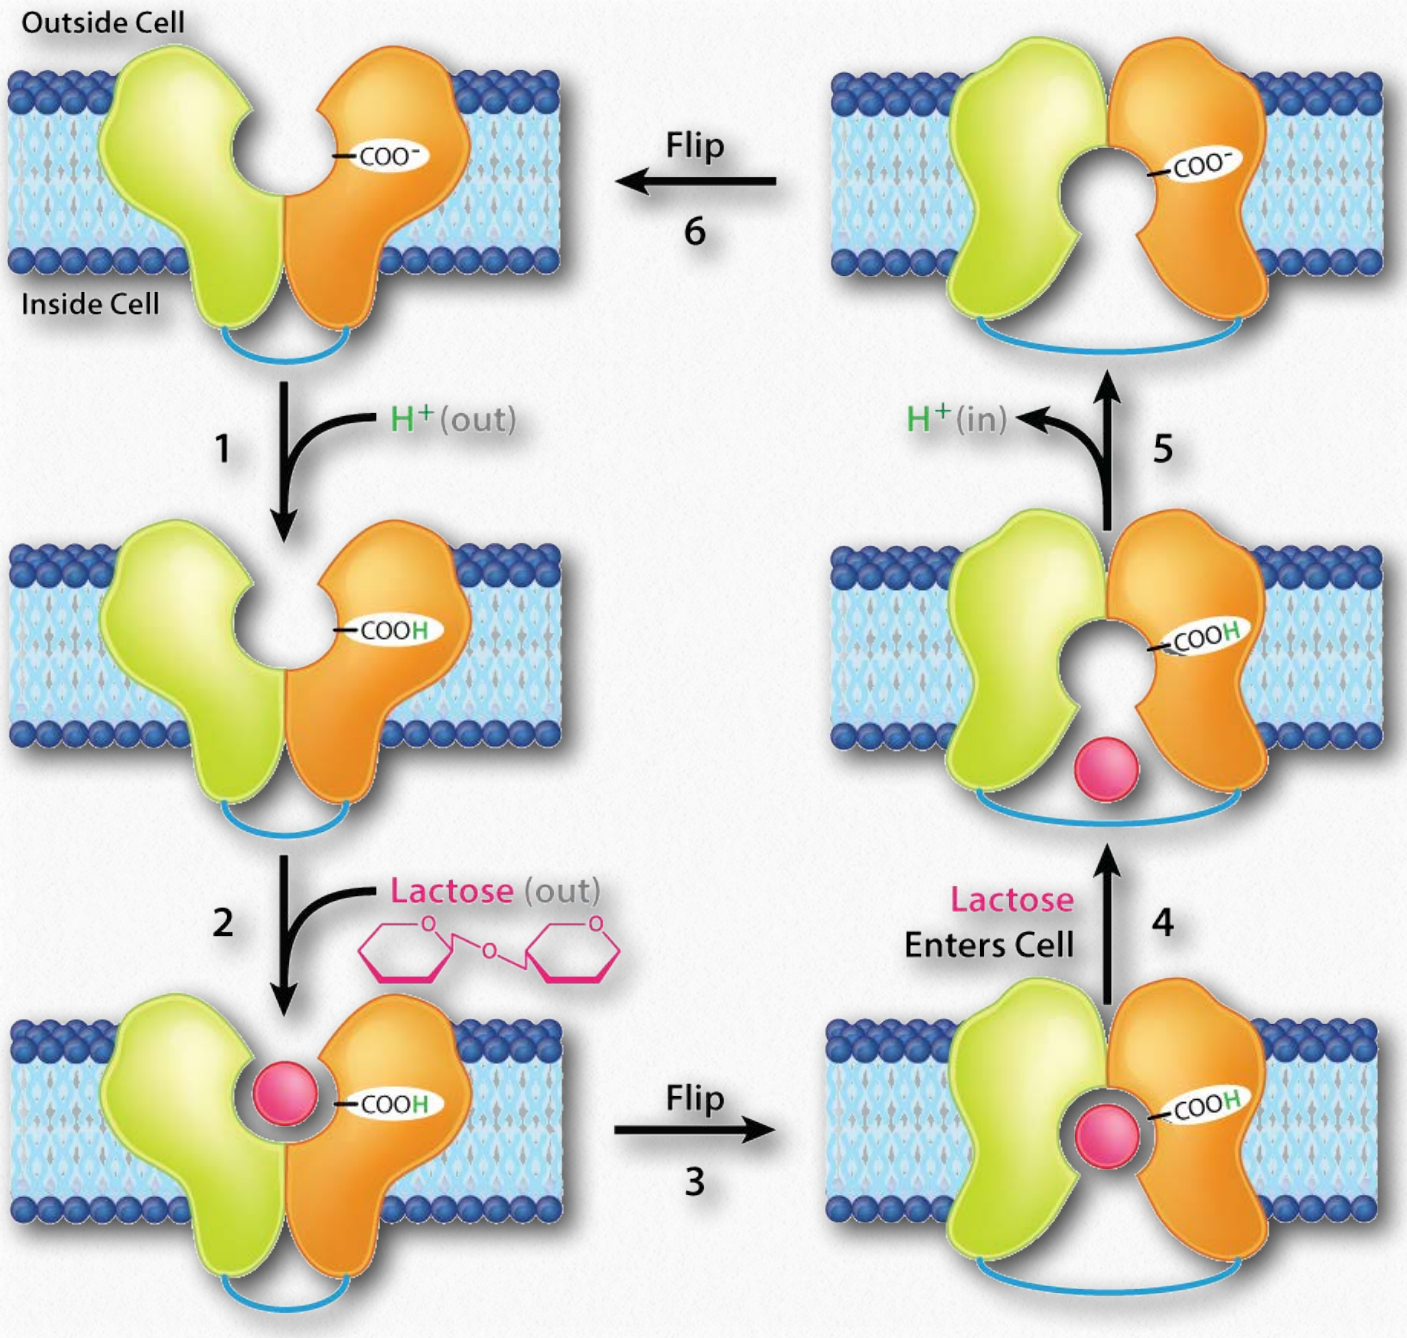

Figure 3.49 - Mechanism of action of lactose permease - Note that the proton acts by altering the charge of a carboxyl group

Image by Aleia Kim

Pgp transports organic cationic or neutral compounds.

Cystic fibrosis

Cystic fibrosis (CF) is a an autosomal recessive genetic disorder arising from mutations in both copies of the gene for the cystic fibrosis transmembrane conductance regulator (CFTR) protein. This ABC transporter system, which moves chloride and thiocyanate ions across epithelial tissue membranes exerts its effect mostly in the lungs but the pancreas, liver, kidneys, and intestine are all also affected by it.

Function

CFTR has roles in the production of sweat, mucus, and digestive fluids. Manifestations of the disease include breathing difficulty and overproduction of mucus in the lungs. When CFTR is functional, these fluids are normally thin, but when the gene is non-functional, they become much thicker and are points of infection.

CFTR contains two ATP-hydrolyzing domains and two cell membrane-crossing domains with 6 α-helices each. It can be activated by phosphorylation by a cAMP-dependent protein kinase. The carboxyl end of CFTR is linked to the cytoskeleton by a PDZ domain.

Lactose permease

Another integral membrane protein performing active transport is lactose permease. It facilitates the movement of the sugar lactose across the lipid bilayer of the cell membrane (Figures 3.49-3.51). The transport mechanism is classified as a secondary active transport since it exploits the inwardly directed H^+ electrochemical gradient as an energy source. When lactose is transported into cells, it is broken down into its substituent monosaccharide sugars - glucose and galactose - for energy creation.

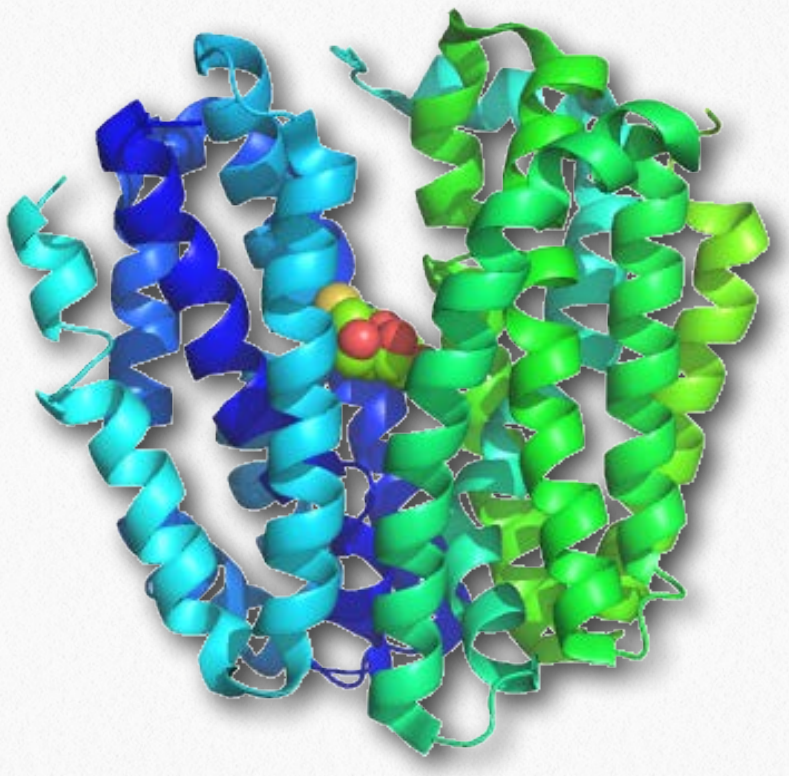

Figure 3.50 - Structure of lactose permease

Wikipedia

The enzyme catalyzing this reaction is known as lactase and deficiency of it in humans leads to lactose intolerance (see HERE).

GLUTs

GLUTs (GLUcose Transport proteins) are uniport, type III integral membrane

proteins that participate in the transport of glucose across membranes into cells. GLUTs are found in all phyla and are abundant in humans, with 12 GLUT genes. GLUT1, in erythrocytes is well-studied. Through GLUT 1, glucose enters and passes through it via facilitated diffusion at a rate that is 50,000 higher than in its absence. GLUTs of various types are found in different cells of the body. The one in red blood cells is known as GLUT 1 and has 12 membrane-spanning hydrophobic helices.

Though the structure of GLUT 1 is not known, it is speculated that the 12 helices form a chamber able to form hydrophilic bonds with glucose to facilitate its passage.

YouTube Lectures by Kevin HERE & HERE

GLUT 1 levels in erythrocytes go up as glucose levels decrease and decrease when glucose levels go down. GLUT 1 can also transport ascorbate (vitamin C) in addition to glucose in mammals (such as humans) that do not produce their own vitamin C.

Glut 4

GLUT 4 is regulated by insulin and is found primarily in adipose and striated muscle tissue. Insulin alters intracellular trafficking pathways in response to increases in blood

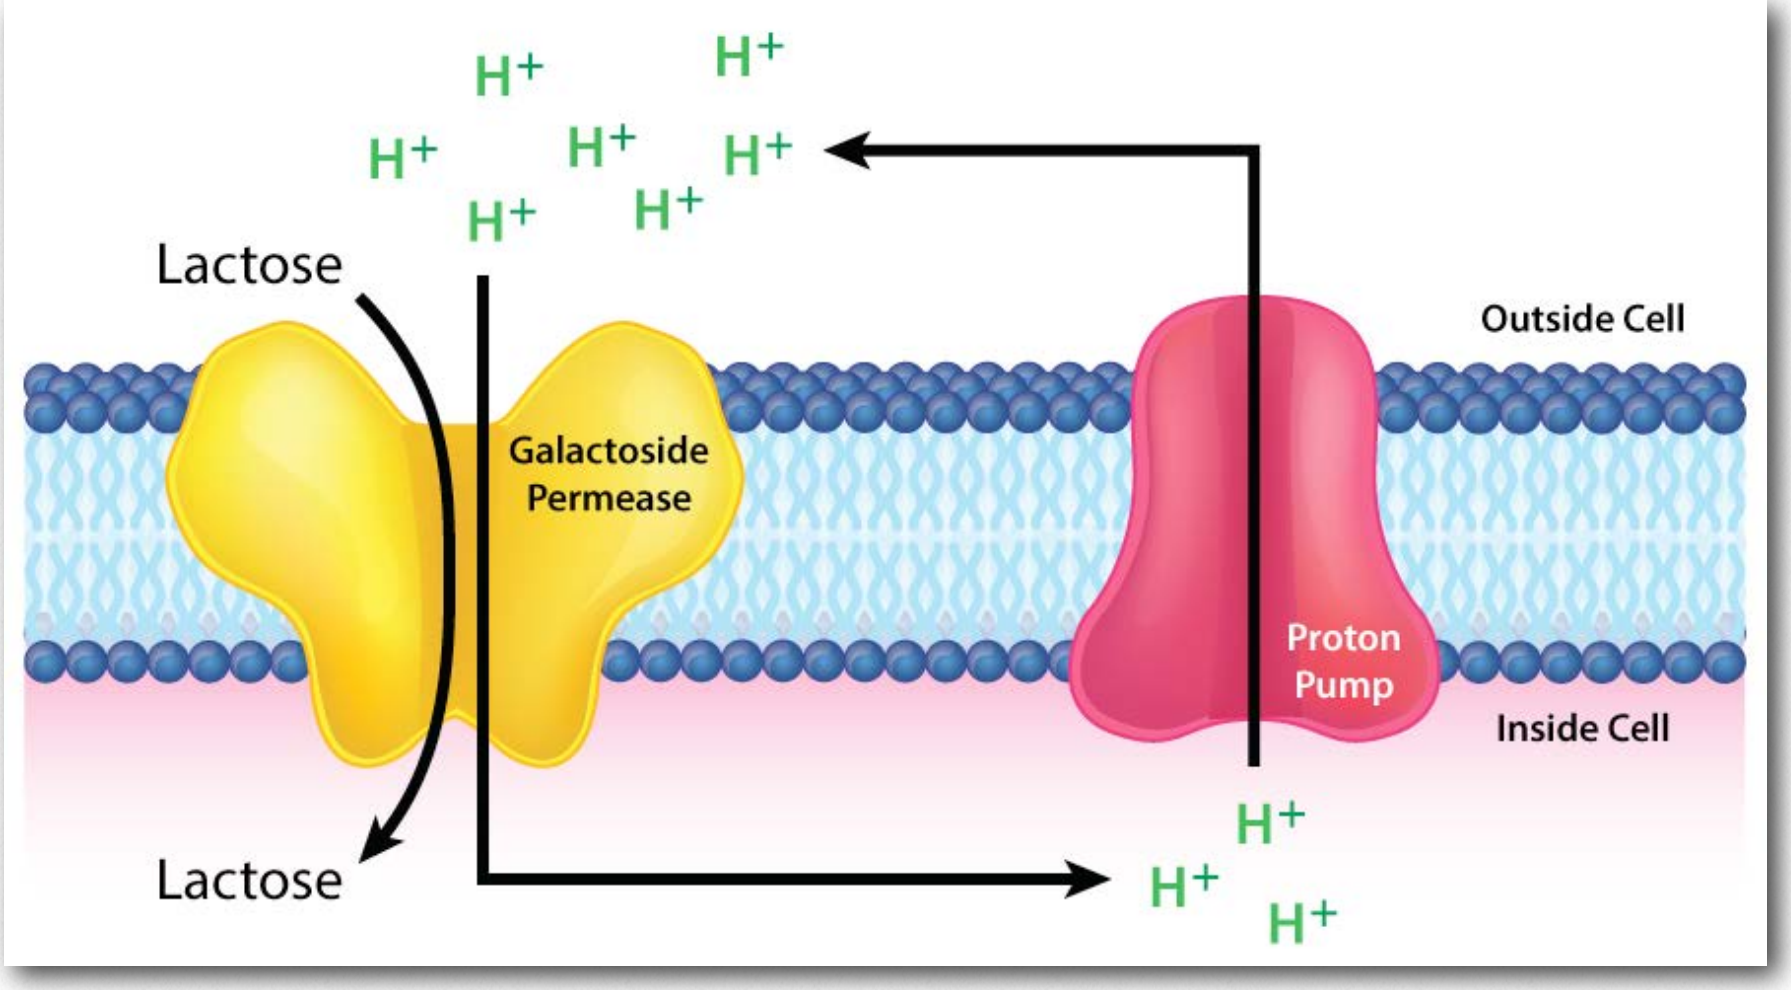

Figure 3.51 - Lactose (galactoside) permease is a secondary transporter, using a proton gradient as an energy source to pump lactose into the cell

Glucose Transporters

Name	Tissue	K_M (μM)	Comments
GLUT1	All mammalian tissues	1	Basal glucose uptake
GLUT2	Liver and pancreatic β cells	15-20	Participates in insulin regulation in the pancreas; removes excess glucose from the blood in the liver
GLUT3	All mammalian tissues	1	Basal glucose uptake
GLUT4	Muscle and fat cells	5	Concentration in plasma membrane of muscles rises with endurance training
GLUT5	Small intestine	---	Fructose transport

Figure 3.52 - GLUTs found in cells

Image by Aleia Kim

sugar to favor movement of various GLUT proteins (including GLUT 4) from intracellular vesicles to the cell membrane, thus stimulating uptake of the glucose. GLUT 4 is also found in the hippocampus where, if trafficking is disrupted, the result can be depressive behavior and cognitive dysfunction.

For all of the GLUT proteins, a key to keeping the glucose in the cell is phosphorylation of it by the glycolysis enzyme, hexokinase, in the cytoplasm. Phosphorylated molecules cannot enter GLUTs and don't have an easy means of exiting the cell.

This Song's For BB 3-5-0

To the tune of "*This Land is My Land*"

Metabolic Melodies Website HERE

It's one o'clock and
Ahern's talkin'
Henderson and
Hasselbalch and
pKa's and
Buffers I should know
This song's for BB three five oh

I hope that maybe
He'll think the way we
Wrote our answers
Wasn't crazy
I really need the
Partial credit - so
This song's for BB three five oh

It's really groovy
That it improves me
Watching lectures
In Quicktime movies
I really need to
Go and download those
Podcasts for BB three five oh

I'm feeling manic
I'm in a panic
I'd better study
My old organic
It has reactions
That I need to know
This song's for BB three five oh

I know he said it
That's why I dread it
'cause I skipped Friday's
Extra credit
'twil pro'bly haunt me
That lowly ze-ro
Grade in BB three five oh

It could be steric
Or esoteric
That carbons get so
Anomeric
I'm too hysteric
Better let it go
This song's for BB three five oh

Membranes: Other Considerations

There are many functions and factors relating to cell membranes that don't fit into broad categories. Those items will be the focus of this section.

Endocytosis

Besides transporter proteins and ion channels, another common way for materials to get into cells is by the process of endocytosis. Endocytosis is an alternate form of active transport for getting materials into cells. Some of these processes, such as phagocytosis, are able to import much larger particles than would be possible via a transporter protein. Like transporter proteins, endocytosis uses energy for the purpose (though it is not as visible as with protein transporters), but unlike protein transporters, the process is not nearly as specific for individual molecules.

YouTube Lectures by Kevin
HERE & HERE

As a result, the process usually involves the importation of many different molecules each time it occurs. The list of compounds entering cells in this way includes LDLs and their

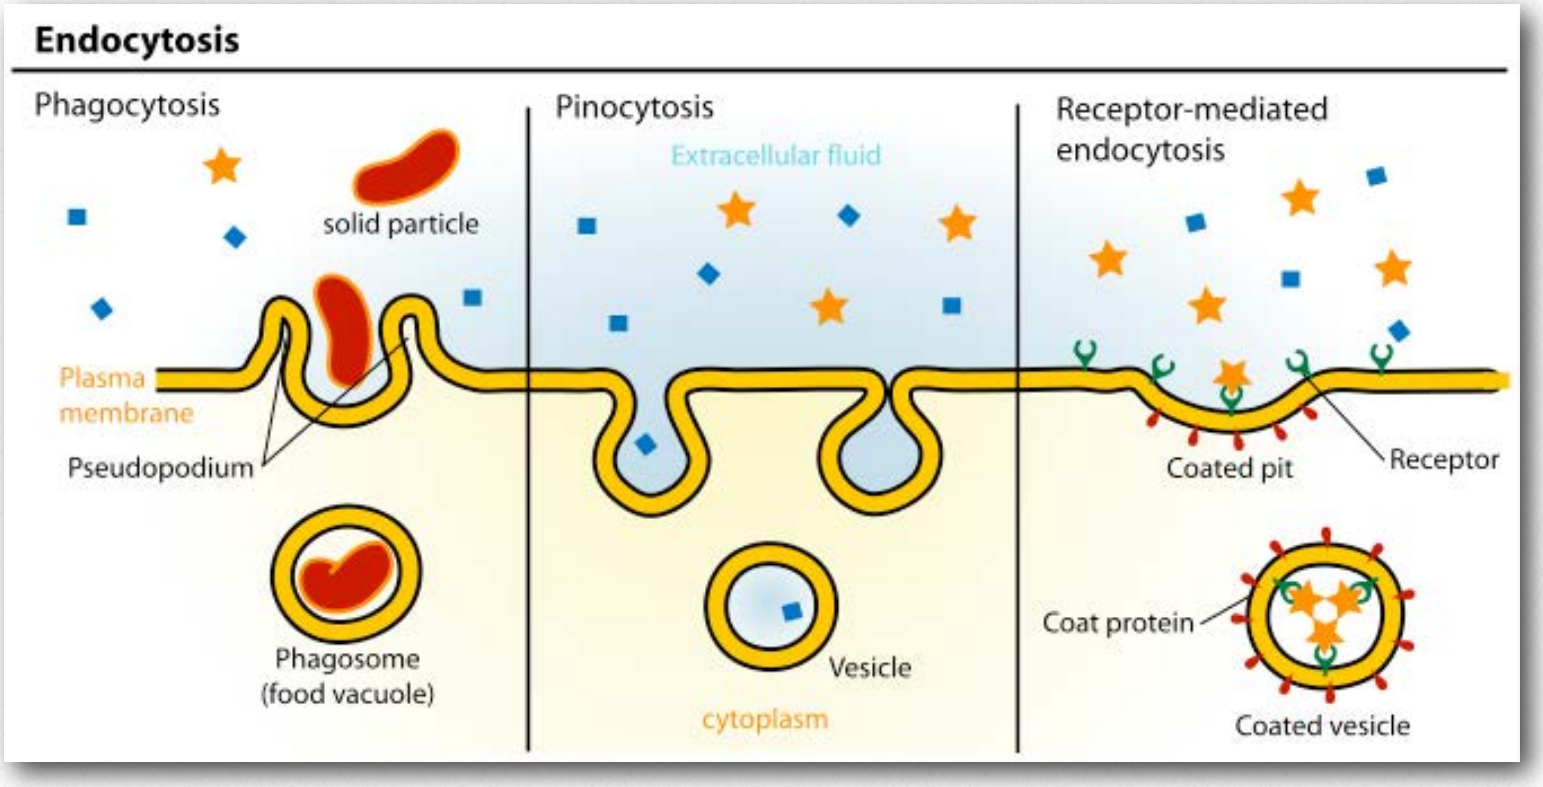

Figure 3.53 - Three types of endocytosis

lipid contents, but it also include things like iron (packaged in transferrin), vitamins, hormones, proteins, and even some viruses sneak in by this means. There are three types of endocytosis we will consider (Figure 3.53).

Receptor mediated endocytosis

The process of receptor mediated endocytosis is a relatively specific means of bringing molecules into cells because it requires the incoming material to be somehow associated with a specific cell surface receptor. In the example of Figure 3.53, the receptor is the cellular LDL receptor. Clathrin-coated invaginations, as

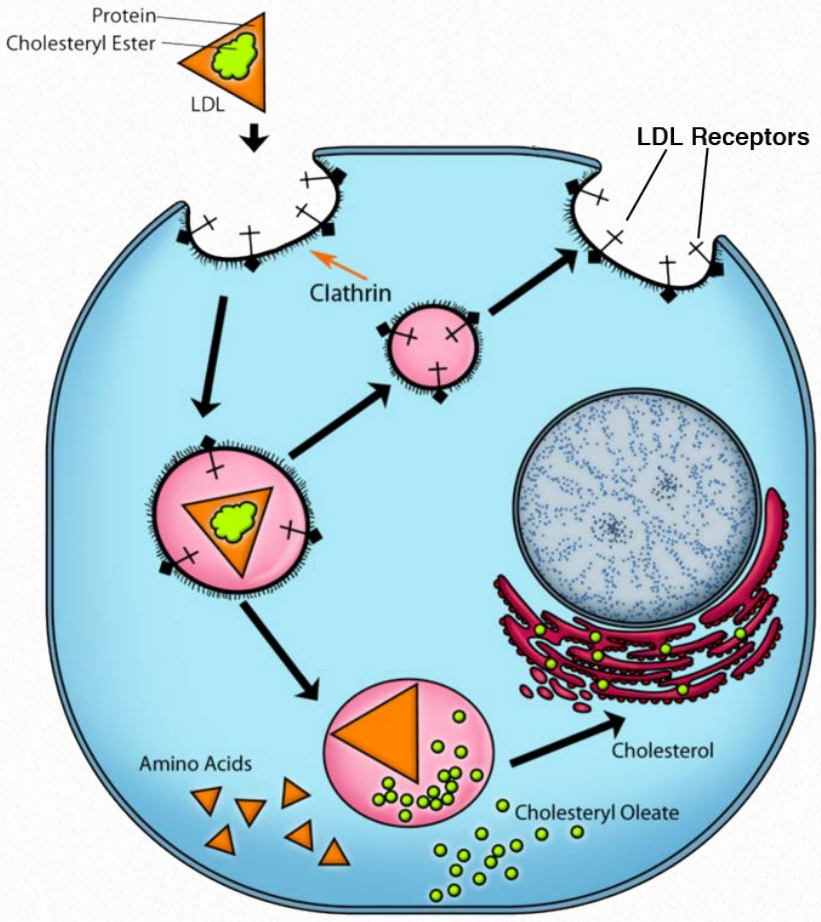

Figure 3.54 - Overview of clathrin-based receptor mediated endocytosis

Image by Aleia Kim

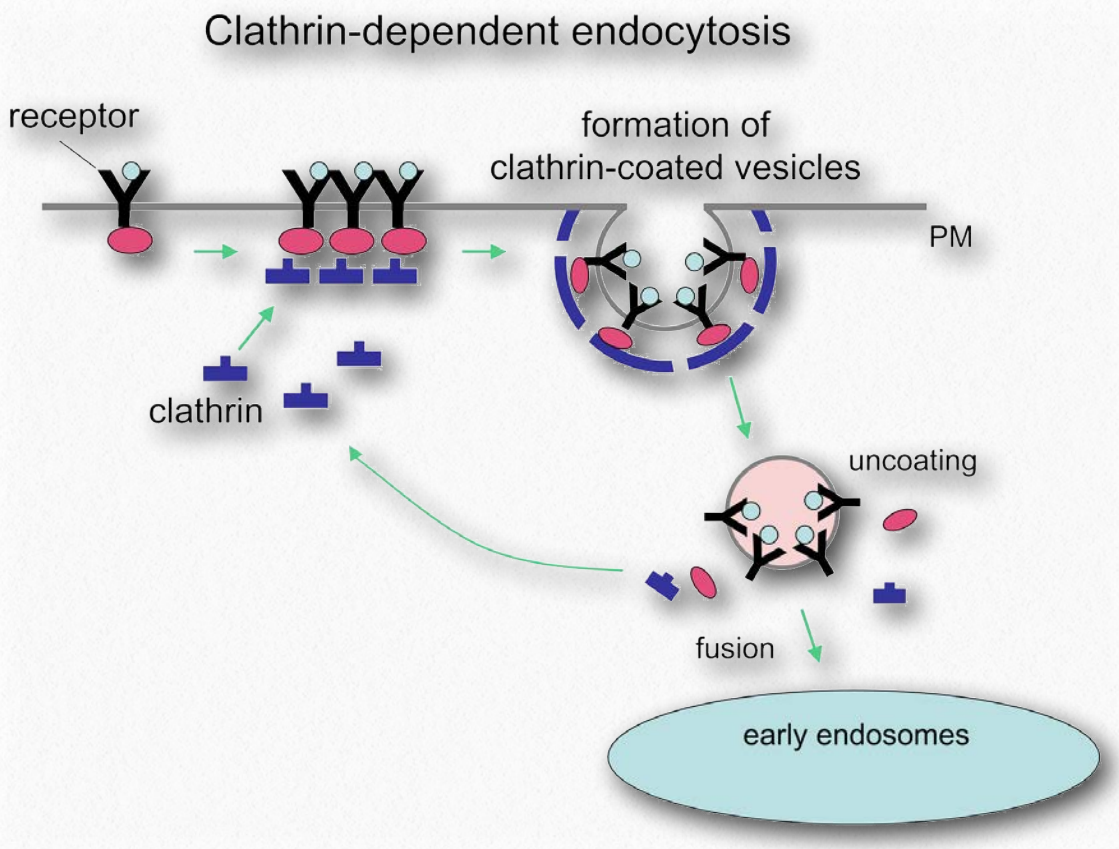

Figure 3.55 - Clathrin-mediated endocytosis of receptors

Wikipedia

shown in the figure are known as “coated pits.” The mechanism proceeds with an inward budding of the plasma membrane receptor (coated vesicles). Binding of the ligand (ApoB-100 of the LDL, for example, in Figure 3.54) to the LDL receptor leads to formation of a membrane invagination. The absorbed LDL particle fuses to form an early endosome (Figure 3.55) and contents are subsequently sorted and processed for use by the cell.

The components from the coated vesicle are recycled to the plasma membrane for additional actions. Receptor mediated endocytosis can also play a role in internalization of cellular receptors that function in the process of signaling. Here, a receptor bound to a ligand is brought into the cell and may ultimately generate a response in the nucleus.

While receptor mediated endocytosis of receptors can have the effect of communicating a signal inwards to the cell, it can also reduce the total amount of signaling occurring, since the number of receptors on the cell surface is decreased by the process.

Non-clathrin endocytosis

There are three types of endocytosis occurring in cells that do not involve clathrin. They are 1) caveolae-based endocytosis, 2) macropinocytosis, and 3) phagocytosis. Caveolae-based endocytosis is based on a receptor molecule known as caveolin. Caveolins are a class of integral membrane proteins that compartmentalize and concentrate signaling molecules in the process of endocytosis. They are named for the cave-like caveolae structures of the plasma membrane where they are found.

Caveolins

Caveolins have affinity for cholesterol and associate with it in the membrane of cells, causing the formation of membrane invaginations of about 50 nm. The caveolin proteins can oligomerize and this is important for

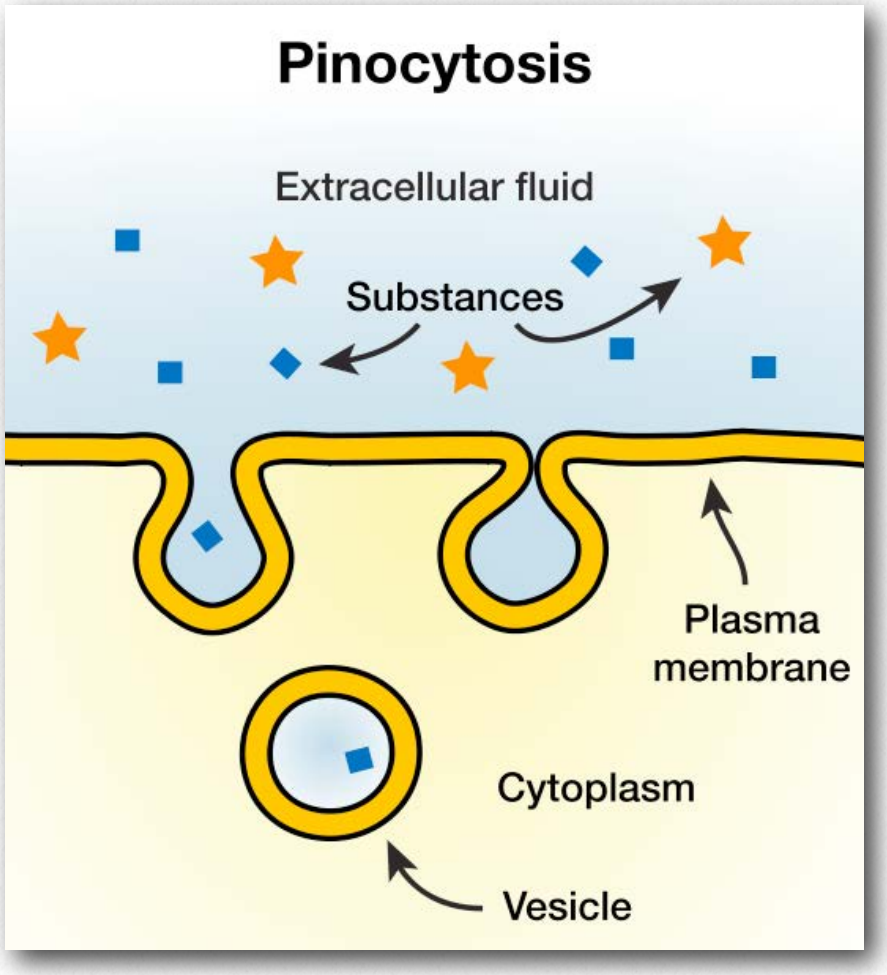

Figure 3.56 - **Macropinocytosis**

the coating and formation of the cave-like structures.

There are three caveolin genes found in vertebrate cells, CAV1, CAV2, and CAV3. Down-regulation of caveolin-1 results in less efficient cellular migration *in vitro*. Caveolins are implicated in both formation and suppression of tumors. High expression of them inhibits cancer-related growth factor signaling pathways, but some caveolin-expressing cancer cells are more aggressive and metastatic, possible due to an enhanced capacity for anchorage-independent growth.

Macropinocytosis

A phenomenon known as "cell drinking," macropinocytosis literally involves a cell "taking a gulp" of the extracellular fluid. It does this, as shown in Figure 3.56, by a simple invagination of ruffled surface features of the plasma membrane. A pocket results, which pinches off internally to create a vesicle containing extracellular fluid and dissolved molecules. Within the cytosol, this internalized vesicle will fuse with endosomes and lysosomes. The process is non-specific for materials internalized.

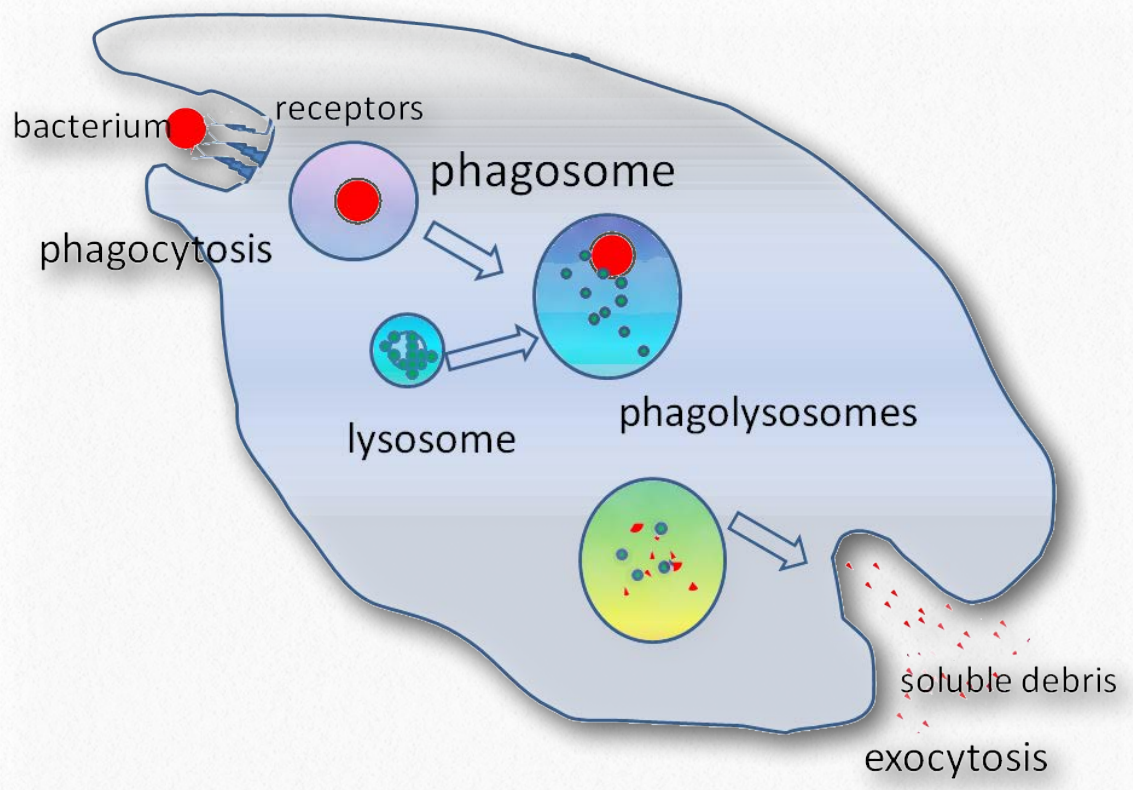

Figure 3.57 - **Generalized scheme for phagocytosis of a bacterium**

Wikipedia

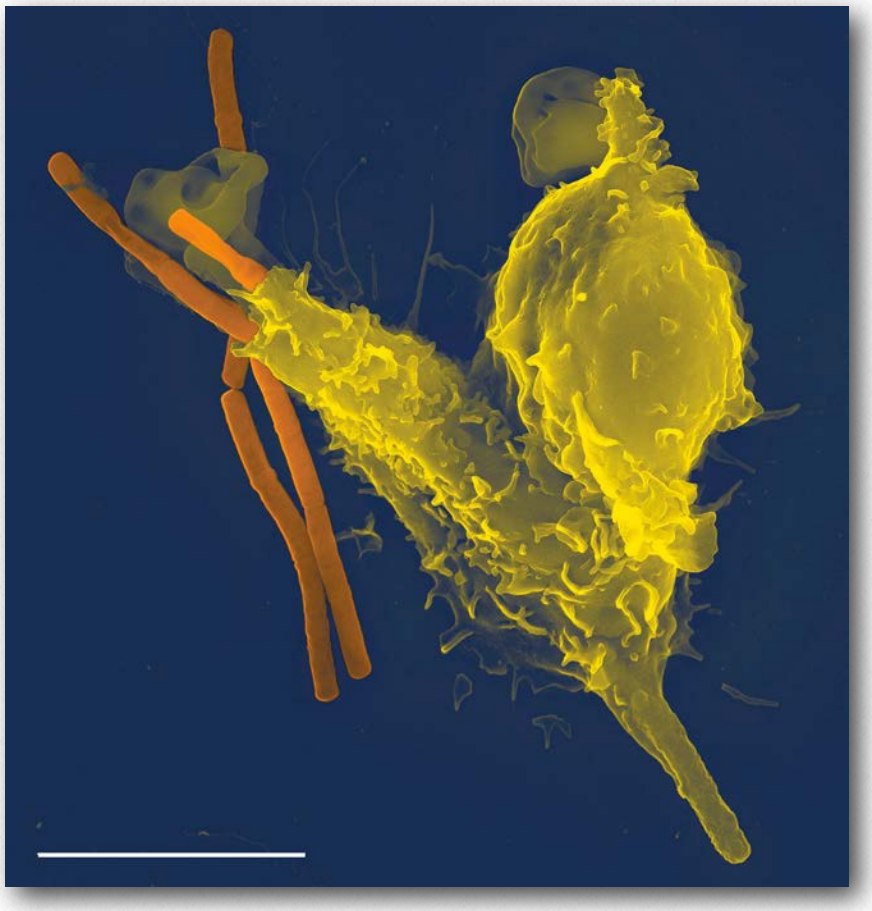

Figure 3.58 - Phagocytosis by a neutrophil (yellow) of an *Anthrax bacillus* (orange)

Wikipedia

Phagocytosis

Phagocytosis is a process whereby relatively large particles (0.75 µm in diameter) are internalized. Cells of the immune system, such as neutrophils, macrophages, and others, use phagocytosis to internalize cell debris, apoptotic cells, and microorganisms.

The process operates through specific receptors on the surface of the cell and phagocytosing cell engulfs its target by growing around it. The internalized structure is known as a phagosome, which quickly merges with a lysosome to create a phagolysosome (Figure 3.58), which subjects the engulfed particle to toxic conditions to kill it, if it is a cell, and/or to digest it into smaller pieces. In some cases, as shown in the figure, soluble debris may be released by the phagocytosing cell.

Endosomes

Internalized material from endocytosis that doesn't involve phagocytosis passes through an internalized structure called an endosome. Endosomes are membrane bounded structures inside of eukaryotic cells that play a role in endocytosis (Figure 3.59). They have a sorting function for material internalized into the cell, providing for retrieval of

Figure 3.59 - Internalization of the epidermal growth factor receptor (EGFR) into endosomes. Early (E) and late (M) endosomes and lysosomes (L) are labeled.

Wikipedia

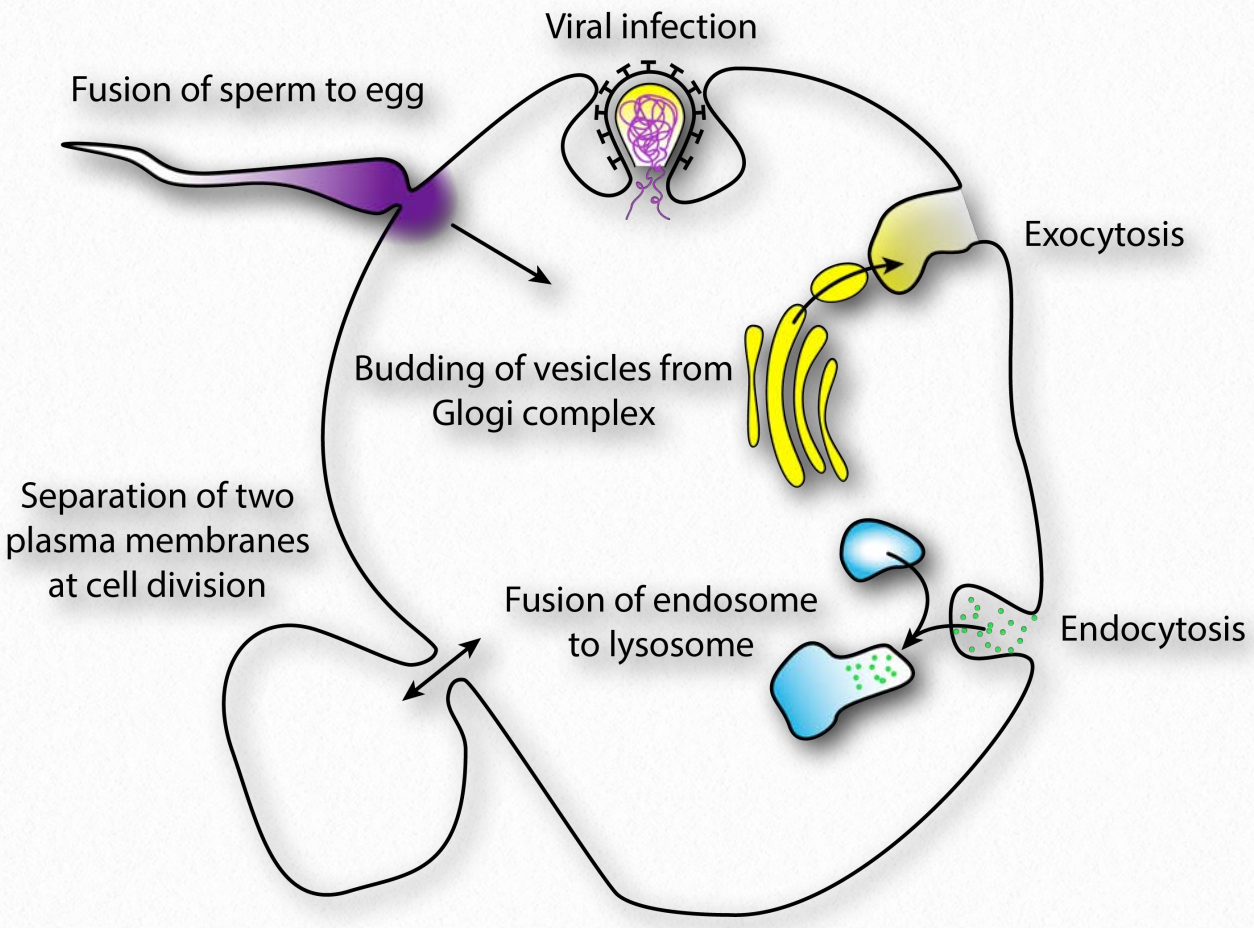

Figure 3.60 - Cell membrane fusions
Image by Pehr Jacobson

materials not destined for destruction in the lysosomes. LDLs, for example, are targeted after endocytosis to the endosomes for processing before part of them is delivered to the lysosome. The endosomes can also receive molecules from the *trans*-Golgi network. These can be delivered to the lysosomes, as well, or redirected back to the Golgi. Endosomes come in three forms - 1) early, 2) late, and 3) recycling.

Exocytosis

The process of exocytosis is used by cells to export molecules out of cells that would not otherwise pass easily through the plasma membrane. In the process, secretory vesicles fuse with the plasma membrane and release their contents extracellularly. Materials, such as proteins and lipids embedded in the membranes of the vesicles become a part of the plasma membrane when fusion between it and the vesicles occurs.

YouTube Lectures by Kevin HERE & HERE

Membrane fusion

Fusion is a membrane process where two distinct lipid bilayers merge their hydrophobic cores, producing one interconnected structure. Membrane fusion involving vesicles is the mechanism by which the processes of endocytosis and exocytosis occur.

When the fusion proceeds through both leaflets of both bilayers, an aqueous bridge results and the contents of the two structures mix.

Common processes involving membrane fusion (Figure 3.60) include fertilization of an egg by a sperm, separation of membranes in cell division, transport of waste products, and neurotransmitter release (Figure 3.61). Artificial membranes such as liposomes can also fuse with cellular mem-

branes. Fusion is also important for transporting lipids from the point of synthesis inside the cell to the membrane where they are used. Entry of pathogens can also be governed by fusion, as many bilayer-coated viruses use fusion proteins in entering host cells.

SNARE proteins

Mediation of fusion of vesicles in exocytosis is carried out by proteins known as SNAREs (Soluble NSF Attachment Protein REceptor). This large superfamily of proteins spans a wide biological range, from yeast to mammals. Common vesicle fusions occur when synaptic vesicles dock with neurons (Figure 3.61) and release neurotransmitters. These are well-studied. The SNAREs involved in this process can be proteolytically cleaved by bacterial neurotoxins that give rise to the conditions of botulism and tetanus.

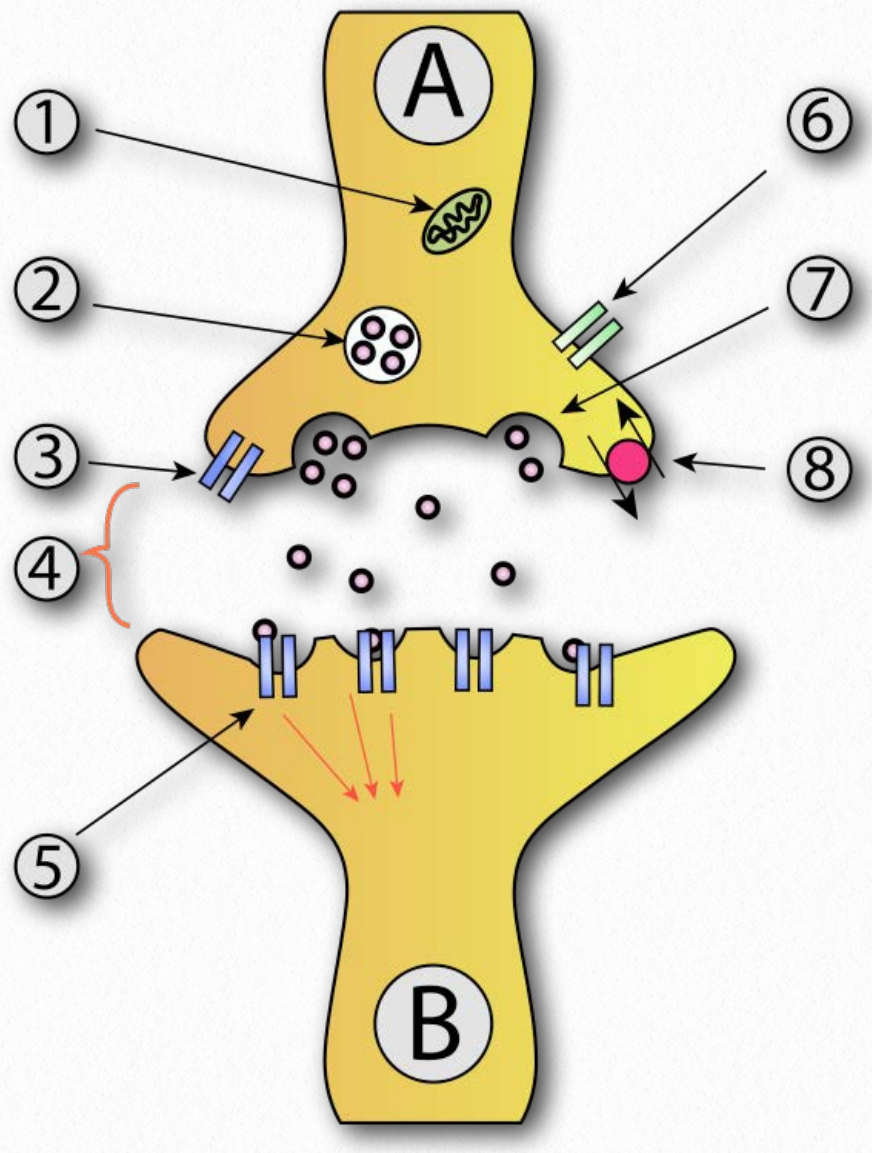

Figure 3.61 - Release of neurotransmitters (small circles) from presynaptic neuron A to postsynaptic neuron B. 1 = Mitochondrion / 2 = Synaptic vesicle with neurotransmitter / 3 = Autoreceptor / 4 = Synaptic cleft / 5 = Neurotransmitter receptor / 6 = Calcium channel / 7 = Fused vesicle releasing neurotransmitter / 8 = Neurotransmitter re-uptake pump

Wikipedia

SNAREs are found in two locations. v-SNAREs are found in the membranes of transport vesicles during the budding process, whereas t-SNARES can be found in the membranes of targeted compartments.

The act of vesicle fusion coincides with increases of intracellular calcium. Fusion of synaptic vesicles in neurotransmission results in activation of voltage-dependent calcium channels in the targeted cell. Influx of calcium helps to stimulate vesicle fusion. In the endocrine system, binding of hormones to G protein coupled receptors activate the IP_3/DAG system to increase levels of calcium.

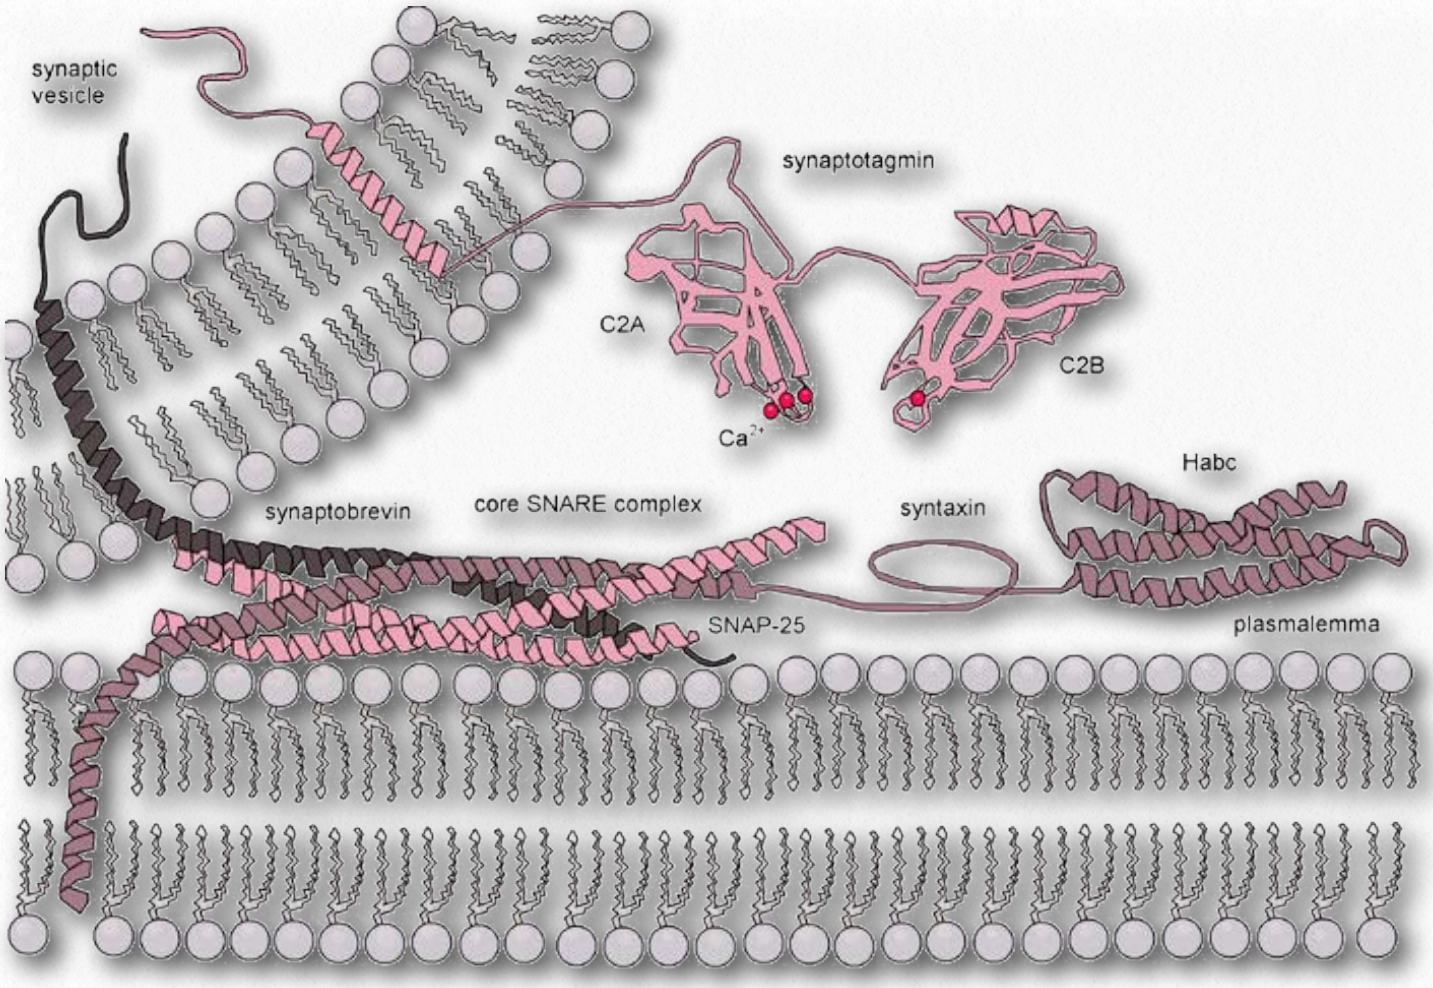

Figure 3.62 - Proteins involved in vesicle fusion in neurotransmission. A SNARE complex between α-helices of synaptobrevin, syntaxin and SNAP-25 intertwine and "zip" membranes together. Synaptotagmin is a calcium sensor regulating the process of zipping

Wikipedia

In the process of membrane fusion (Figure 3.62), the v-SNAREs of a secretory vesicle (upper left) interact with the t-SNAREs of a target membrane (bottom). The v- and t-SNAREs "zipper" themselves together to bring the membrane vesicle and the target membrane closer together.

Zippering also causes flattening and lateral tension of the curved membrane surfaces, favoring hemifusion of the outer layers of each membrane. Continued tension results in subsequent fusion of the inner membranes as well, yielding opening of the contents of the vesicle chamber to its target (usually outside the cell).

Shuttles

Another way to transport items across a membrane for which there is no specific transport system available is the use of shuttles. Shuttles are important when there is no transport mechanism for moving material across a membrane for which no transport system exists.

A great example is NADH. NADH is an important electron carrier that is produced in the cytoplasm and mitochondria of the cell. NADH produced in the mitochondrion goes directly to the electron transport system and delivers electrons to Complex I. NADH produced in the cytoplasm (such as from glycolysis) does not have this option, since the inner membrane of the mitochondrion is impermeable to the molecule

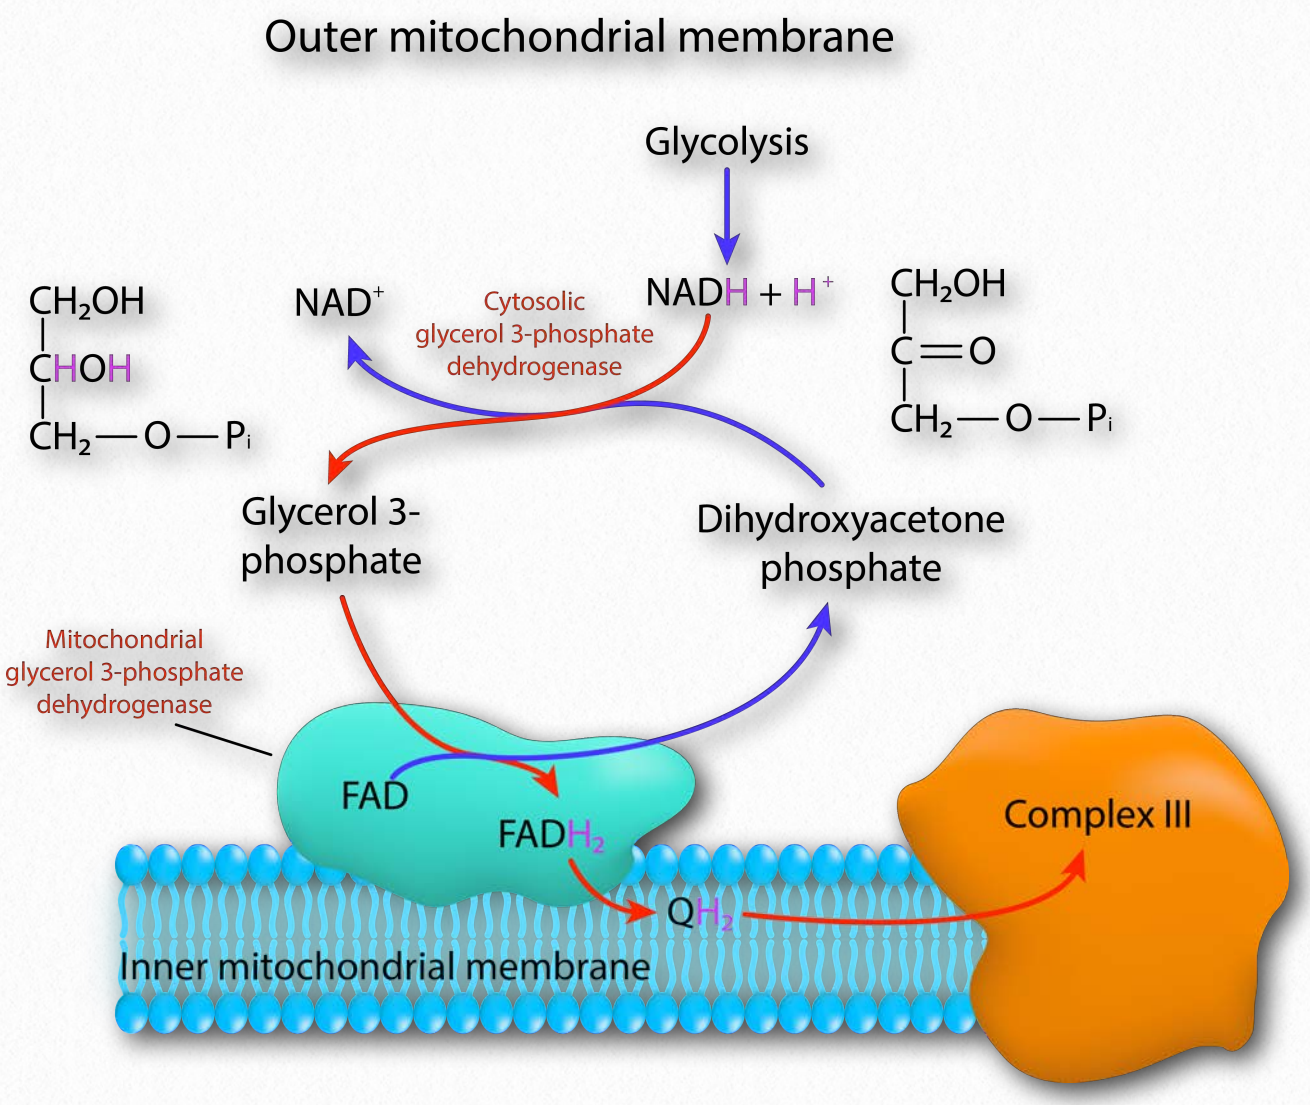

Figure 3.63 - Glycerol phosphate shuttle system in the intermembrane space of a mitochondrion

Image by Pehr Jacobson

Glycerol phosphate shuttle

The first of these methods is the least efficient, but it is rapid. It found commonly in muscles which have needs for rapid energy and brain tissue. This shuttle is referred to as the glycerol phosphate shuttle and is shown in Figure 3.63. It operates in the intermembrane space between the inner and outer mitochondrial membranes. The outer mitochondrial membrane is very porous, allowing many materials to pass freely through it. In the intermembrane space, the cytoplasmic enzyme, glyceraldehyde-3-phosphate dehydrogenase (cGPD) catalyzes transfer of electrons from NADH to dihdydroxyacetone phosphate (#2 in the figure), yielding NAD^+ and glyceraldehyde-3-phosphate (#1 in the figure). The glyceraldehyde-3-phosphate then binds to a glyceraldehyde-3-phosphate dehydrogenase (mGPD) embedded in the outer portion of the inner mitochondrial membrane. mGPD catalyzes the transfer of electrons from glyceraldehyde-3-phosphate to FAD, producing dihycroxyacetone phosphate

and no transporter exists to move it across. The important part of the NADH is its electron cargo, so cells have evolved two ways to move the electrons into the mitochondrial matrix apart from NADH.

Both methods involve shuttles. In each case, an acceptor molecule receives electrons from NADH and the reduced form of the acceptor molecule is transported. It gets transported into the matrix where it is oxidized (electrons are lost) and then donated to the electron transport system.

and $FADH_2$. $FADH_2$ then transfers its electrons to the electron transport system through CoQ (Q above), forming $CoQH_2$ (QH_2 above). As will be discussed in the section on electron transport, this is not an efficient shuttle system because it does not result in production of as much ATP as occurs when electrons are transferred to NAD^+ instead of FAD.

Malate-aspartate shuttle

A more efficient system of transferring electrons is the malate-aspartate shuttle and it is shown in Figure 3.64. As is apparent in the figure, this shuttle involves more steps than the glycerol phosphate shuttle, but the advantage of the malate-aspartate shuttle is that it is more efficient. NADH outside of

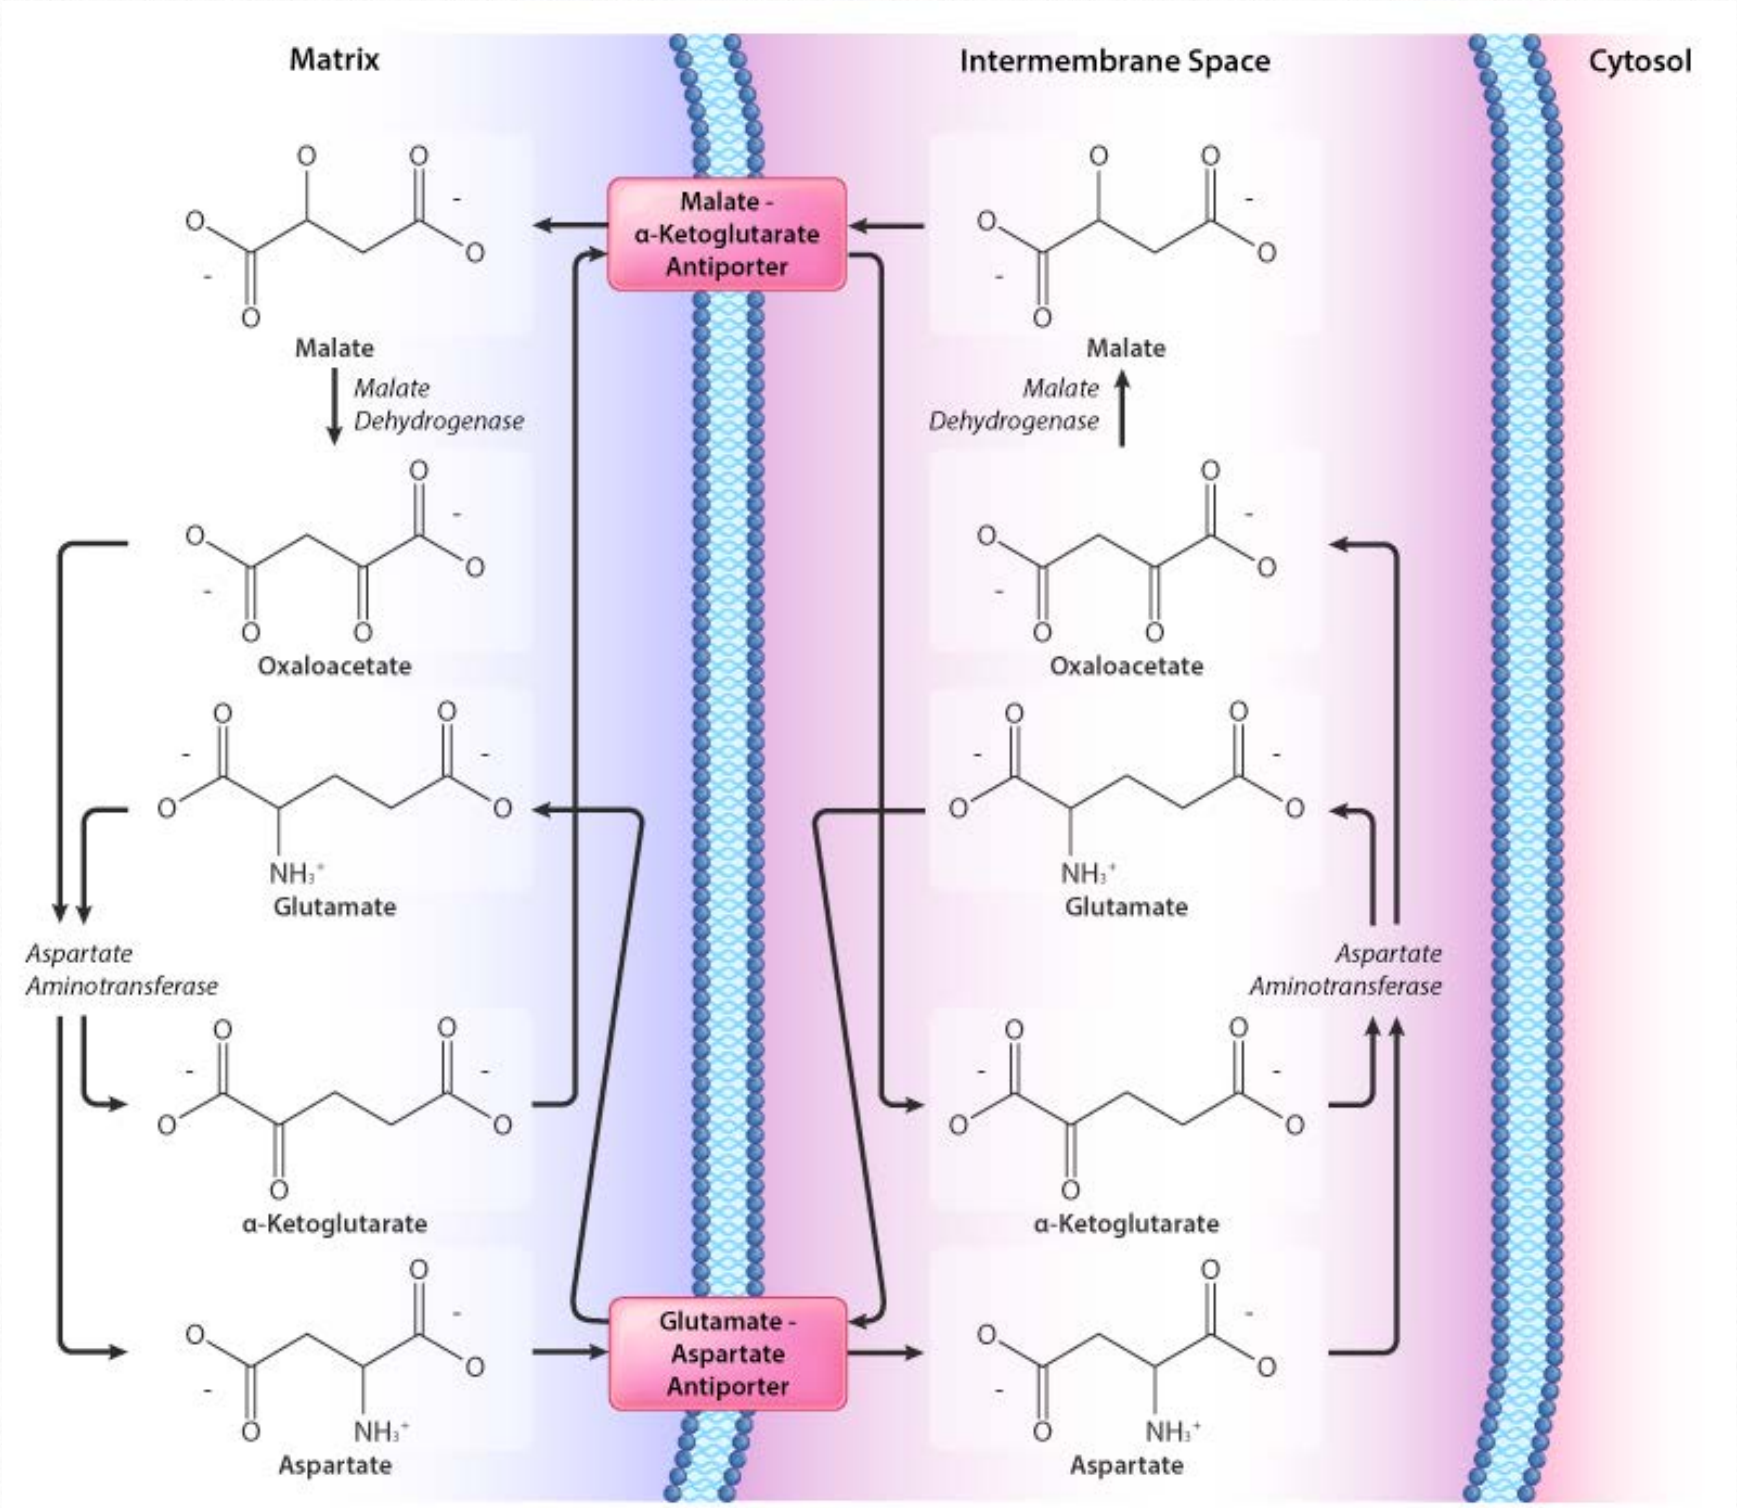

Figure 3.64 - The malate aspartate shuttle

Image by Aleia Kim

the mitochondrion transfers its electrons to the shuttle and then NADH is re-made on the inside of the shuttle. No energy is expended in the process.

When NADH accumulates in the cytoplasm, it moves to the intermembrane space where the enzyme malate dehydrogenase catalyzes the transfer of electrons to oxaloacetate to yield NAD^+ and malate. A transport system for malate moves malate into the mitochondrial matrix in exchange for α-ketoglutarate.

Inside the mitochondrion, malate is reoxidized to oxaloacetate and electrons are given to NAD^+ to recreate NADH. NADH then donates electrons to Complex I of the electron transport system. That's really all there is to the shuttle. The remaining steps are simply to balance the equation of the process. Oxaloacetate accepts an amine group from glutamic acid to yield aspartic acid and α-ketoglutarate. Aspartate then moves out of the mitochondrion through an antiport transport protein that swaps it for glutamate. A series of reactions in the intermembrane space balance the equation.

It is easy to get lost in the mess of balancing equations. The most important thing to understand here is that oxaloacetate accepts electrons on the outside to become malate which is the carrier of electrons across the membrane. Once inside the matrix, malate is converted back to oxaloacetate and its electrons are given to NAD^+, forming NADH. Everything else is simple equation balancing.

YouTube Lectures by Kevin HERE & HERE

Acetyl-CoA shuttle

Another kind of shuttle also involves the mitochondrion and in this case, the item being moved is a molecule, not a pair of electrons. The molecule of interest here is acetyl-CoA, for which no transport system operates, but which is needed in the cytoplasm for fatty acid synthesis when the cell has abundant energy.

Acetyl-CoA is mostly in the mitochondrion and so long as the citric acid cycle is operating efficiently, its concentration is relatively stable. However, when the citric acid cycle slows, acetyl-CoA and the citrate made from it in the cycle begin to accumulate.

A membrane transport system for citrate exists, so it gets moved out to the cytoplasm. In the cytoplasm, an enzyme known as citrate lyase cleaves citrate to acetyl-CoA and oxaloacetate. Oxaloacetate can be reduced to malate and moved back into the mitochondrion.

As for acetyl-CoA, the more of that cells have in the cytoplasm, the more likely they will begin making fatty acids and fat, since acetyl-CoA is the starting material for fatty acid syn-

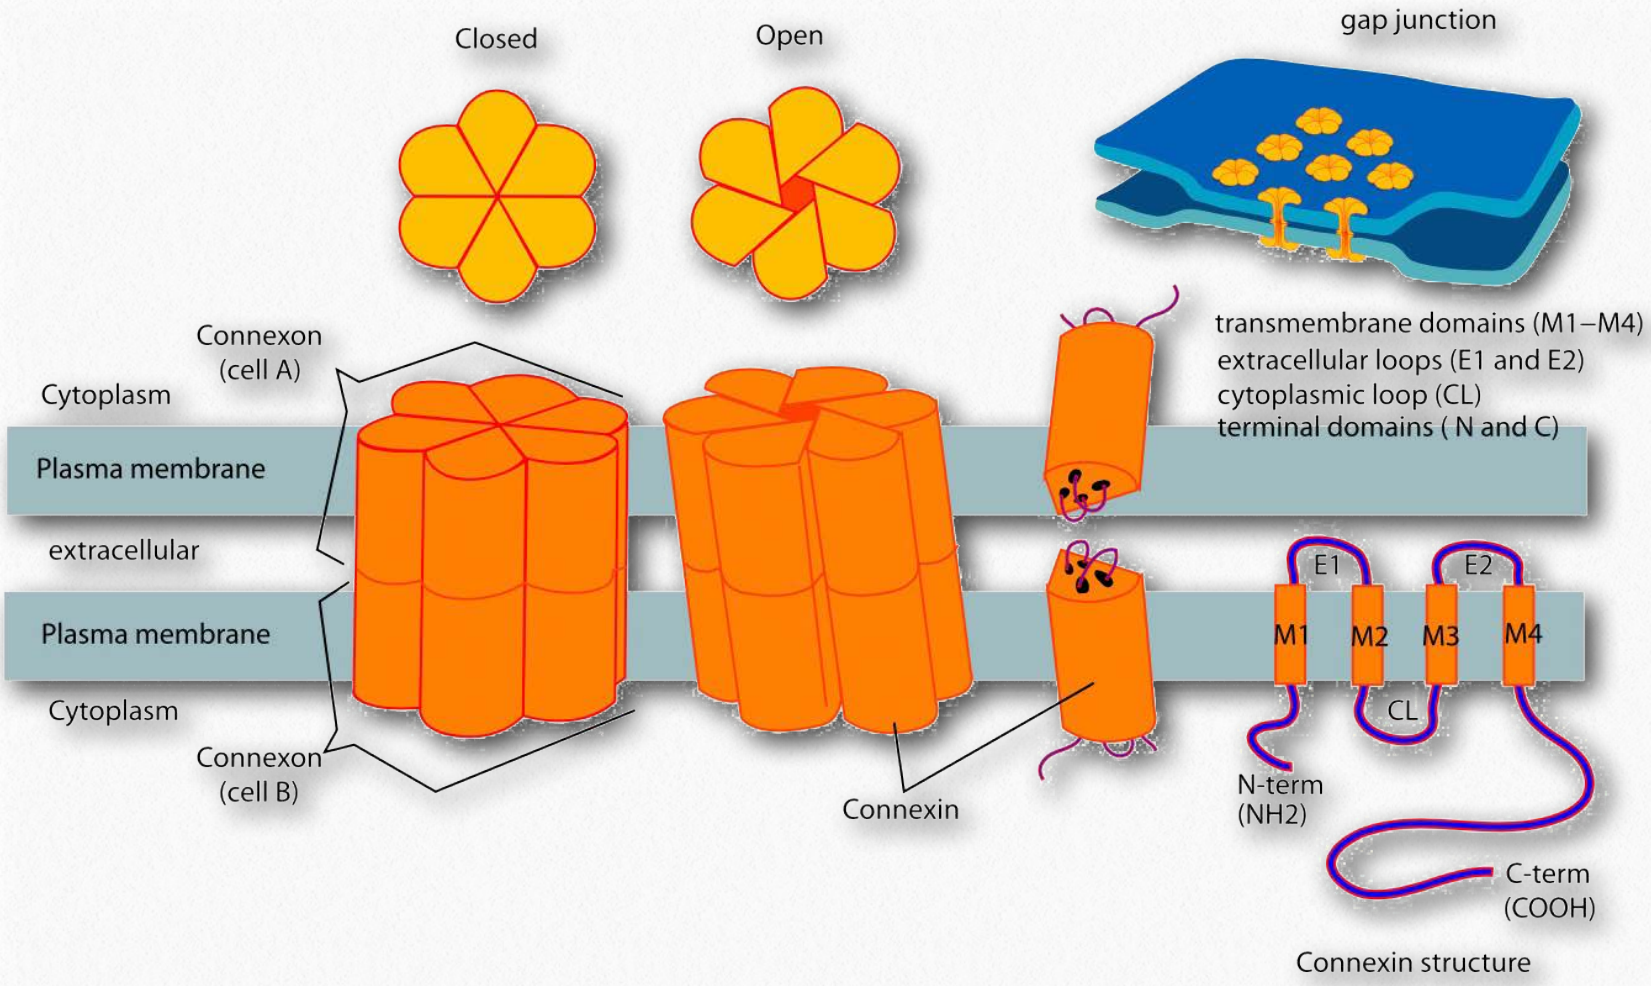

Figure 3.65 - Structure of connexons joining two cells. Bundles of six copies of connexin proteins in the plasma membrane of each cell comprise the connexon structures

thesis, which occurs in the cytoplasm. When does this process occur? As noted above, it occurs when the citric acid cycle stops and this occurs when levels of NADH and $FADH_2$ increase. These, of course, increase when one is not burning off as many calories as one is consuming as a byproduct of respiratory control. Lack of exercise leads to higher levels of reduced electron carriers.

Cell junctions

Cells in multicellular organisms are in close contact with each other and links between them are called junctions. In vertebrate organisms, there are three main types of cell junctions and one of them (gap junctions) is important for movement of materials between cells. The three types are

1. Gap junctions

2. Adherens junctions, (Anchoring Junctions, desmosomes and hemidesmosomes)

3. Tight junctions

Cell junctions in multicellular plants are structured differently from those in vertebrates and are called plasmodesmata. They too

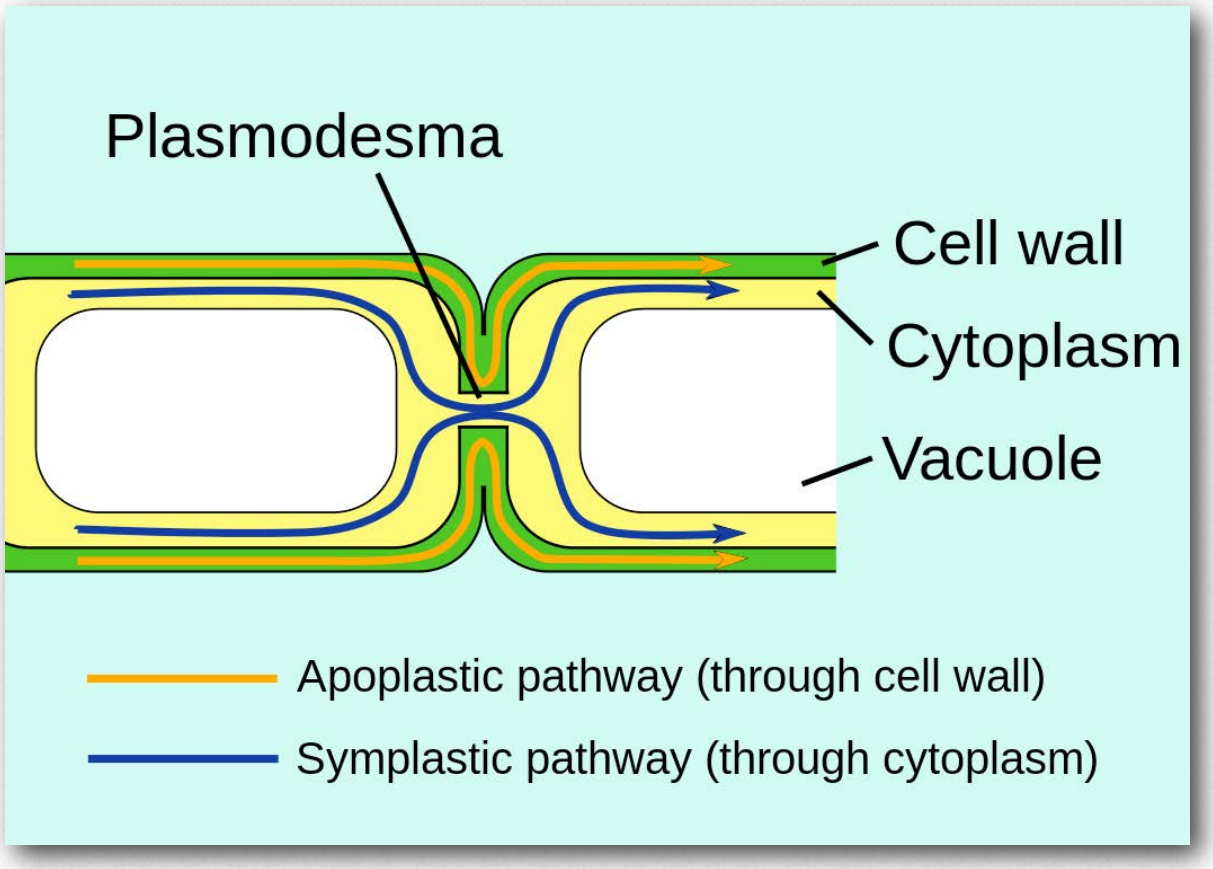

Figure 3.66 - Two means of intercellular communication in plant cells - apoplastic pathway (through cell wall) and symplastic pathway (through the plasodesma)

function in exchange of materials between individual cells.

Gap junctions

Gap junctions are specialized structures made up of two sets of structures called connexons (one from each cell - see Figure 3.65) directly link the cytoplasms of the connected cells. Gap junctions are regulated to control the flow of molecules, ions, and electrical impulses between cells. In plants, similar structures known as plasmodesmata traverse the cell wall (Figure 3.66) and perform similar functions.

Adherens junctions

Adherens junctions (Figure 3.67) are protein complexes on the cytoplasmic side of the cell membranes of epithelial and endothelial tissues that link cells to each other or to the extracellular matrix. They correspond to the fascia adherens found in non-epithelial/non-endothelial cells.

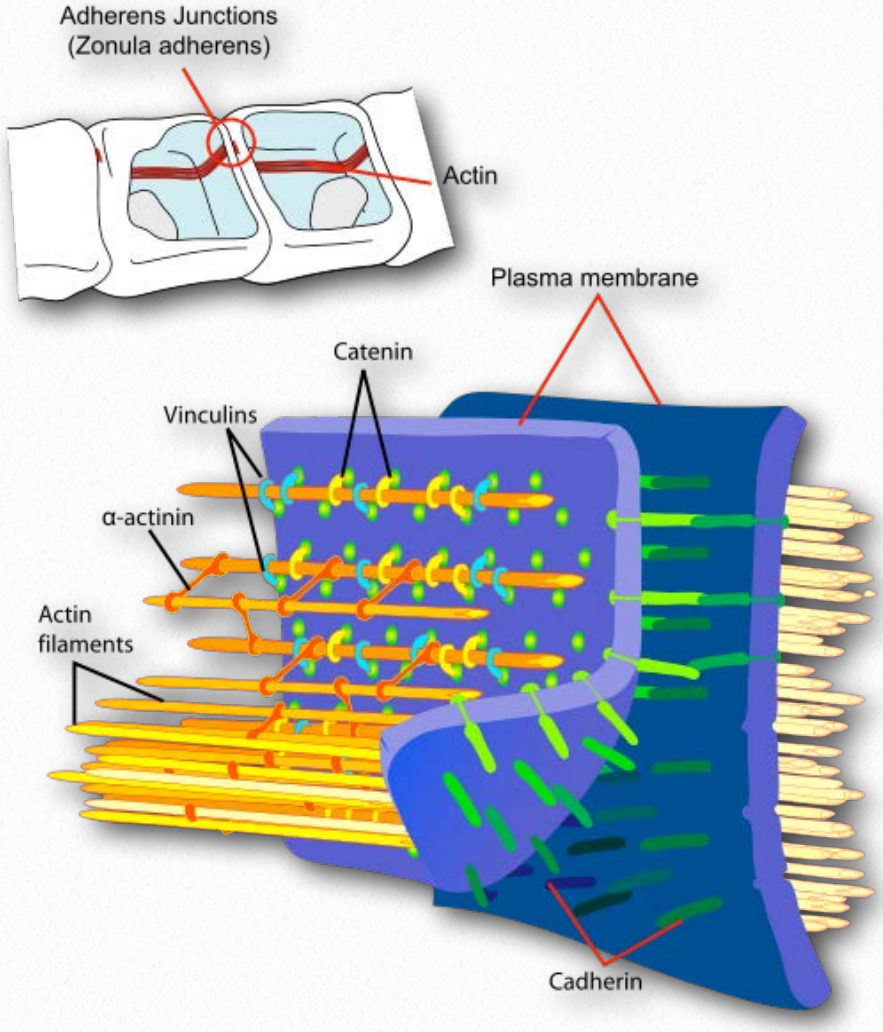

Figure 3.67 - Adherens junction

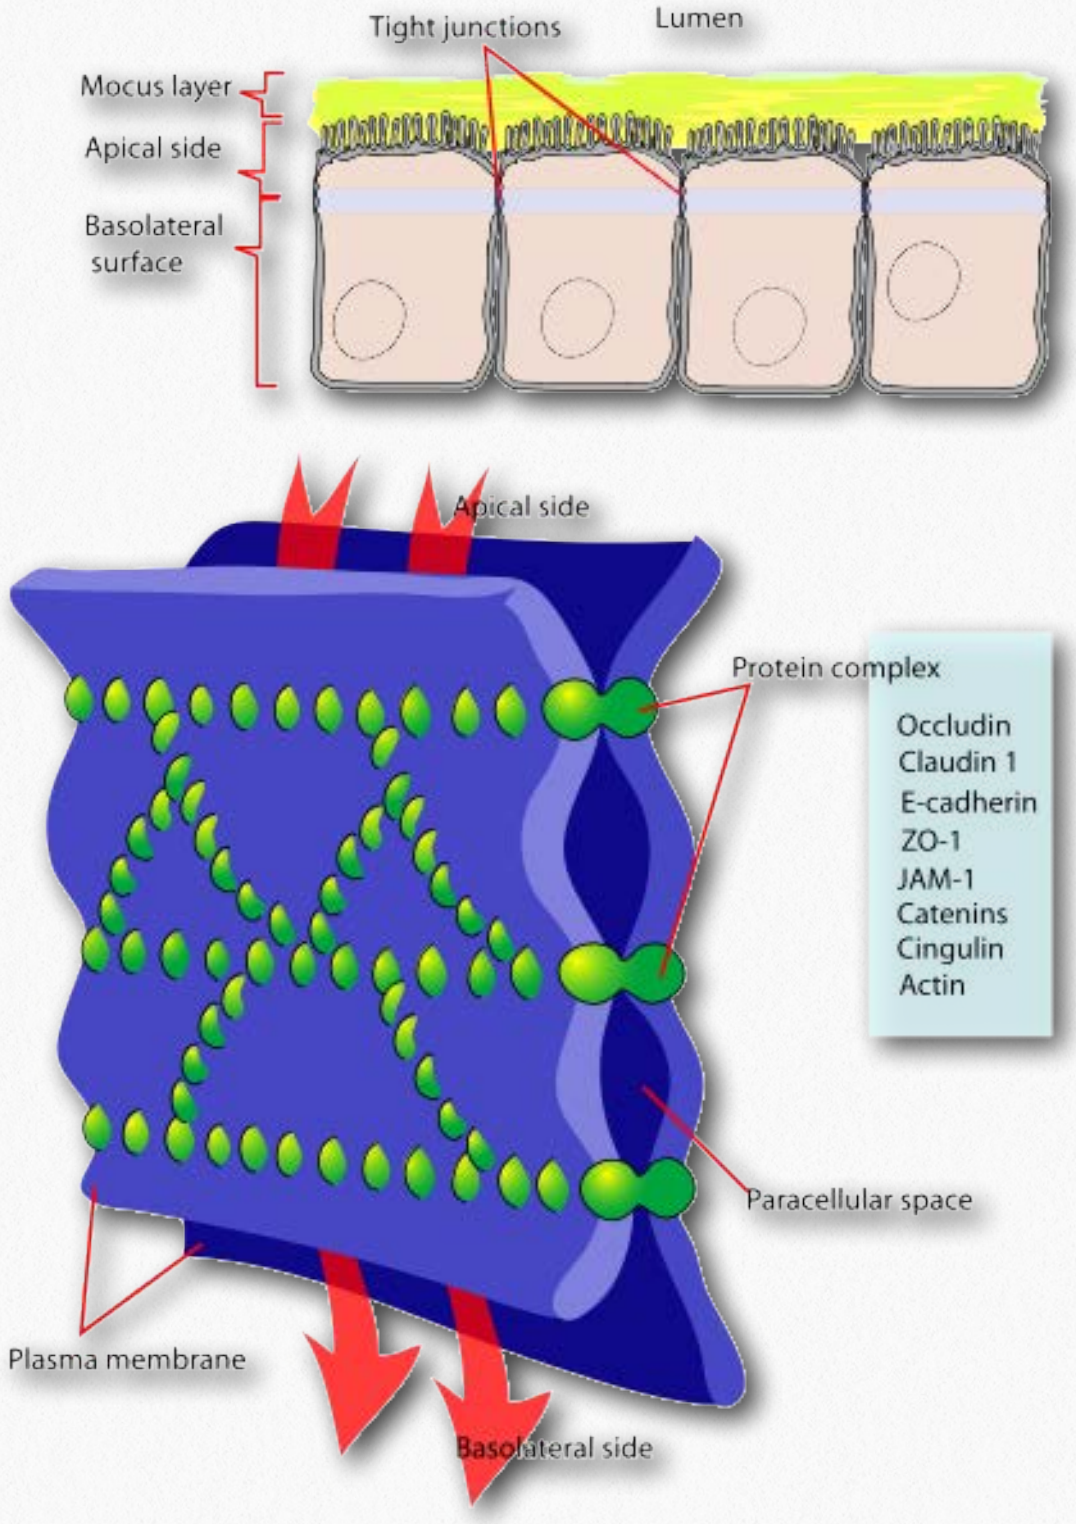

Figure 3.68 - Tight junctions

Adherens junctions contain the following proteins - 1) α-catenin (binds cadherin through β-catenin); 2) β-catenin (attachment for α-catenin to cadherin; 3) γ-catenin (binds to cadherin); 4) cadherins (group of transmembrane proteins that dimerize with cadherins on adjacent cells; 5) p120 (also called Δ-catenin - binds to cadherin); 6) plakoglobin (catenin family protein homologous to and acting like β-catenin); 7) actin; 8) actinin; and 9) vinculin. Adherens junctions may help to maintain the actin contractile ring which forms in the process of cytokinesis.

Tight junctions

Tight junctions (Figure 3.68) are a network of protein strands that seal cells together and restrict the flow of ions in the spaces between them. The effect of their structure is to restrict the movement of materials through tissues by requiring them to pass through cells instead of around them. Tight junctions join together the cytoskeletons of cells and through their structure maintain their apical and basolateral polarity.

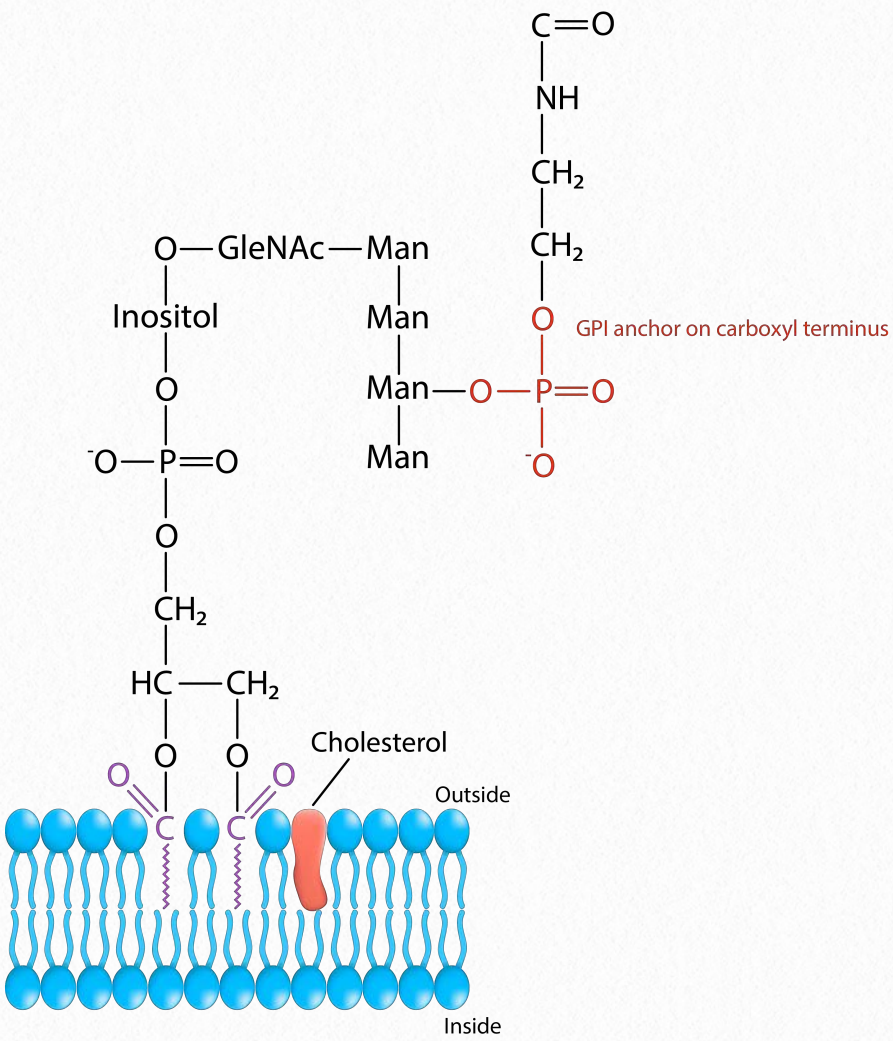

Figure 3.69 - A glypiated protein linked to a membrane-embedded inositol-based molecule. The protein portion is above the red phosphate ion

Image by Pehr Jacobson

GPI anchors

Membrane proteins attached to glycosylphosphatidylinositol (also known as a GPI anchor) are referred to as being glypiated. The proteins, which play important roles in many biochemical processes, are attached to the GPI anchor at their carboxyl terminus. Phospholipases, such as phospholipase C can cut the bond between the protein and the GPI, freeing the protein from the outer cell membrane. Proteins destined to be glypiated have two signal sequences. They are 1) An N-terminal signal sequence and 2) A C-terminal signal sequence that is recognized by a GPI transamidase (GPIT). The N-terminal signal sequences is responsible for directing co-translational transport into the endoplasmic reticulum. The C-terminal sequence is recognized by GPI transamidase, which links the carboxy terminus of a protein to the GPI anchor.

Liposomes

The spontaneous ability of phosphoglycerolipid and sphingolipid compounds to form lipid bilayers is exploited in the formation of artificial membranous structures called liposomes (Figure 3.69). Liposomes are useful for delivering their contents into cells via

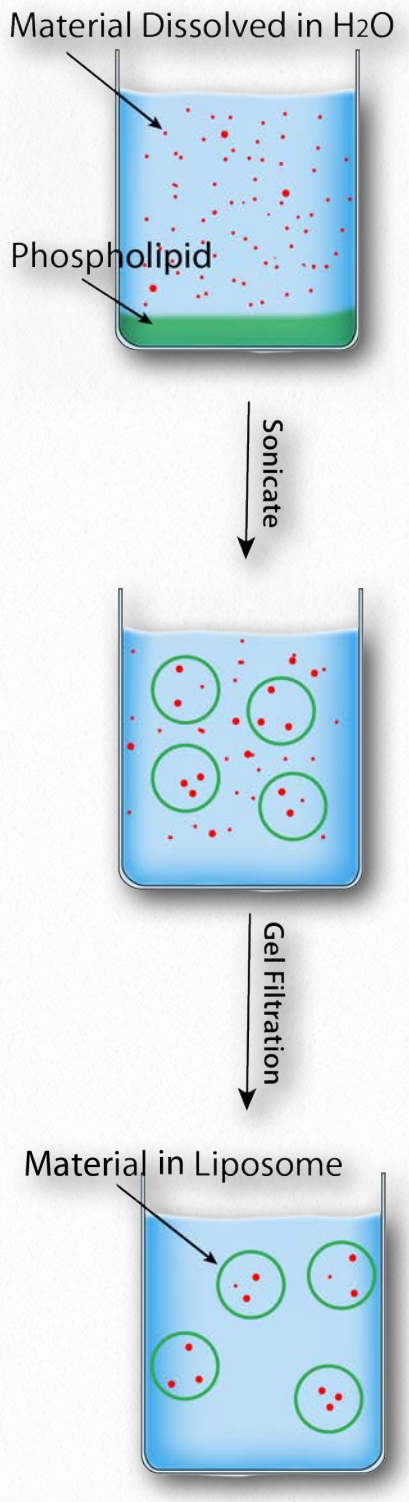

Figure 3.70 - Formation of liposomes from phospholipids in water

Image by Pehr Jacobson

membrane fusion. In the figure, items targeted for delivery to cells would be encased in the middle circular region of the liposome and when the liposome fuses with the cell membrane, it will deliver the contents directly into the cytoplasm.

Hydropathy index

The interior portion of the lipid bilayer is very hydrophobic, which makes it very restrictive to movement of ions and polar substances across it. This property also places limitations on the types of amino acids that will interact with it as well. Because of this, transmembrane protein domains found in integral membrane proteins are biased in the amino acids that interact with either the lipid bilayer or the aqueous material on either side of it.

Hydrophobic amino acids are found within the bilayer, whereas hydrophilic amino acids are found predominantly on the surfaces. An additional clue to identifying membrane crossing regions of a protein is that tryptophan or tyrosine is commonly positioned at nonpolar/polar interface(s) of the lipid bilayer for integral proteins. Such an organization of amino acids can be recognized by computer analysis of amino acid sequences using what is called a hydropathy index/score (Figure 3.71). Though the names and the scorings vary, the idea is to assign a number (usually positive) to amino acid side chains with higher hydrophobicity and negative to those that are ionic. With these scores, a computer program can easily find the average scores of short amino acid segments (say 3 amino acids long) and then plot those values on a graph of hydrophobicity index versus position in polypeptide chain. Doing that for a transmembrane protein such as glycophorin results in the plot shown in Figure 3.72. It is apparent in the analysis that this is a transmembrane protein that has seven domains crossing the lipid bilayer, as labeled.

Wikipedia

Cell walls

Cells walls are found in many cells, including plants, fungi, and bacteria, but are not found

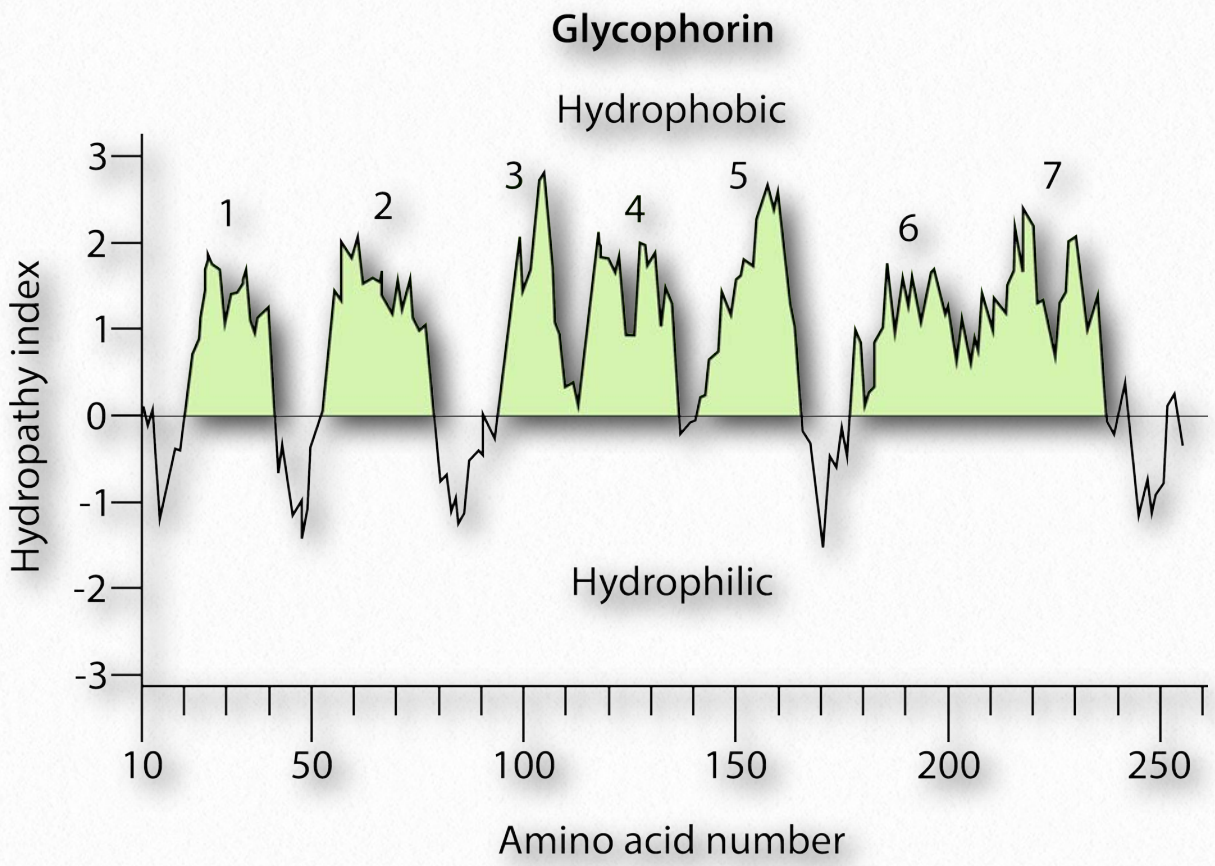

Figure 3.72 - Hydropathy index plot for glycophorin. Each lipid bilayer-crossing domain noted with a number

Image by Pehr Jacobson

in animal cells. They are designed to provide strength and integrity and at least some protection against bursting from osmotic pressure (Figures 3.73-3.75).

Gram positive bacteria (Figure 3.75) have the simplest cell wall design. Moving from outside the cell towards the cytoplasm there is an outer peptidoglycan layer for the cell wall followed by a periplasmic space, a plasma membrane, and then the cytoplasm. Gram negative bacteria add a second protective layer external to all of this, so for them,

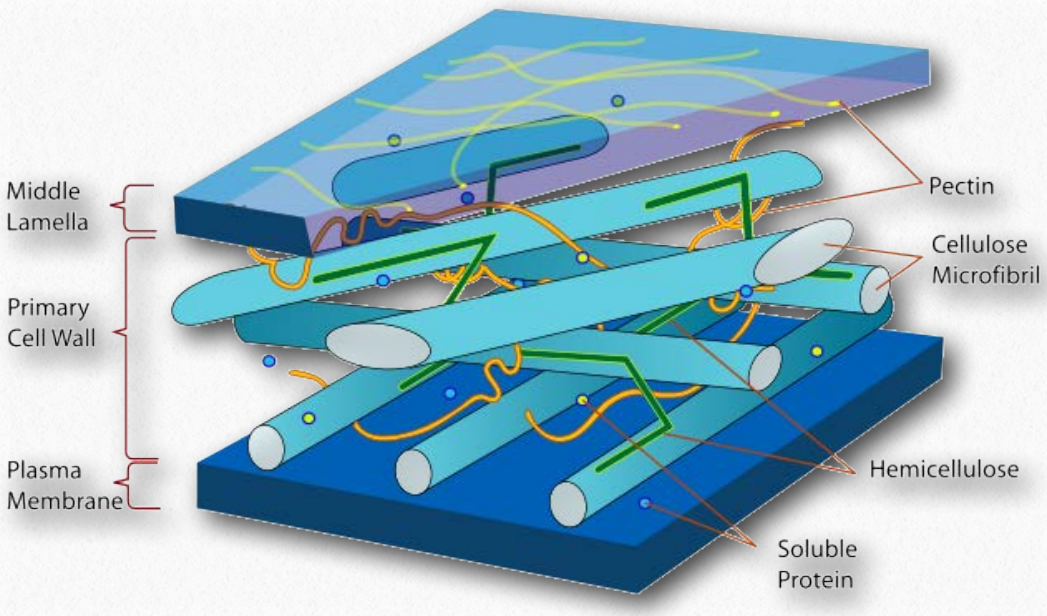

Figure 3.73 - Plant cell wall. Direction of the cytoplasm is down

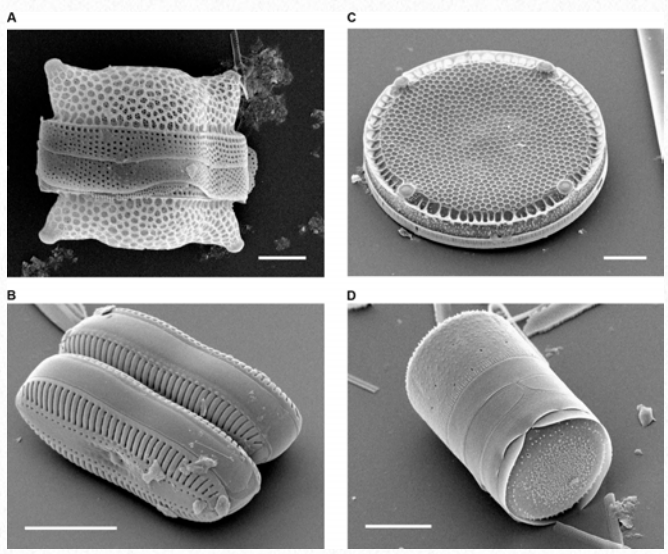

Figure 3.74 - Cell walls of diatoms

Wikipedia

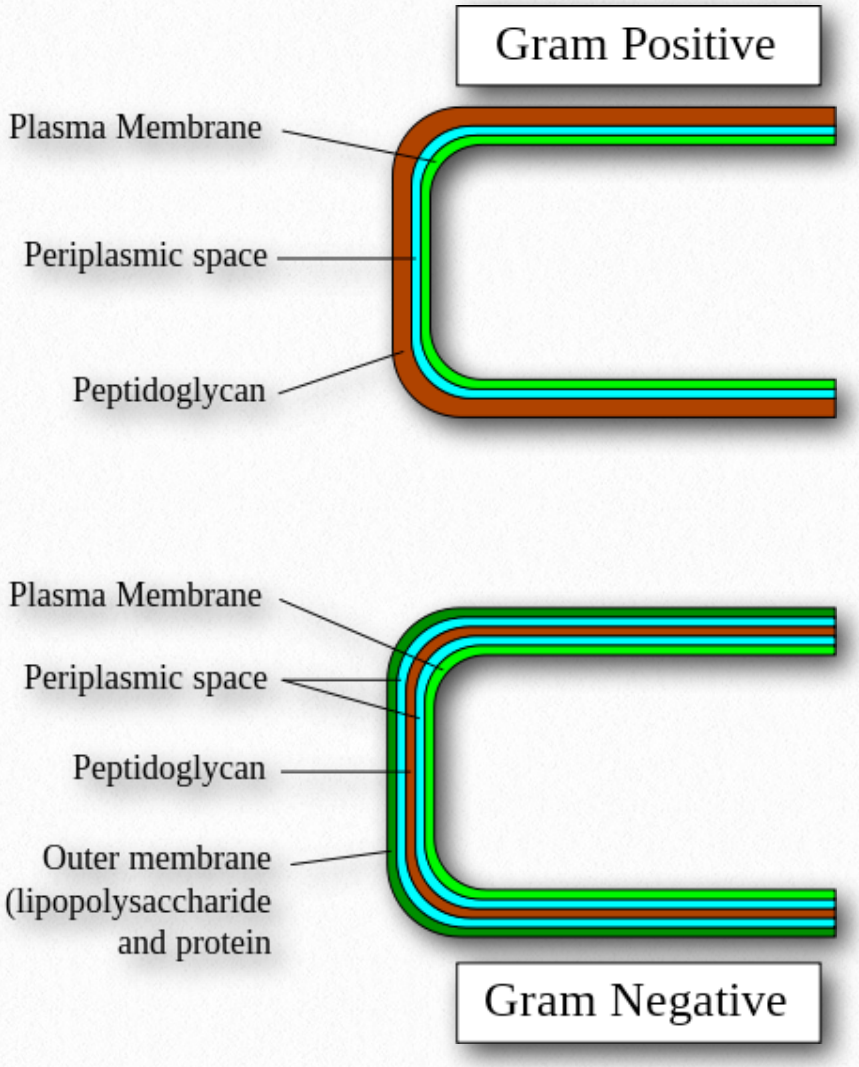

Figure 3.75 - Gram positive versus Gram negative bacteria cell coverings
Wikipedia

starting at the outside and moving inwards, one encounters an outer lipopolysaccharide layer, a periplasmic space, the peptidoglycan cell wall, a second periplasmic space, a plasma membrane and then the cytoplasm.

Herbaceous plants have a rigid outer cell wall (primarily composed of cellulose, hemicellulose, and pectin) and an inner plasma membrane. Woody plants add a second level of wall with lignin between the cellulosic wall and the plasma membrane of herbaceous plants.

Milam Hall - It's 12:30
And Ahern's gettin' wordy

He walks to and fro'
While not talkin' slow
Givin' it to B-B-4-5-0

I was happy when the term got started
Lecture notes and videos galore
MP3s got added to my iPod
But recitations sometimes were a bore

And exams bit me roughly
When the curve turned out ugly

I don't think it's so
My scores are too low
Slidin' by in B-B-4-5-0

Final-LY there's an examination
On December 9th at 6:00 pm
I'll have my card packed with information
So I don't have to memorize it then

And I'll feel like a smarty
With my jam-packed note-cardy
Just one more to go
And then ho-ho-ho
I'll be done with B-B-4-5-0

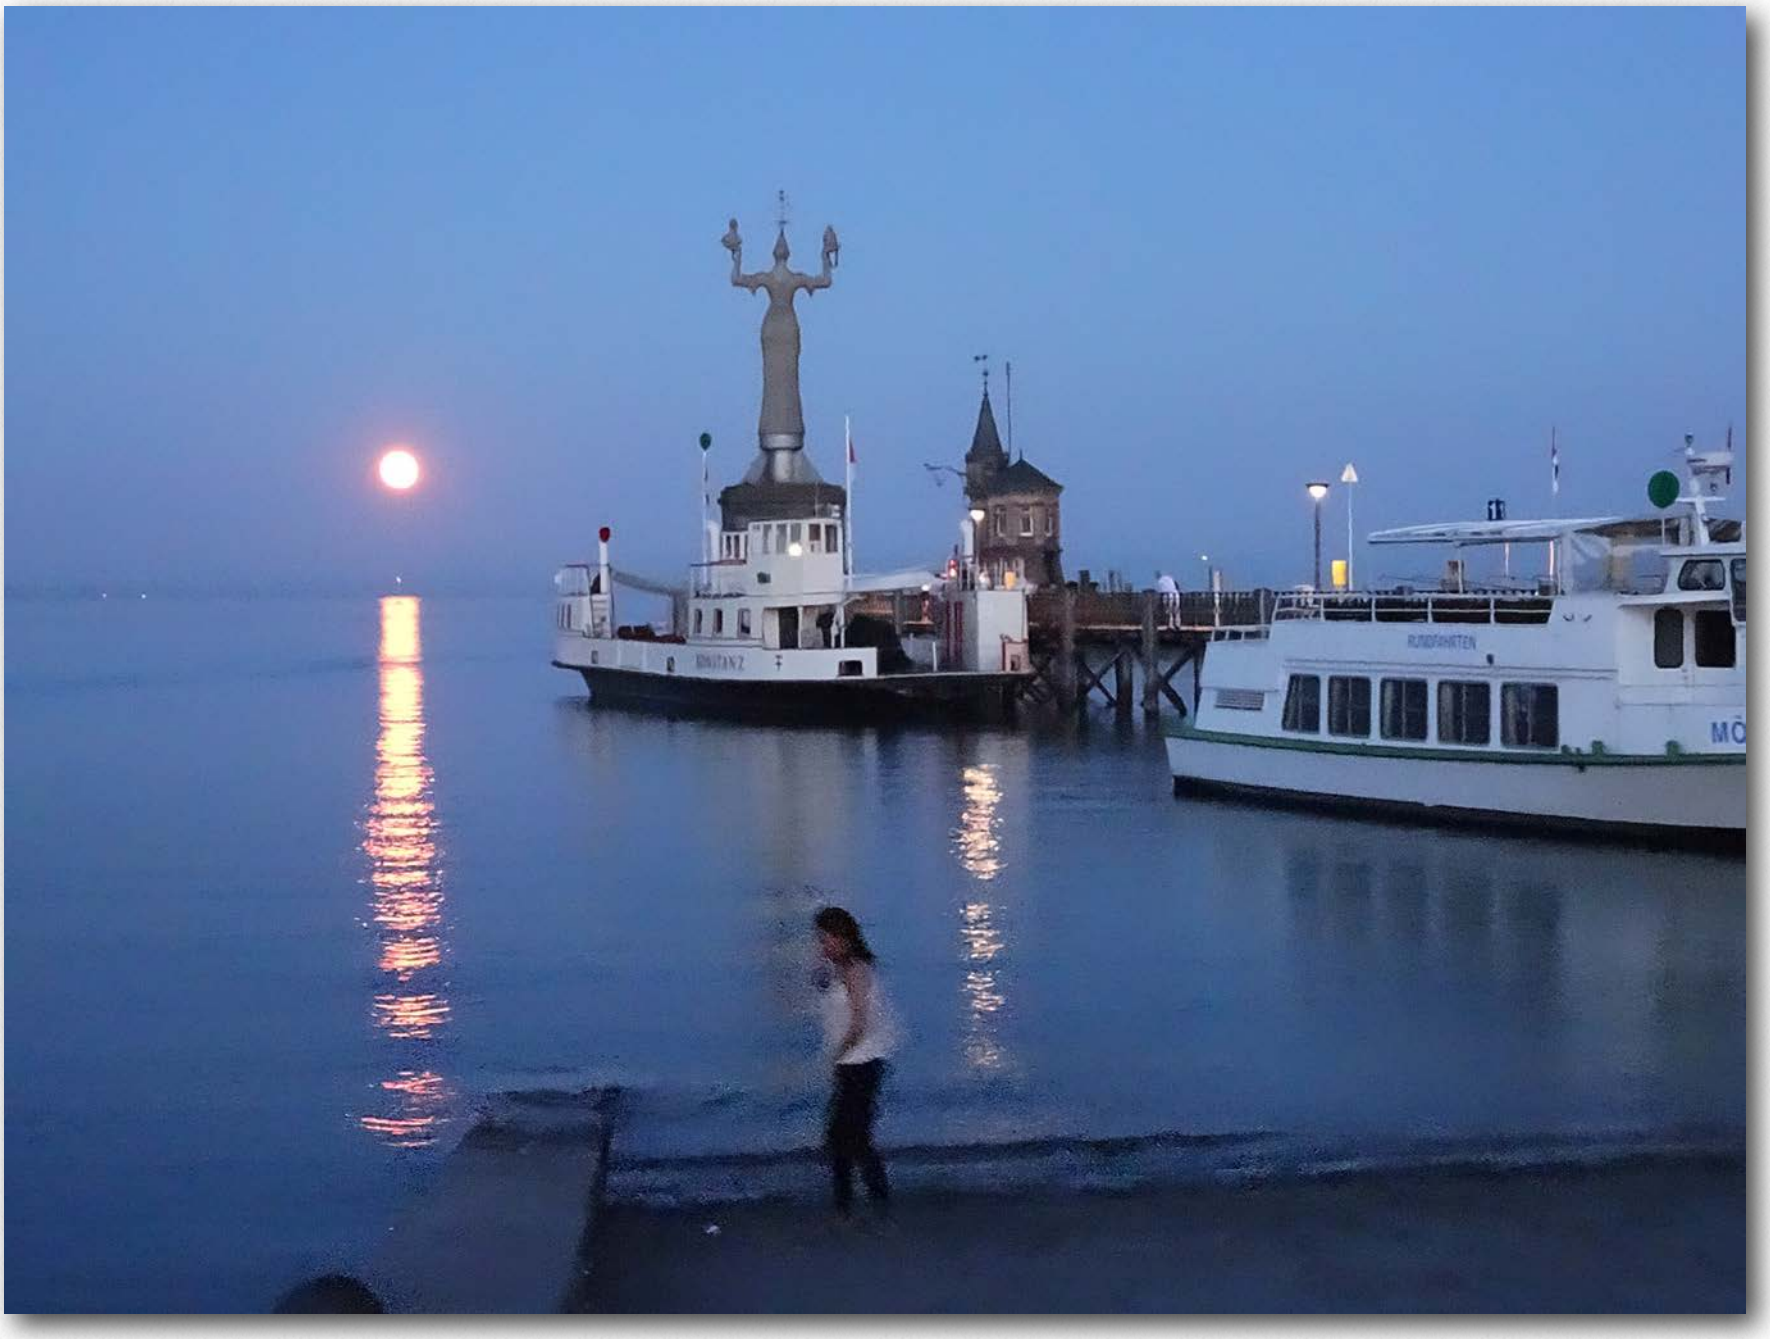
Catalysis

"A clever man commits no minor blunders."

Goethe

Where a good chemical catalyst might accelerate a reaction by a few orders of magnitude, the speed of the best enzyme catalyst boggles the mind, boosting reaction rates by 10^{24} - over 1 trillion trillion times faster than an uncatalyzed one. In this chapter we explore the ways in which the process of enzymatic catalysis occurs.

Catalysis: Basic Principles



If there is a magical component to life, an argument can surely be made for it being catalysis. Thanks to catalysis, reactions that can take hundreds of years to complete in the uncatalyzed "real world," occur in seconds in the presence of a catalyst. Chemical catalysts, such as platinum, can speed reactions, but enzymes (which are simply super-catalysts with a "twist," as we shall see) put chemical catalysts to shame (Figure 4.1). To understand enzymatic catalysis, it is necessary first to understand energy. Chemical reactions follow the universal trend of moving towards lower energy, but they often have a barrier in place that must be overcome. The secret to catalytic action is reducing the magnitude of that barrier.

YouTube Lectures by Kevin HERE & HERE

Equilibrium

Before discussing enzymes, it is appropriate to pause and discuss an important concept relating to chemical/biochemical reactions. That concept is equilibrium and it is very of-

ten misunderstood. The “equi" part of the word relates to equal, as one might expect, but it does not relate to absolute concentrations. What happens when a biochemical reaction is at equilibrium is that the concentrations of reactants and products do not change over time. This does not mean that the reactions have stopped. Remember that reactions are reversible, so there is a forward reaction and a reverse reaction: if you had 8 molecules of A, and 4 of B at the beginning, and 2 molecules of A were converted to B, while 2 molecules of B were simultaneously converted back to A, the number of molecules of A and B remain unchanged, i.e., the reaction is at equilibrium. However, you will notice that this does not mean that there are equal numbers of A and B molecules.

Concentration matters

So, contrary to the perceptions of many students, the concentrations of products and reactants are not equal at equilibrium, *unless* the **Δ**G°’ for a reaction is zero, because when this is the case,

$\Delta G = \ln\{[Products]/[Reactants]$,

since the ΔG°’ is zero. Because ΔG itself is zero at equilibrium, then [Products] = [Reactants]. This is the only circumstance where [Products] = [Reactants] at equilibrium.

Reiterating, at equilibrium, the concentrations of reactant and product do not change over time. That is, for a reaction

A <=> B

[A] at time zero when equilibrium is reached, $[A]_{T0,}$ will be the same 5 minutes later (assuming A and B are chemically stable). Thus,

$[A]_{T0} = [A]_{T+5}$.

Similarly,

$[B]_{T0} = [B]_{T+5}$

Enzyme	Nonenzymatic Half-Life	Uncatalyzed Rate (k_{un} s^{-1})	Catalyzed Rate (k_{cat} s^{-1})	Rate Enhancement (k_{cat} s^{-1}/k_{un} s^{-1})
OMP decarboxylase	78,000,000 years	28×10^{-16}	39	1.4×10^{17}
Staphylococcal nuclease	130,000 years	1.7×10^{-13}	95	5.6×10^{14}
Carboxypeptidase A	7.3 years	3.0×10^{-9}	578	1.9×10^{11}
Ketosteroid isomerase	7 weeks	1.7×10^{-7}	66,000	3.9×10^{11}
Triose phosphate isomerase	1.9 days	4.3×10^{-6}	4,300	1.0×10^{9}
Chorismate mutase	7.4 hours	2.6×10^{-5}	50	1.9×10^{6}
Carbonic anhydrase	5 seconds	1.3×10^{-1}	1×10^{6}	7.7×10^{6}

Abbreviations:
OMP - Orotine monophosphate
AMP - Adenosine monophosphate

Figure 4.1 - Rate enhancement for several enzymes

Image by Aleia Kim

For that matter, at any amount of time X after equilibrium has been reached,

$$[A]_{T0} = [A]_{T+5} = [A]_{TX}$$

and

$$[B]_{T0} = [B]_{T+5} = [B]_{TX}$$

However, unless $\Delta G^{\circ\prime} = 0$, it is *wrong* to say

$$[A]_{T0} = [B]_{T0}$$

As we study biochemical reactions and reaction rates, it is important to remember that 1) reactions do not generally start at equilibrium; 2) all reactions move in the direction of equilibrium; and 3) reactions in cells behave just like those in test tubes - they do not begin at equilibrium, but they move towards it.

Dynamic reactions

The reactions occurring in cells, though, are very dynamic and complex. In a test tube, they can be studied one at a time. In cells, the product of one reaction is often the substrate for another one. Reactions in cells are interconnected in this way, giving rise to what are called metabolic pathways.

There are, in fact, thousands of different interconnected reactions going on continuously in cells. Attempts to study a single reaction in the chaos of a cell is daunting to say the least. For this reason, biochemists isolate enzymes from cells and study reactions individually.

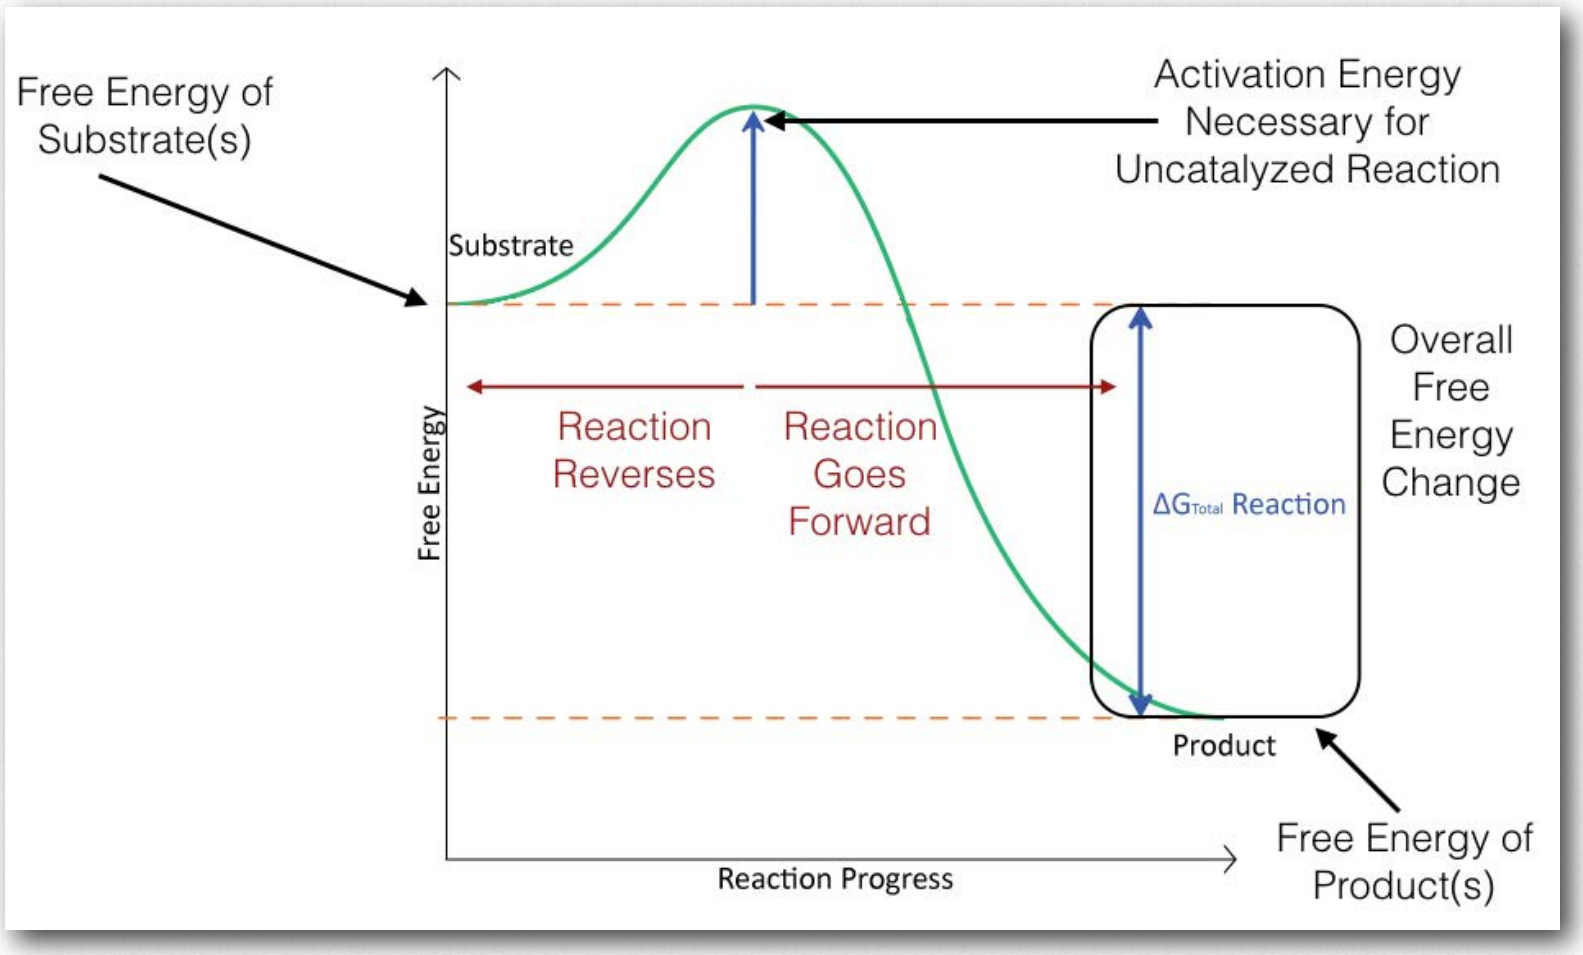


Figure 4.2 - Energy changes during the course of an uncatalyzed reaction

Image by Aleia Kim

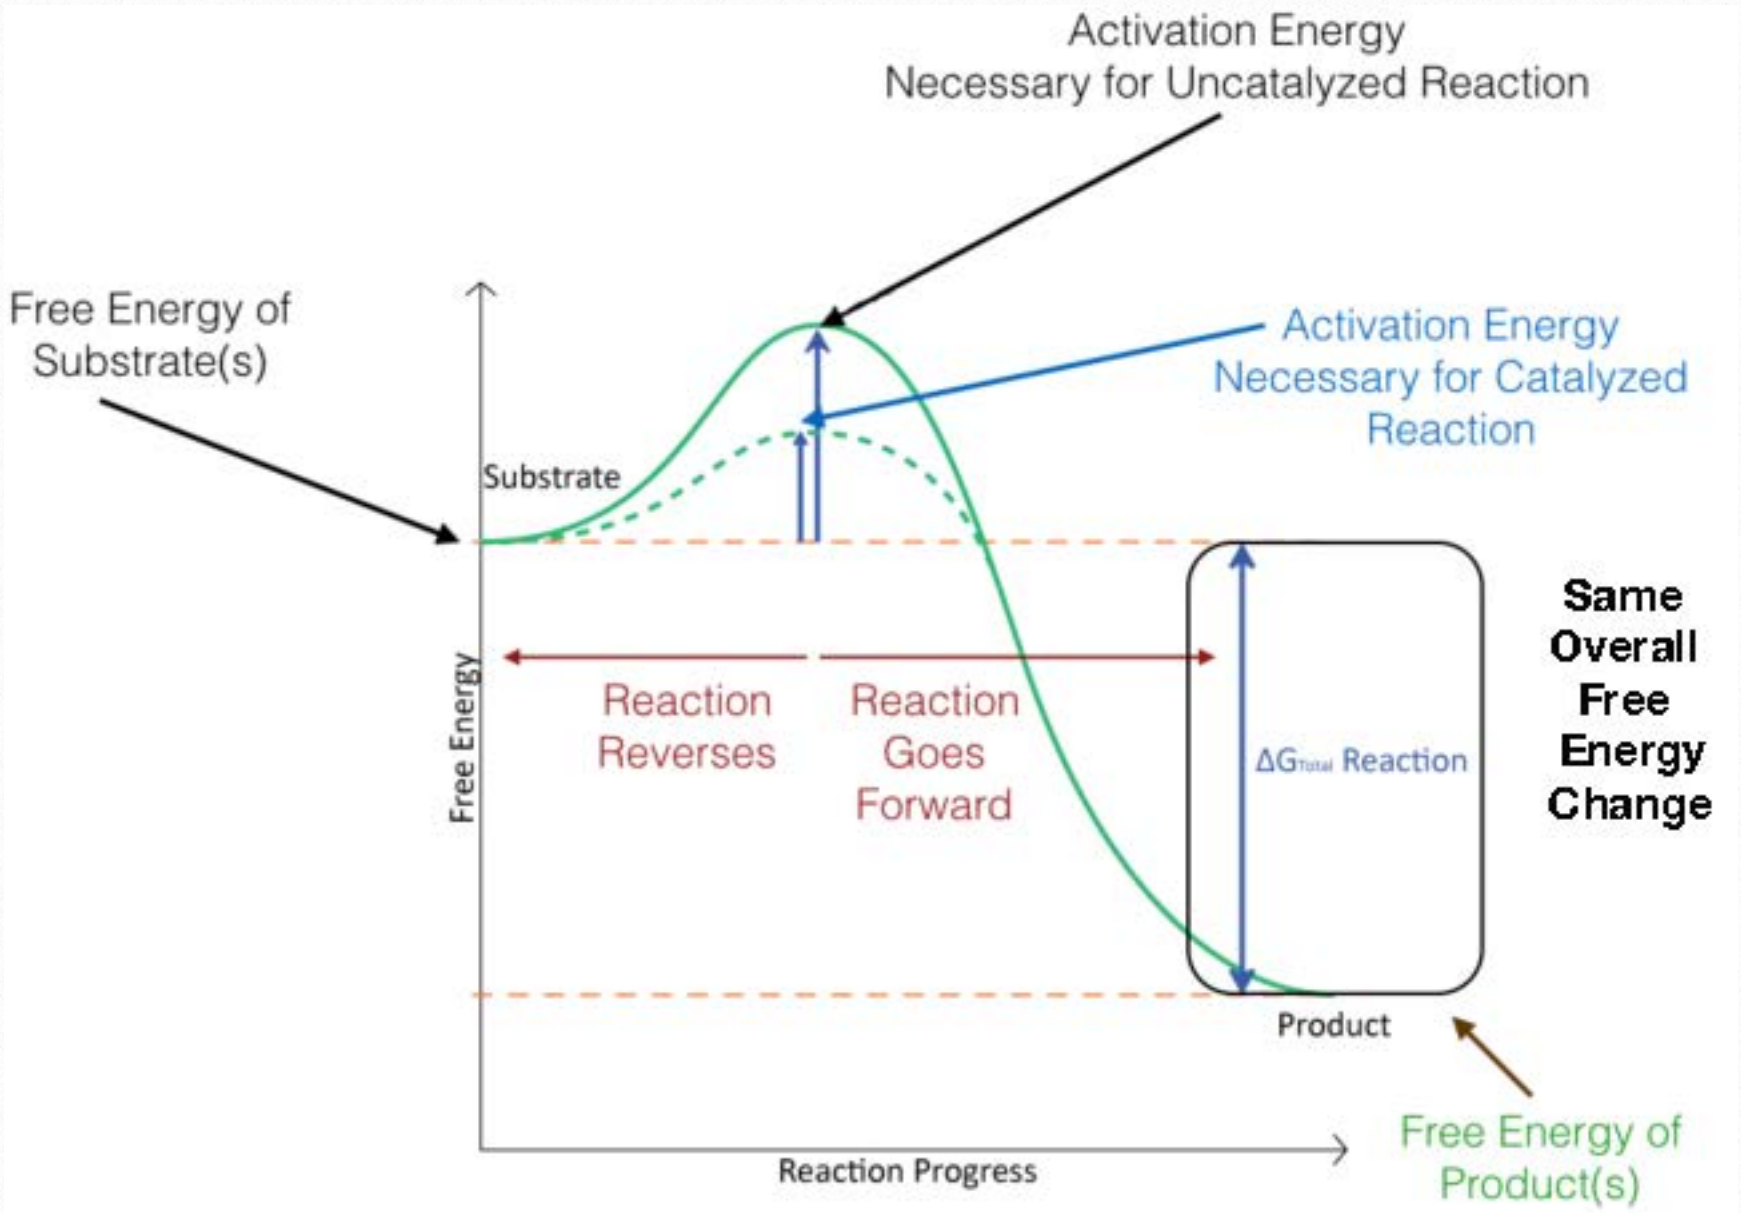

Figure 4.3 - Energy changes during the course of an uncatalyzed reaction (solid green line) and a catalyzed reaction (dotted green line).

Image by Aleia Kim

It is with this in mind that we begin our consideration of the phenomenon of catalysis by describing, first, the way in which enzymes work.

Activation energy

Figure 4.2 schematically depicts the energy changes that occur during the progression of a simple reaction. In order for the reaction to proceed, an activation energy must be overcome in order for the reaction to occur.

Interactive Learning Module HERE

In Figure 4.3, the activation energy for a catalyzed reaction is overlaid. As you can see, the reactants start at the same energy level for both catalyzed and uncatalyzed reactions and that the products end at the same energy for both as well. The catalyzed reaction, however, has a lower energy of activation (dotted line) than the un-

catalyzed reaction. This is the secret to catalysis - overall ΔG for a reaction does NOT change with catalysis, but the activation energy is lowered.

Reversibility

The extent to which reactions will proceed forward is a function of the size of the energy difference between the product and reactant states. The lower the energy of the products compared to the reactants, the larger the percentage of molecules that will be present as *products* at equilibrium. It is worth noting that since an enzyme lowers the activation energy for a reaction that it can speed the reversal of a reaction just as it speeds a reaction in the forward direction. At equilibrium, of course, no change in concentration of reactants and products occurs. Thus, enzymes speed the time required to reach equilibrium, but do not affect the balance of products and reactants at equilibrium.

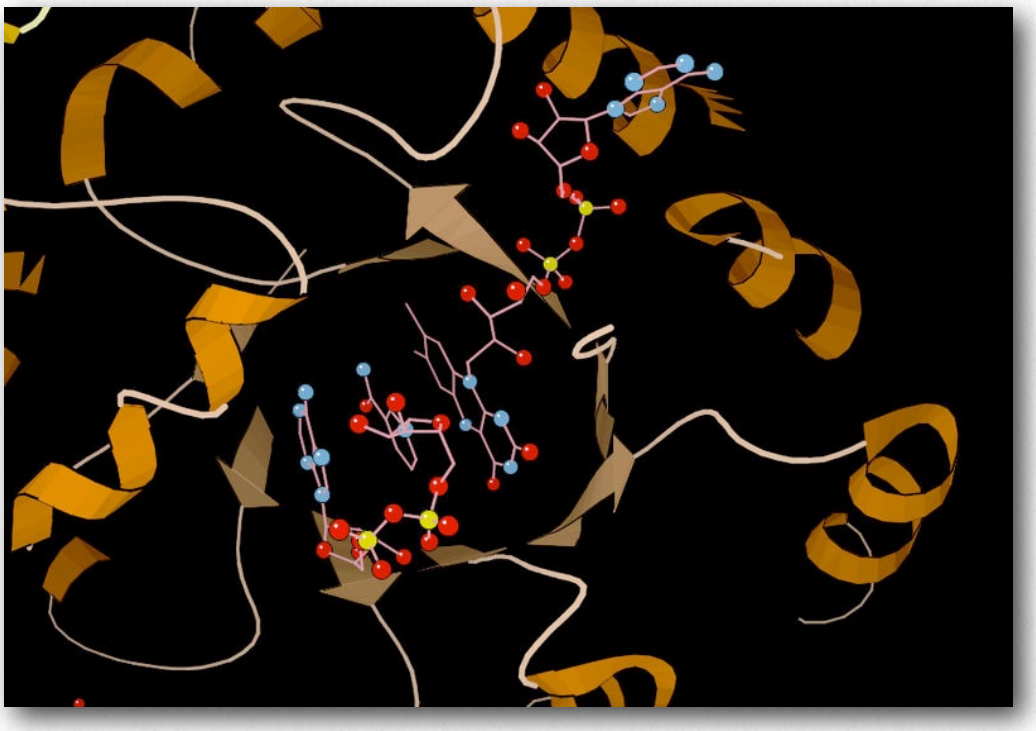

Figure 4.4 - Substrate binding by methylenetetrahydrofolate reductase

YouTube Lectures by Kevin
HERE & HERE

Exceptions

The reversibility of enzymatic reactions is an important consideration for equilibrium, the measurement of enzyme kinetics, for Gibbs free energy, for metabolic pathways, and for physiology.

There are some minor exceptions to the reversibility of reactions, though. They are related to the disappearance of a substrate or product of a reaction. Consider the first reaction below which is catalyzed by the enzyme carbonic anhydrase:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons HCO_3^- + H^+$$

In the forward direction, carbonic acid is produced from water and carbon dioxide. It can either remain intact in the solution or ionize to produce bicarbonate ion and a proton. In the reverse direction, water and carbon dioxide are produced. Carbon dioxide, of course, is a gas and can leave the solution and escape.

When reaction molecules are removed, as they would be if carbon dioxide escaped, the reaction is pulled in the direction of the molecule being lost and reversal cannot occur unless the missing molecule is replaced. In the second reaction occurring on the right, carbonic acid (H_2CO_3) is "removed" by ionization. This too would limit the reaction going back to carbon dioxide in water. This last type of "removal" is what occurs in metabolic pathways. In this case, the product of one reaction (carbonic acid) is the substrate for the next (formation of bicarbonate and a proton).

In the metabolic pathway of glycolysis, ten reactions are connected in this manner and reversing the process is much more complicated than if just one reaction was being considered.

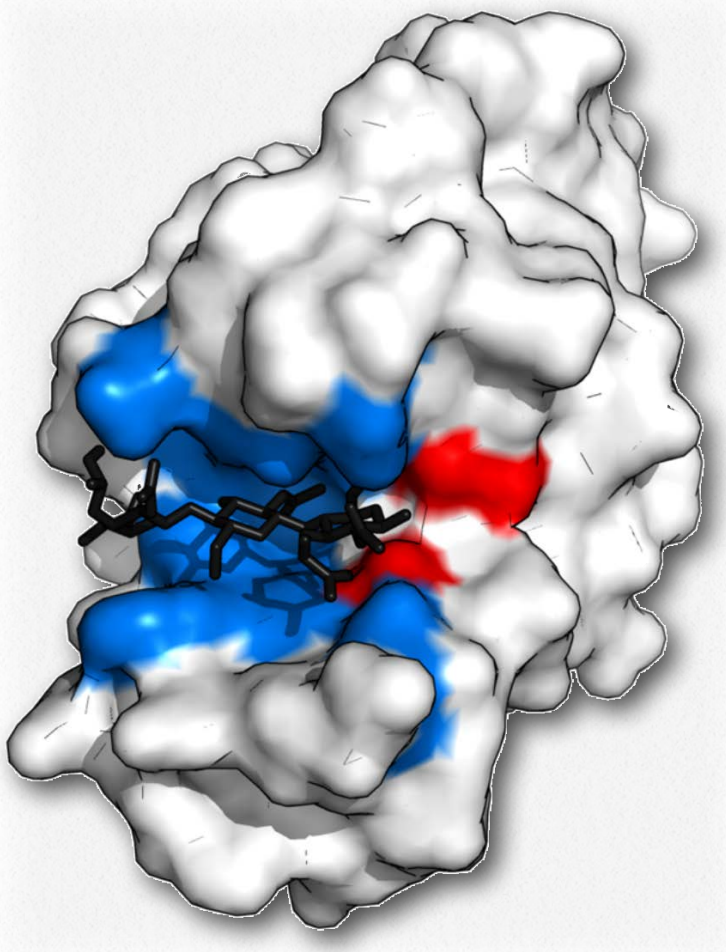

Figure 4.5 - Lysozyme with substrate binding site (blue), active site (red) and bound substrate (black).

Wikipedia

General mechanisms of action

As noted above, enzymatically catalyzed reactions are orders of magnitude faster than uncatalyzed and chemical-catalyzed reactions.

The secret of their success lies in a fundamental difference in their mechanisms of action.

Every chemistry student has been taught that a catalyst speeds a reaction without being consumed by it. In other words, the catalyst ends up after a reaction just the way it started so it can catalyze other reactions, as well. Enzymes share this property, but in the middle, during the catalytic action, an enzyme is transiently changed. In fact, it is the ability of an enzyme to change that leads to its incredible efficiency as a catalyst.

Changes

These changes may be subtle electronic ones, more significant covalent modifications, or structural changes arising from the flexibility inherent in enzymes, but not present in chemical catalysts. Flexibility allows movement and movement facilitates alteration of electronic environments necessary for catalysis. Enzymes are, thus, much more efficient than rigid chemical catalysts as a result of their abilities to facilitate the changes necessary to optimize the catalytic process.

Substrate binding

Another important difference between the mechanism of action of an enzyme and a chemical catalyst is that an enzyme has binding sites that not only 'grab' the substrate (molecule involved in the reaction being catalyzed), but also place it in a position to be electronically induced to react, either within itself or with another substrate.

The enzyme itself may play a role in the electronic induction or the induction may occur as a result of substrates being placed in very close proximity to each other. Chemical catalysts have no such ability to bind substrates and are dependent upon them colliding in the right orientation at or near their surfaces.

Active site

Reactions in an enzyme are catalyzed at a specific location within it known as the 'active site'. Substrates bind at the active site and are oriented to provide access for the relevant portion of the molecule to the electronic environment of the enzyme where catalysis occurs.

Enzyme flexibility

As mentioned earlier, a difference between an enzyme and a chemical catalyst is that an enzyme is flexible. Its slight changes in shape (often arising from the binding of the substrate itself) help to optimally position substrates for reaction after they bind.

Induced fit

These changes in shape are explained, in part, by Koshland's Induced Fit Model of Catalysis (Figure 4.6), which illustrates that not only do enzymes change substrates, but that substrates also transiently change enzyme struc-

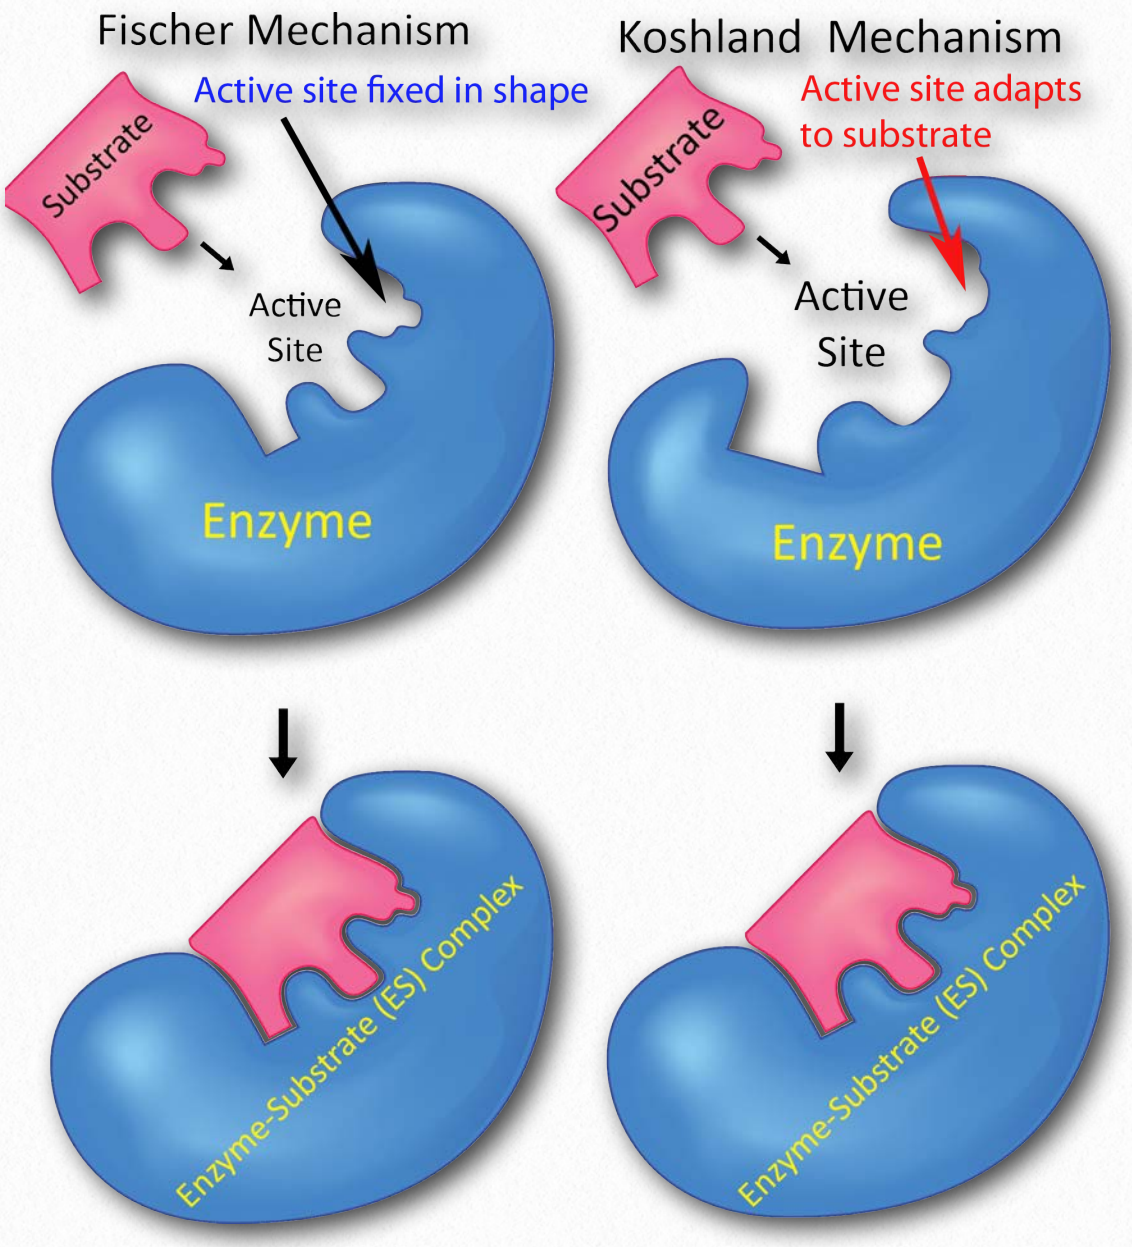

Figure 4.6 - Fischer's lock and key model (left) Vs. Koshland's induced fit model (right)

Image by Aleia Kim

ture. At the end of the catalysis, the enzyme is returned to its original state. Koshland's model is in contrast to the Fischer Lock and Key model, which says simply that an enzyme has a fixed shape that is perfectly matched for binding its substrate(s). Enzyme flexibility also is important for control of enzyme activity. Enzymes alternate between the T (tight) state, which is a lower activity state and the R (relaxed) state, which has greater activity.

Induced Fit

The Koshland Induced Fit model of catalysis postulates that enzymes are flexible and change shape on binding substrate. Changes in shape help to 1) aid binding of additional substrates in reactions involving more than one substrate and/or 2) facilitate formation of an electronic environment in the enzyme that favors catalysis. This model is in contrast to the Fischer Lock and Key Model of catalysis which considers enzymes as having pre-formed substrate binding sites.

Ordered binding

The Koshland model is consistent with multi-substrate binding enzymes that exhibit ordered binding of substrates. For these systems, binding of the first substrate induces structural changes in the enzyme necessary for binding the second substrate.

There is considerable experimental evidence supporting the Koshland model. Hexokinase, for example, is one of many enzymes known to undergo significant structural alteration after binding of substrate. In this case, the two substrates are brought into very close proximity by the induced fit and catalysis is made possible as a result.

Types of Reactions

Single Substrate - Single Product : $A \rightleftarrows B$

Single Substrate - Multiple Products : $A \rightleftarrows B + C$

Multiple Substrates - Single Products : $A + B \rightleftarrows C$

Multiple Substrates - Multiple Products : $A + B \rightleftarrows C + D$

Figure 4.7 - Categories of enzymatic reactions

Reaction types

Enzymatic reactions can be of several types, as shown in Figure 4.7.

Enzymes that catalyze reactions involving more than one substrate, such as

$$A + B \rightleftarrows C + D$$

can act in two different ways. In one mechanism, called sequential reactions, at some point in the reaction, both substrates will be bound to the enzyme. There are, in turn, two

different ways in which this can occur - random and ordered.

Consider lactate dehydrogenase, which catalyzes the reaction below:

NADH + Pyruvate

⇅

Lactate + **NAD**$^+$

This enzyme requires that NADH must bind prior to the binding of pyruvate. As noted earlier, this is consistent with an induced fit model of catalysis. In this case, binding of the NADH changes the enzyme shape/ environment so that pyruvate can bind and without binding of NADH, the substrate cannot access the pyruvate binding site.

This type of multiple substrate reaction is called sequential ordered binding, because the binding of substrates must occur in the right order for the reaction to proceed.

YouTube Lectures by Kevin HERE & HERE

For this enzyme, substrates can bind to it in any order. Creatine kinase displays sequential random binding. It is worth mentioning that random binding is *not* inconsistent with Koshland's induced fit model. Rather, random binding simply means that the enzyme's induced fit doesn't affect substrate binding sites and involves other parts of the enzyme. In summary, sequential binding can occur as ordered binding or as random binding.

Random binding

A second mechanism of binding/catalysis is exhibited by creatine kinase which catalyzes the following reaction:

Creatine + **ATP**

⇅

Creatine phosphate + **ADP**

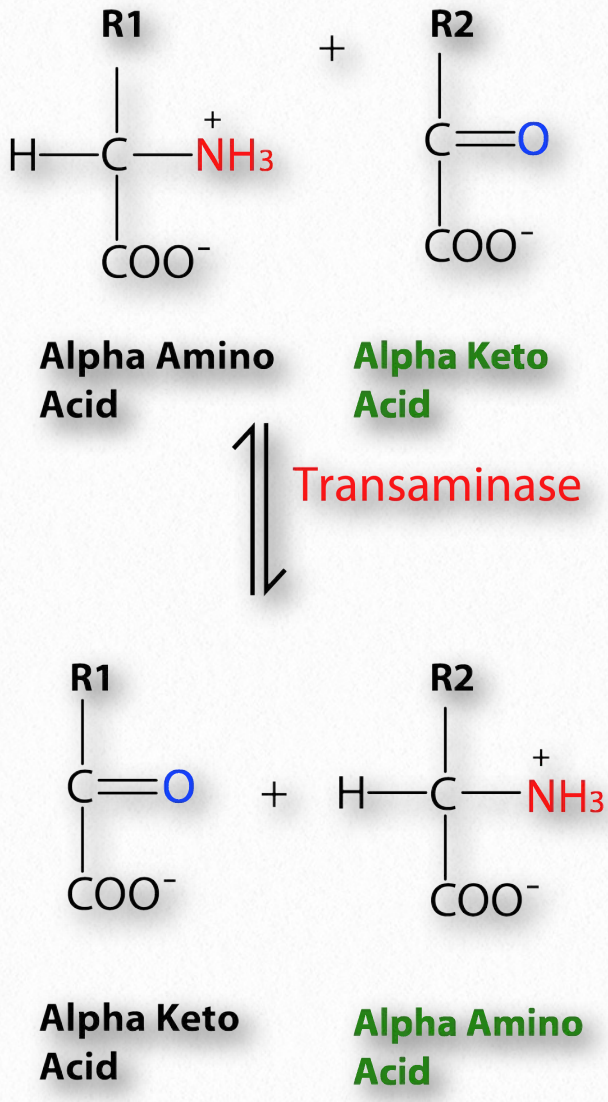

Figure 4.8 - Double displacement reaction mechanism of a transaminase

Double displacement reactions

Not all enzymes that catalyze multi-substrate reactions, though, bind A and B by the sequential mechanisms above. This other category of enzyme includes those that exhibit what are called "ping-pong" (or double displacement) mechanisms. In these enzymes, the enzyme functions as both a catalyst and a carrier of a group between individually bound substrates. Examples of this type of enzyme include the class of enzymes known as transaminases. A general form of the reactions catalyzed by these enzymes is shown in Figure 4.8.

In reversible transaminase reactions, an oxygen and an amine are swapping between the molecules. It can be represented as follows (where N is the amine and O is the oxygen).

$$A{=}O + C{=}N \rightleftarrows B{-}N + D{=}O$$

This reaction occurs not as one transfer reaction swapping the N and the O, but rather as a set of two half-reactions. In this case, the enzyme is a both donor and a carrier of the group being swapped. The first half-reaction goes as follows

$$A{=}O + Enz{-}N \rightleftarrows B{-}N + Enz{=}O$$

Next a second half-reaction goes as

$$C{-}N + Enz{=}O \rightleftarrows D{=}O + Enz{=}N$$

The sum of these half-reactions then is

$$A{=}O + C{=}N \rightleftarrows B{-}N + D{=}O$$

Note that at no time did the enzyme bind both A and C simultaneously. It is also important to recognize that the enzyme existed in two states - Enz=O and Enz-N. The shuffling of the enzyme between these two states is what

gives rise to the ping-pong name of this mechanism - it literally goes back and forth like a ping-pong ball in a table tennis match.

Enzyme kinetics

To understand how an enzyme enhances the rate of a reaction, we must understand enzyme kinetics. We present a model here proposed by Leonor Michaelis and Maud Menten. In order to understand the model, it is necessary to understand a few parameters.

First, we describe a reaction in simple terms proceeding as follows

$$E + S \rightleftarrows ES \rightarrow E + P$$

where E is enzyme, S is substrate, and P is product. In this scheme, ES is the Enzyme-Substrate complex, which is simply the enzyme bound to its substrate.

We could define the ES state a bit further with

$$E + S \rightleftarrows ES \rightarrow ES^* \rightarrow EP \rightarrow E + P$$

where ES* is the activated state and EP is the enzyme-product complex before release of the product.

The first consideration we have is

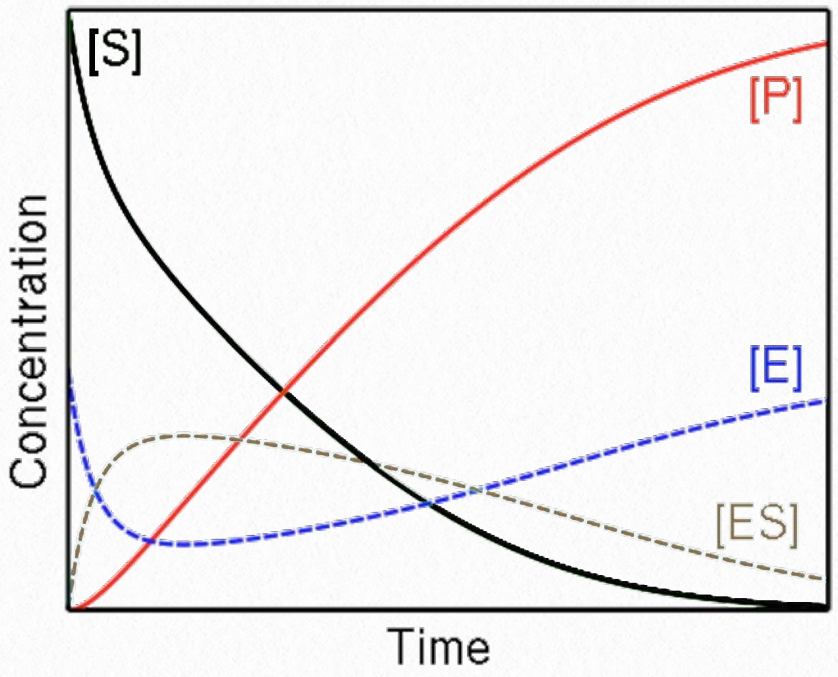

Figure 4.15 - Concentration of product (P), substrate (S), enzyme (E), and enzyme-substrate complex (ES) versus time for an enzymatic reaction

velocity. The velocity of a reaction is the rate of creation of product over time, measured as the concentration of product per time. The time is a critical consideration when measuring velocity. In a closed system (in which an enzyme operates), all reactions will advance towards equilibrium. Enzymatically catalyzed reactions are no different in the end result from non-enzymatic reactions, except that they get to equilibrium faster.

Equilibrium

At equilibrium, the ratio of product to reactant does not change. That is a property of equilibrium. Since the system is closed, the concentration of product over time will not change. The velocity will thus be zero under these conditions and we will have learned nothing about the reaction if we wait too long to study it.

Velocity

Consequently, in Michaelis-Menten kinetics, velocity is measured as initial velocity (V_0). This is accomplished by measuring the rate of formation of product early in the

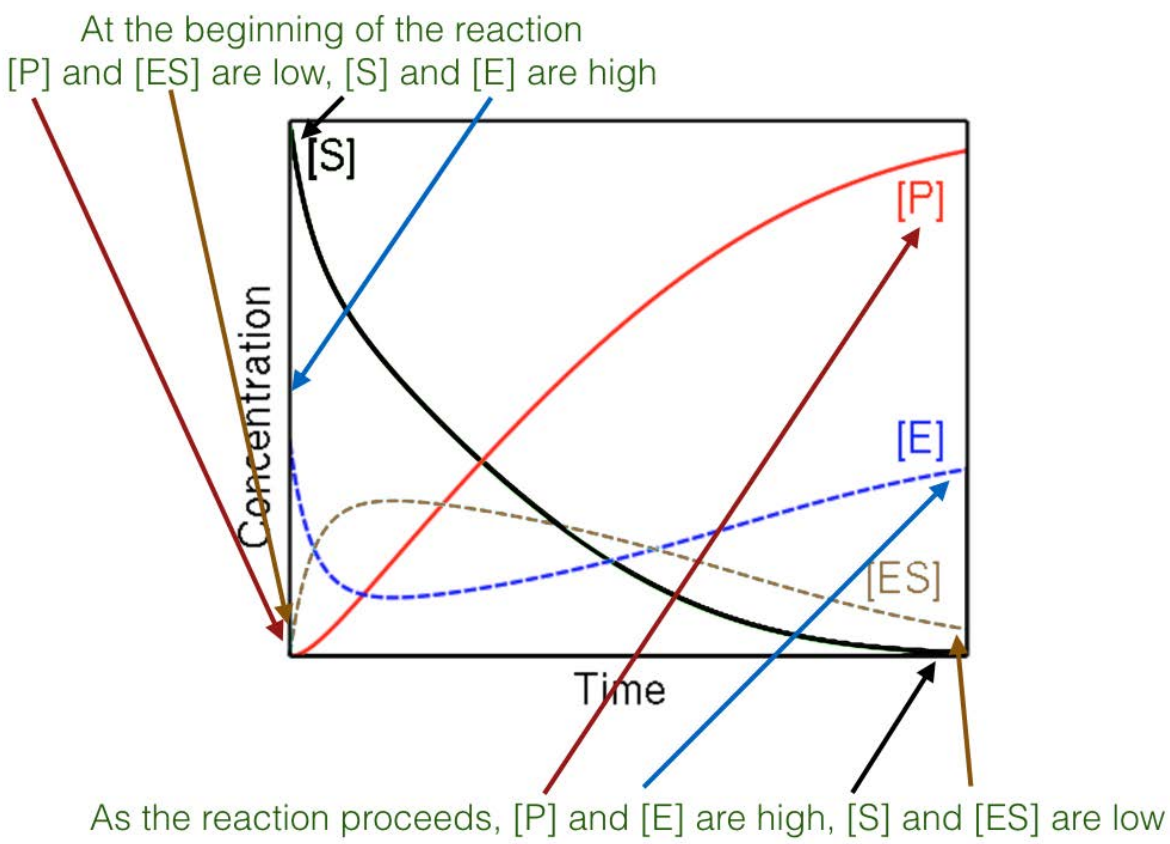

Figure 4.16 - Change in concentration of reaction materials over time

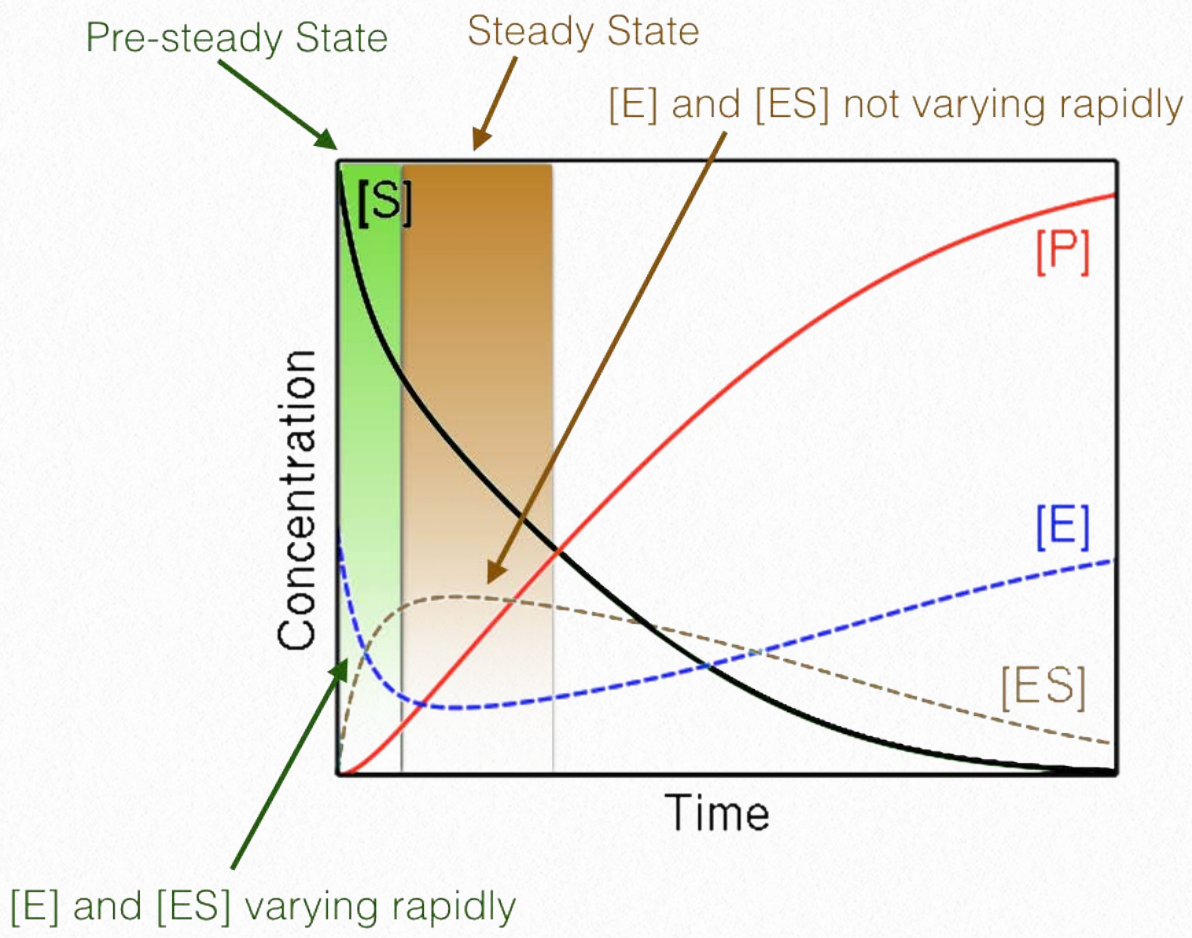

Figure 4.17 - Steady state versus non-steady state conditions

reaction before equilibrium is established and under these conditions, there is very little if any of the reverse reaction occurring.

The other two assumptions are related. First, we use conditions where there is much more substrate than enzyme. This makes sense. If the substrate is not in great excess, then the enzyme's conversion of substrate to product will occur much faster than the enzyme can bind substrate.

Waiting for substrate

Thus, the enzyme would "wait" for substrate to bind if there were not sufficient amounts of it to bind to the enzyme in a timely fashion (when substrate concentration is low). This would not give an accurate measure of velocity, since the enzyme would be inactive a good deal of the time. Because of this, we assume saturation of the enzyme with substrate will give a maximal velocity of the reaction.

Interactive Learning Module HERE

Steady state

Last, the high concentration of substrate combined with measuring initial conditions results in studying reactions that are under so-called steady state conditions (Figure 4.17). When steady state occurs, the concentration of the ES complex over time is not significantly changing during the period of analysis.

Reiterating, the three assumptions for Michaelis-Menten kinetics are

1. Measurement of initial velocity of a reaction

2. Substrate in great excess compared to enzyme

3. Reaction conditions occurring under steady state

YouTube Lectures by Kevin HERE & HERE

Experimental considerations

Now we turn our attention to how studies of the kinetic properties of an enzyme are conducted. To perform an analysis, one would do the following experiment - 20 different tubes would be set up with enzyme buffer (to keep the enzyme stable), the same amount of enzyme, and then a different amount of substrate in each tube, ranging from tiny amounts in the first tubes to very large amounts in the last tubes. The reaction would be allowed to proceed for a fixed, short amount of time and then the reaction would be stopped and the amount of product contained in each tube would be determined.

The initial velocity (V_0) of the reaction then would be the concentration of product found in each tube divided by the time that the reaction was allowed to run. Data from the experiment would be plotted on a graph using initial velocity (V_0) on the Y-axis and the concentration of substrate on the X-axis, each tube, of course having a unique reaction velocity corresponding to a unique substrate concentration.

For an enzyme following Michaelis-Menten kinetics, a curve like that shown in Figure 4.18 or 4.19 would result. At low concentration of substrate, it is limiting and the enzyme converts it into product as soon as it can bind it. Consequently, at low concentrations of substrate, the rate of increase of [P] is almost linear with [S] (Figure 4.19).

Non-linear increase

As the substrate concentration increases, however, the velocity of the reaction in tubes with higher substrate concentration ceases to in-

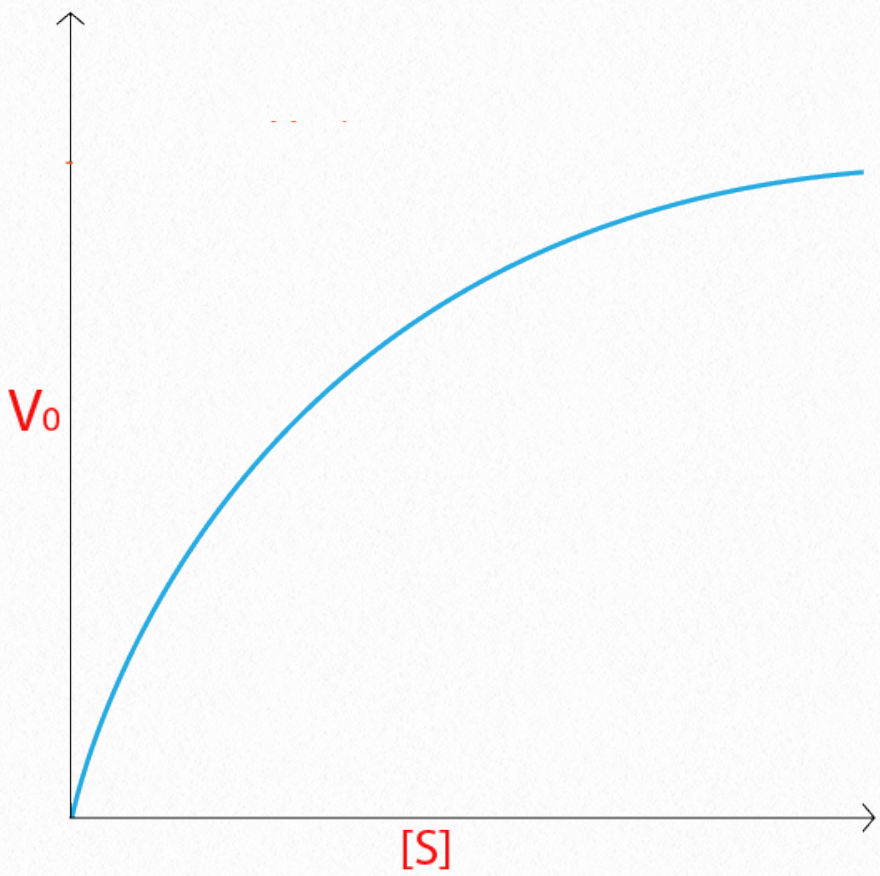

Figure 4.18 - Kinetics of an enzyme obeying Michaelis-Menten kinetics

Image by Aleia Kim

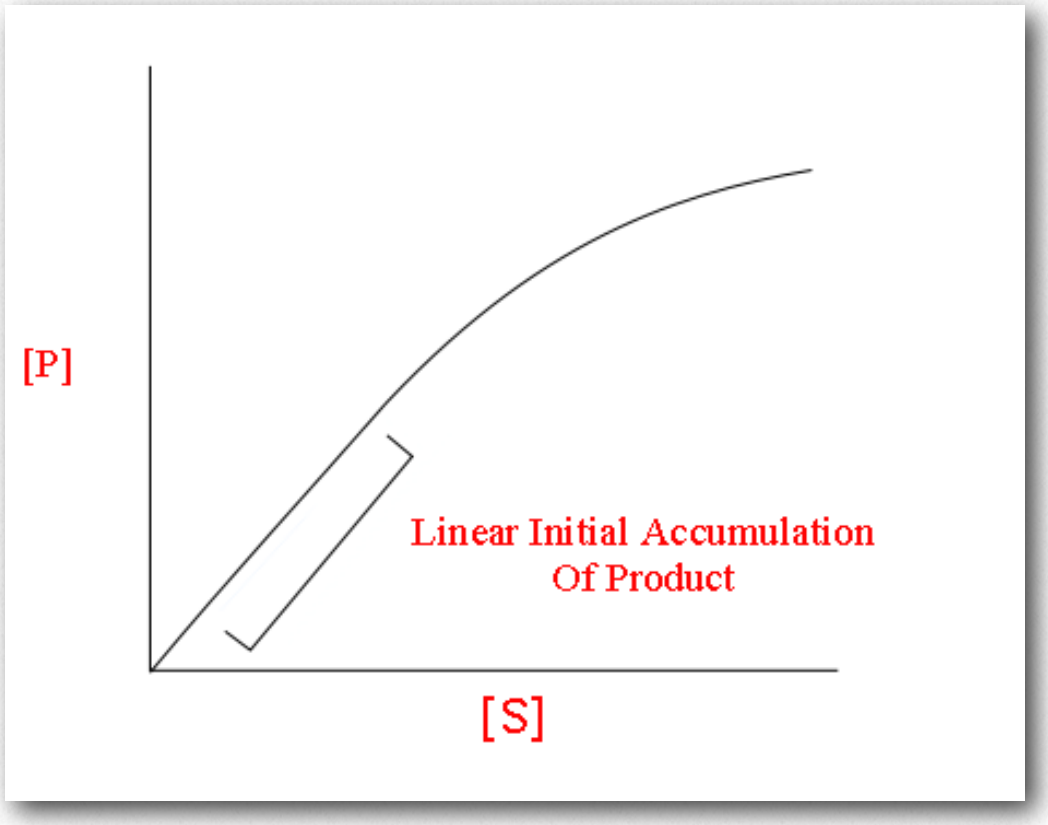

Figure 4.19 - Linear relationship between [P] and [S] at low [S]

crease linearly and instead begins to flatten out, indicating that as the substrate concentration gets higher and higher, the enzyme has a harder time keeping up to convert the substrate to product.

Saturation

Not surprisingly, when the enzyme becomes completely saturated with substrate, it will not have to wait for substrate to diffuse to it and will therefore be operating at maximum velocity.

For an enzyme following Michaelis-Menten kinetics will have its velocity (v) at any given substrate concentration given by the following equation:

$$v = \frac{V_{max}[S]}{K_m + [S]}$$

V_{max}

Two terms in the equation above require explanation. The first is V_{max}. It refers to the maximum velocity of an enzymatic reaction. Maximum velocity for a reaction occurs when an enzyme is saturated with substrate. Saturation is important because it means (per the assumption above) that none of the enzyme molecules are "waiting" for substrate after a product is released. Saturation ensures that another substrate is always instantly available. The unit of V_{max} is concentration of product per time = [P]/time.

On a plot of initial velocity versus substrate concentration (V_0 vs. [S]), V_{max} is the value on the Y axis that the curve asymptotically approaches (dotted line in Figure 4.20). It should be noted that the value of V_{max} depends on the amount of enzyme used in a reaction. If you double the amount of enzyme used, you will double the V_{max}. If one wanted to compare the velocities of two different enzymes, it would be necessary to use the same amounts of enzyme in the reaction each one catalyzes.

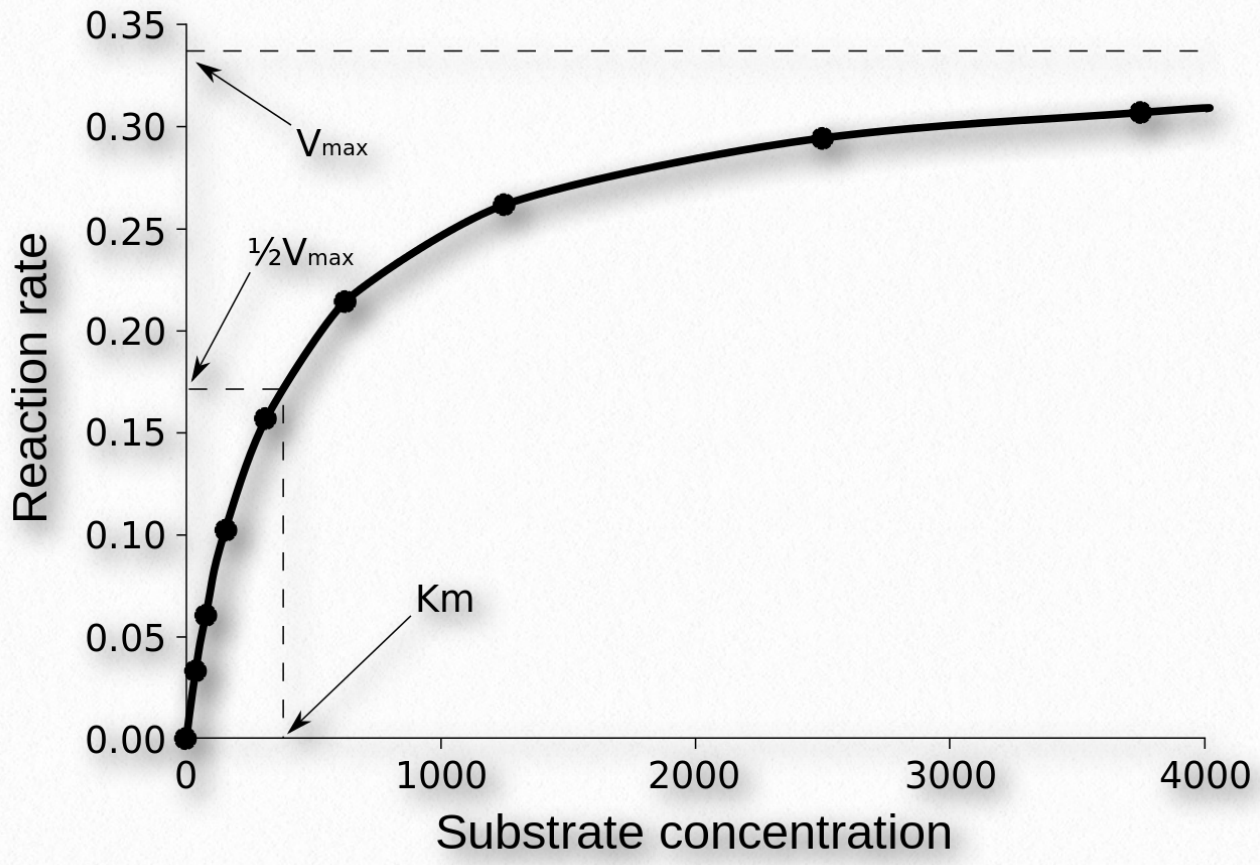

Figure 4.20 - V_{max}, $V_{max}/2$, and K_m

Affinities of enzymes for substrates vary considerably, so knowing K_m helps us to understand how well an enzyme is suited to the substrate being used. Measurement of K_m depends on the measurement of V_{max}.

Common mistake

A common mistake students make in describing V_{max} is saying that $K_m = V_{max}/2$. This is, of course, not true. K_m is a substrate concentration and is the amount of substrate it takes for an enzyme to reach $V_{max}/2$. On the other hand $V_{max}/2$ is a velocity and a velocity certainly cannot equal a concentration.

K_m

The second term is Km (also known as K_s). Referred to as the Michaelis constant, K_m is the substrate concentration that causes the enzyme to work at half of maximum velocity ($V_{max}/2$). What it measures, in simple terms, is the affinity an enzyme has for its substrate. The value of K_m is inversely related to the affinity of the enzyme for its substrate. Enzymes with a high K_m value will have a lower affinity for their substrate (will take more substrate to get to $V_{max}/2$) whereas those with a low K_m will have high affinity and take less substrate to get to $V_{max}/2$. The unit of K_m is concentration.

Interactive Learning Module HERE

K_{cat}

It is desirable to have a measure of velocity that is independent of enzyme concentration. Remember that V_{max} depended on the amount of enzyme used. For this, we use the K_{cat}, also known as the turnover number. K_{cat} is a number that requires one to first determine V_{max} for an enzyme and then divide the V_{max} by the concentration of enzyme used to determine V_{max}. Thus,

$$K_{cat} = V_{max} / [Enzyme]$$

Since V_{max} has units of concentration per time and [Enzyme] has units of concentration, the units on K_{cat} are time^{-1}. While that might seem unintuitive, it means that the value of K_{cat} is the number of molecules of product made by each molecule of enzyme in the time given. So, a K_{cat} value of 1000/sec means each enzyme molecule in the reaction at V_{max} is producing 1000 molecules of product per second. Note that since K_{cat} is a calculated value, it cannot be read from a V vs [S] graph as V_{max} and K_m can.

Amazing K_{cat} values

A K_{cat} value of 1000 molecules of product per enzyme per second might seem like a high value, but there are enzymes known (carbonic anhydrase, for example) that have a K_{cat} value of over 600,000/second (Figure 4.21). This astonishing value illustrates clearly why enzymes seem almost magical in their action.

Enzyme	Turnover Number (per second)
Carbonic anhydrase	600,000
3-Ketoesteroid isomerase	280,000
Acetylcholinesterase	25,000
Penicillinase	2,000
Lactate dehydrogenase	1,000
Chymostrypsin	100
DNA Polymerase I	15
Tryptophan synthetase	2
Lysozyme	0.5

Figure 4.21 - K_{cat} (turnover number) values for several enzymes

Image by Aleia Kim

In contrast to V_{max}, which varies with the amount of enzyme used, K_{cat} is a constant for an enzyme under given conditions.

As seen earlier, enzymes that follow Michaelis-Menten kinetics produce hyperbolic plots of Velocity (V0) versus Substrate Concentration [S] (Figure 4.18). Not all enzymes, though, follow Michaelis-Menten kinetics. Many enzymes have multiple protein subunits and these sometimes interact differently upon binding of a substrate or an external molecule. See ATCase (HERE) for an example.

Perfect enzymes

Now, if we think about what an ideal enzyme might be, it would be one that has a very high velocity and a very high affinity for its substrate. That is, it wouldn't take much substrate to get to V_{max}/2 and the K_{cat} would be very high. Such enzymes would have values of K_{cat} / K_m that are maximum. Interestingly, there are several en-

Enzyme	K_{Cat} / K_M ($s^{-1}M^{-1}$)
Acetylcholinesterase	1.6×10^8
Carbonic anhydrase	8.3×10^7
Catalase	4.0×10^7
Crotonase	2.8×10^8
Fumarase	1.6×10^8
Triose phosphate isomerase	2.4×10^8
β-Lactamase	1.0×10^8
Superoxide dismutase	7.0×10^9

Figure 4.22 - K_{cat}/K_m values for perfect enzymes

Image by Aleia Kim

zymes that have this property and their maximal K_{cat} / K_m values are all approximately the same. Such enzymes are referred to as being "perfect" because they have reached the maximum possible value.

YouTube Lectures by Kevin HERE & HERE

Diffusion limitation

Why should there be a maximum possible value of K_{cat} / K_m? The answer is that movement of substrate to the enzyme becomes the limiting factor for perfect enzymes. Movement of substrate by diffusion in water has a fixed rate at any temperature and that limitation ultimately determines the maximum speed an enzyme can catalyze at. In a macroscopic world analogy, factories can't make products faster than suppliers can deliver materials. It is safe to say for a perfect enzyme that the only speed limit it has is the rate of substrate diffusion in water.

Given the "magic" of enzymes alluded to earlier, it might seem that all enzymes should have evolved to be "perfect." There are very good reasons why most of them have not.

Speed

Speed is a dangerous thing. The faster a reaction proceeds in catalysis by an enzyme, the harder it is to control. As we all know from learning to drive, speeding causes accidents. Just as drivers need to have speed limits for operating automobiles, so too must cells exert some control on the 'throttle' of their enzymes. In view of this, one might wonder then why any cells have evolved any enzymes to perfection. There is no single answer to the ques-

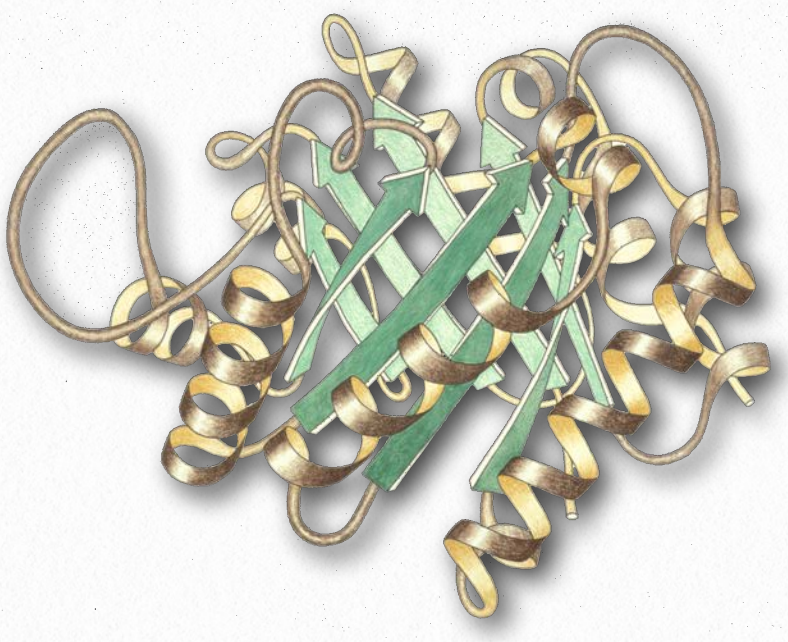

Figure 4.23 - Triose phosphate isomerase - A perfect enzyme

Wikipedia

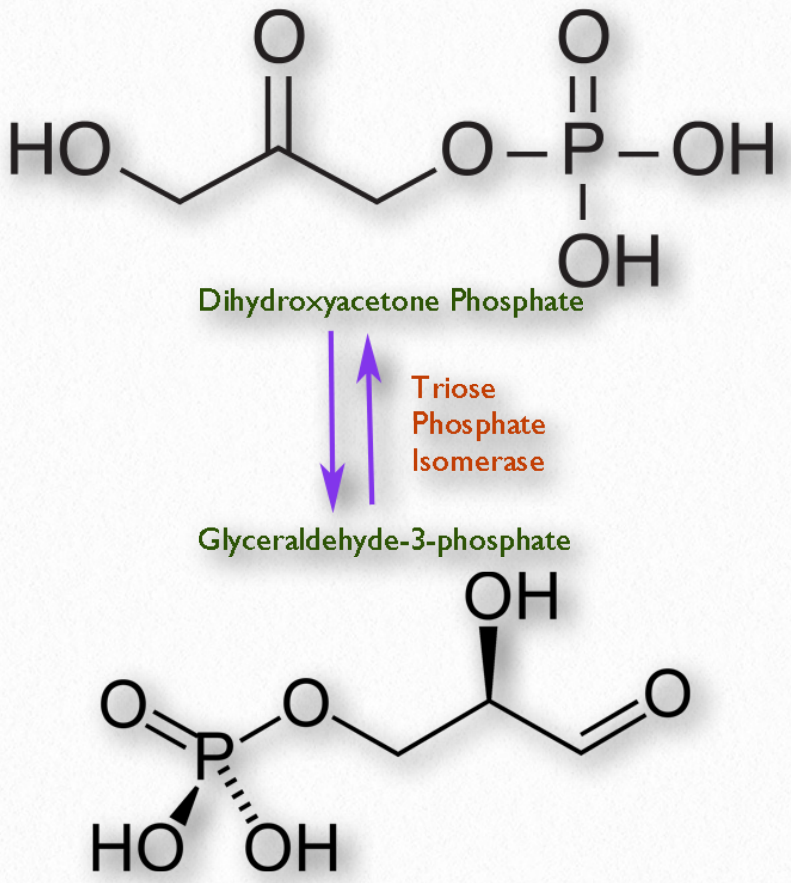

Figure 4.24 - Triose phosphate isomerase-catalyzed reaction

tion, but a common one is illustrated by triose phosphate isomerase, which catalyzes a reaction in glycolysis shown in Figure 4.24.

The enzyme appears to have evolved this ability because at lower velocities, there is breakdown of an unstable enediol intermediate that then readily forms methyl glyoxal, a cytotoxic compound (Figure 4.25). Speeding up the reaction provides less opportunity for the unstable intermediate to accumulate and fewer undesirable byproducts to be made.

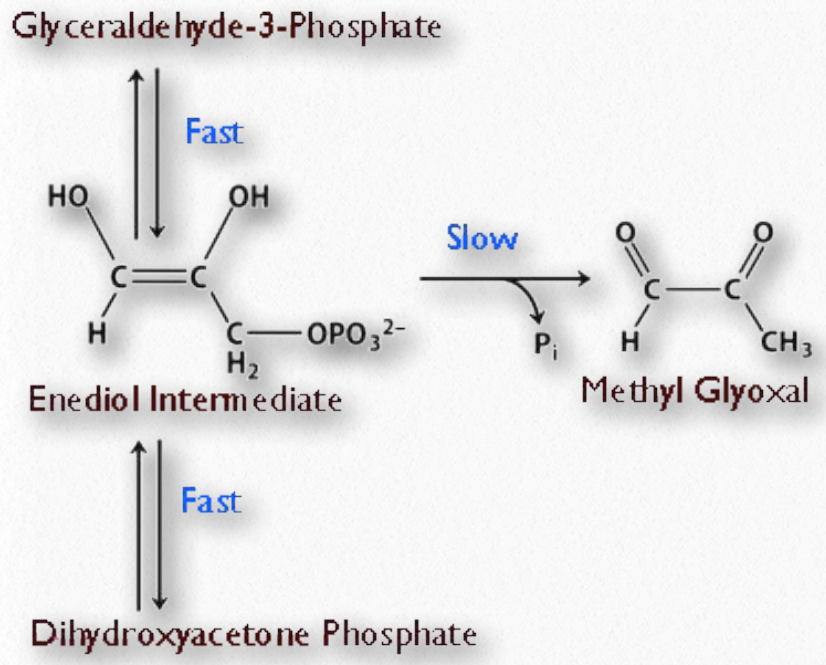

Figure 4.25 - A high speed reaction avoids production of methyl glyoxal

Image by Aleia Kim

Dissociation constant

In studying proteins and ligands, it is important to understand the "tightness" with which a protein (P) "holds onto" a ligand (L). This is measured with the dissociation constant (K_d).

The formation of a ligand-protein complex LP occurs as

$$L + P <=> LP$$

The dissociation of the complex, therefore, is the reverse of this reaction, or

$$LP <=> L + P$$

so the corresponding dissociation constant is defined as

$$K_d = [L][P]/[LP]$$

where [L], [P], and [LP] are the molar concentrations of the protein, ligand and the complex when they are joined together.

Smaller values of K_d indicate tight binding, whereas larger values indicate loose binding. The dissociation constant is the inverse of the association constant.

$K_a = 1/K_d$

Where multiple molecules bond together, such as

$$JxKy <=> xJ + yK$$

(complex JxKy is breaking down into x subunits of J and y subunits of K)

the dissociation constant is then defined as

$$K_d = [J]^x[K]^y/[JxKy]$$

where [J], [K], and [JxKy] are the concentrations of J, K, and the complex JxKy, respectively.

Lineweaver-Burk plots

The study of enzyme kinetics is typically the most math intensive component of biochemistry and one of the most daunting aspects of the subject for many students. Although attempts are made to simplify the mathematical considerations, sometimes they only serve to confuse or frustrate students. Such is the case with modified enzyme plots, such as Lineweaver-Burk (Figure 4.26).

Indeed, when presented by professors as simply another thing to memorize, who can blame students? In reality, both of these plots are aimed at simplifying the determination of parameters, such as K_m and V_{max}. In making either of these modified plots, it is important to recognize that the same data is used as in making a V_0 vs. [S] plot. The data are simply manipulated to make the plotting easier.

Double reciprocal

For a LineWeaver-Burk plot, the manipulation is using the reciprocal of the values of both the velocity and the substrate concentration. The inverted values are then plotted on a graph as $1/V_0$ vs. $1/[S]$. Because of these

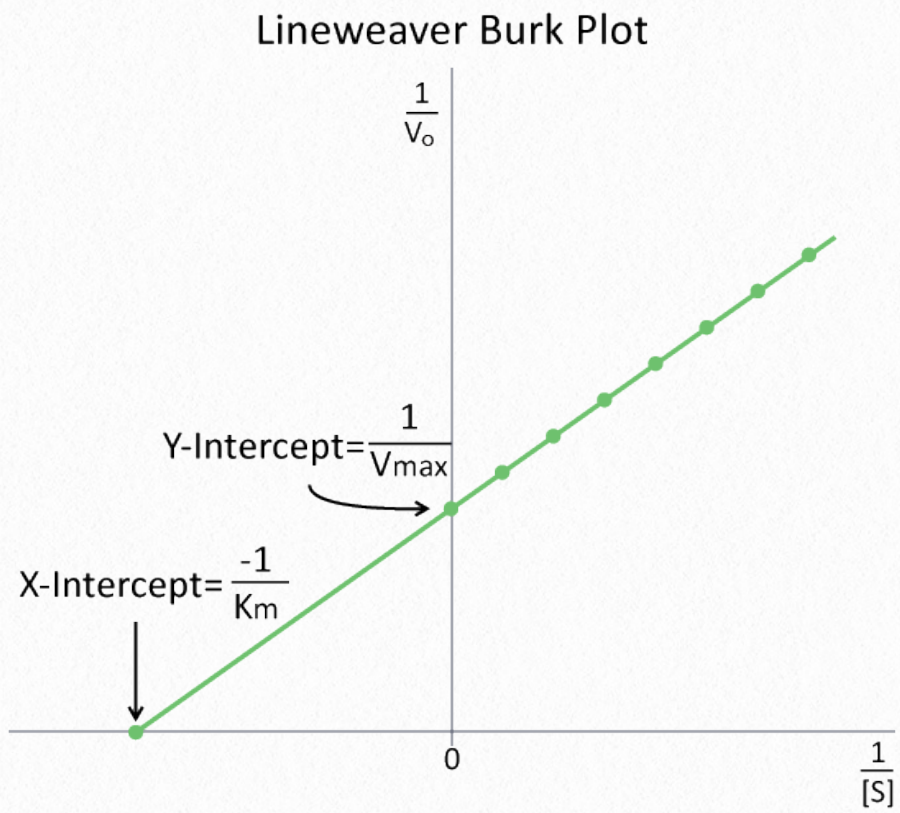

Figure 4.26 - A Lineweaver-Burk plot of $1/V_0$ vs $1/[S]$

Image by Aleia Kim

inversions, Lineweaver-Burk plots are commonly referred to as ‘double-reciprocal’ plots. As can be seen in Figure 4.26, the value of K_m on a Lineweaver Burk plot is easily determined as the negative reciprocal of the x-intercept , whereas the V_{max} is the inverse of the y-intercept. Other related manipulation of kinetic data include Eadie-Hofstee diagrams, which plots V_0 vs $V_0/[S]$ and gives V_{max} as the Y-axis intercept with the slope of the line being $-K_m$.

Molecularity of reactions

The term molecularity refers to the number of molecules that must come together in order for a reaction to take place. Reactions of the sort of A -> B (where ‘A’ is the reactant and ‘B’ is the product) are unimolecular, since A is directly changed into B. The rate of the reaction is related only to the concentration of reactant A. For a bimolecular reaction where A + B ⇄ C the reaction depends on the concentration of both A and B and its

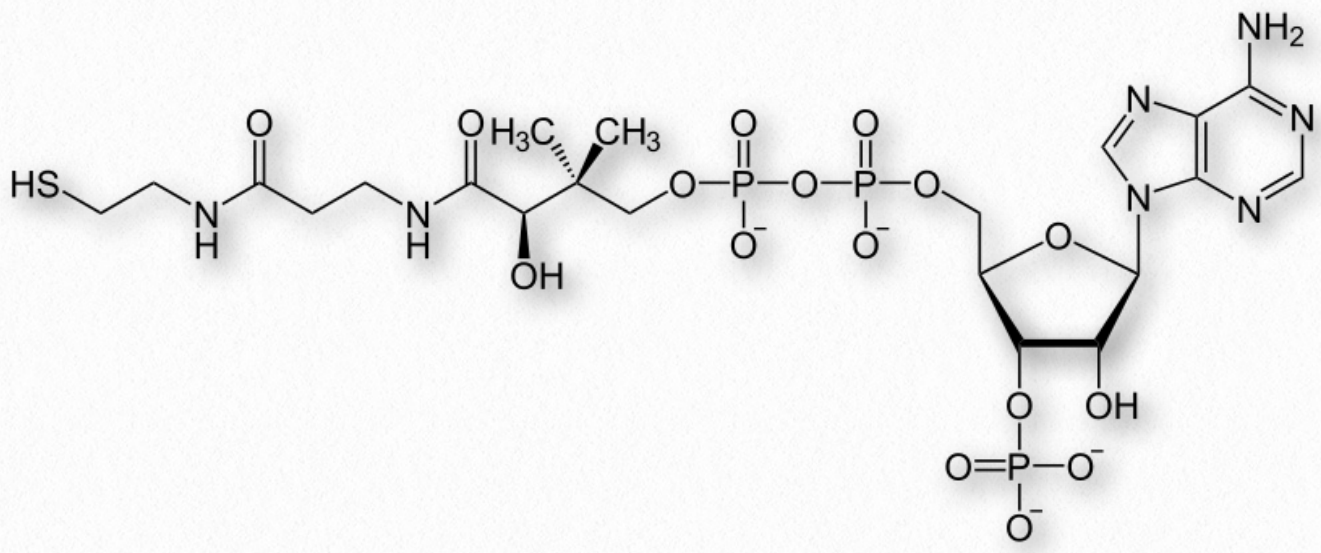

Figure 4.28 - Coenzyme A (CoA)

rate will be related to the product of the concentration of A and of B.

Coenzymes

Organic molecules that assist enzymes and facilitate catalysis are co-factors called coenzymes. The term co-factor is a broad category usually subdivided into inorganic ions and coenzymes. If the coenzyme is very tightly or covalently bound to the enzyme, it is referred to as a prosthetic group. Enzymes without their co-factors are inactive and referred to as apoenzymes. Enzymes containing all of their co-factors are called holoenzymes.

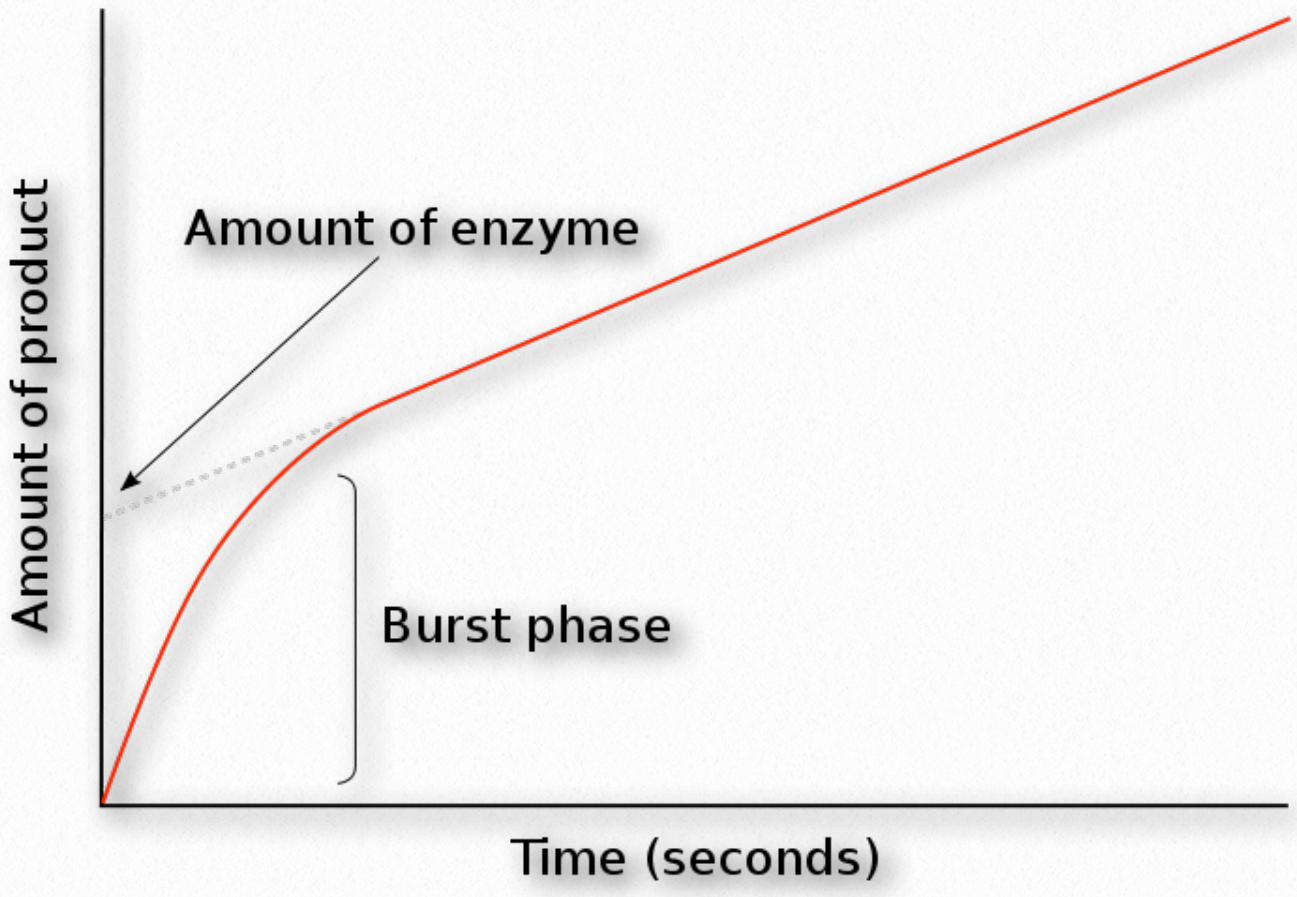

Figure 4.29 - Burst phase of product formation

YouTube Lectures by Kevin HERE & HERE

Pre-steady state kinetic studies

In the study of kinetic rates of enzymatic reactions, time zero is a very critical point. It establishes when the mixing of substrate with enzyme and measurement of formation of product begins. At time zero, there is no product. As shown in Figure 4.29, the appearance of product (on a short time scale) goes through an early burst phase with a steep slope for [product]/time and then changes.

This change occurs during a critical period in an enzymatic reaction and gives information about the rate of reaction cycles. The duration of the burst phase tells how long a single reaction turnover occurs, whereas the slow of the line post-burst phase tells the amount of “functional” enzyme performing the reaction.

After the burst phase, the slope of the line of the amount of product versus time decreases. This is due to the reaction entering conditions of steady state, used to study Michaelis-

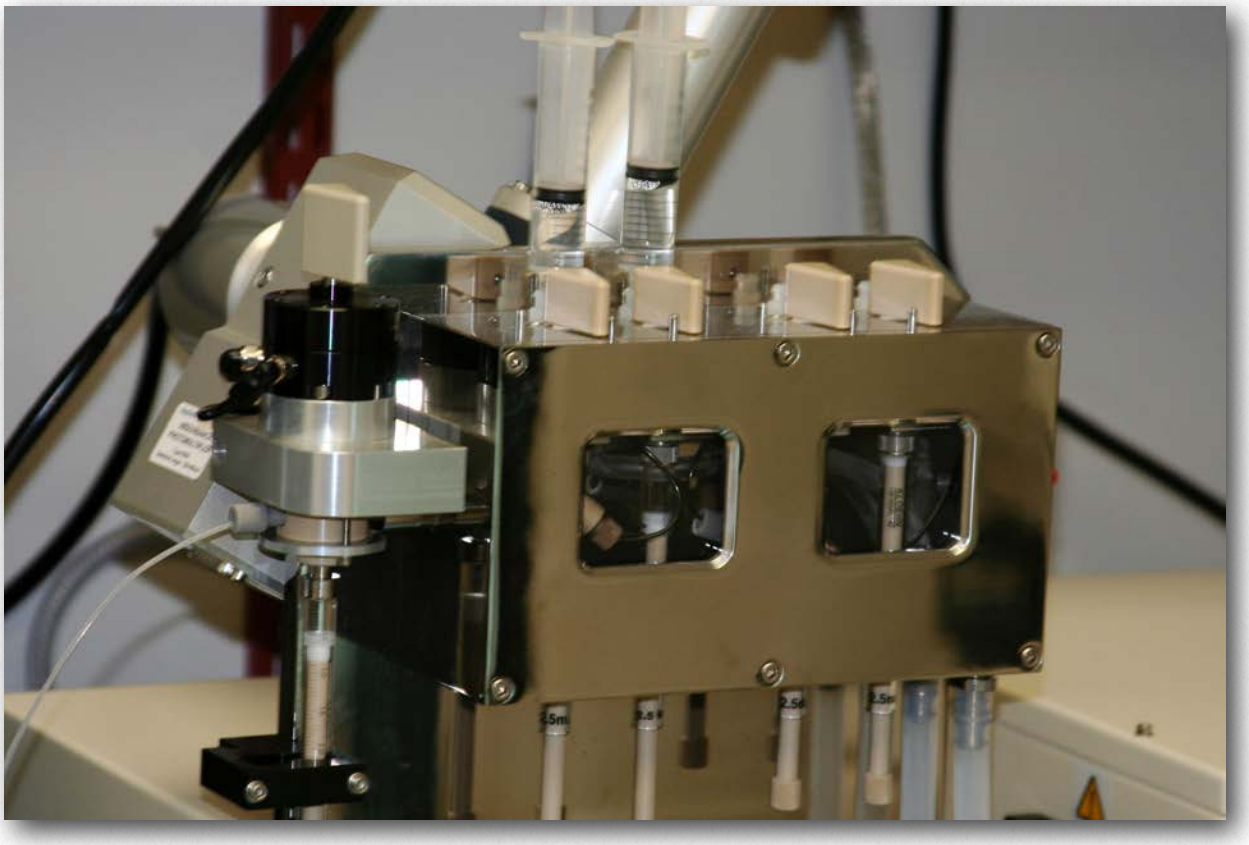

Figure 4.30 - Stopped flow instrument for studying pre-steady state kinetics

Wikipedia

Menten kinetics. In steady state conditions, the amount of the enzyme-substrate complex (ES) is relatively constant over time. In simple terms, this occurs when the rate of formation of the ES complex equals the rate of conversion of the substrate to product by the enzyme with release of the product.

Earlier events

Events occurring prior to the conditions of steady state are referred to as pre-steady state. Depending on the enzyme, in as short as a few milliseconds, steady state conditions can be present meaning that if one hopes to study formation of reaction intermediates in pre-steady state, tools for this analysis must work very rapidly. One instrument commonly used for studying pre-steady state kinetics is called a stopped flow instrument.

It loads an enzyme solution and a substrate into separate syringes whose output is pointed into a mixing chamber. The solutions are rapidly mixed and measurements of product concentration begin. With a stopped flow instrument, dead times (time between mixing and detection) can be achieved of as small as 0.3 msec.

Ribozymes

Proteins do not have a monopoly on acting as biological catalysts. Some RNA molecules are also capable of speeding reactions. The most famous of these molecules was discovered by Tom Cech in the early 1980s Studying excision of an intron in *Tetrahymena*, Cech was puzzled at his inability to find any proteins catalyzing the process. Ultimately, the catalysis was recognized as coming from the intron itself. It was a self-splicing RNA and since then, many other examples of catalytic

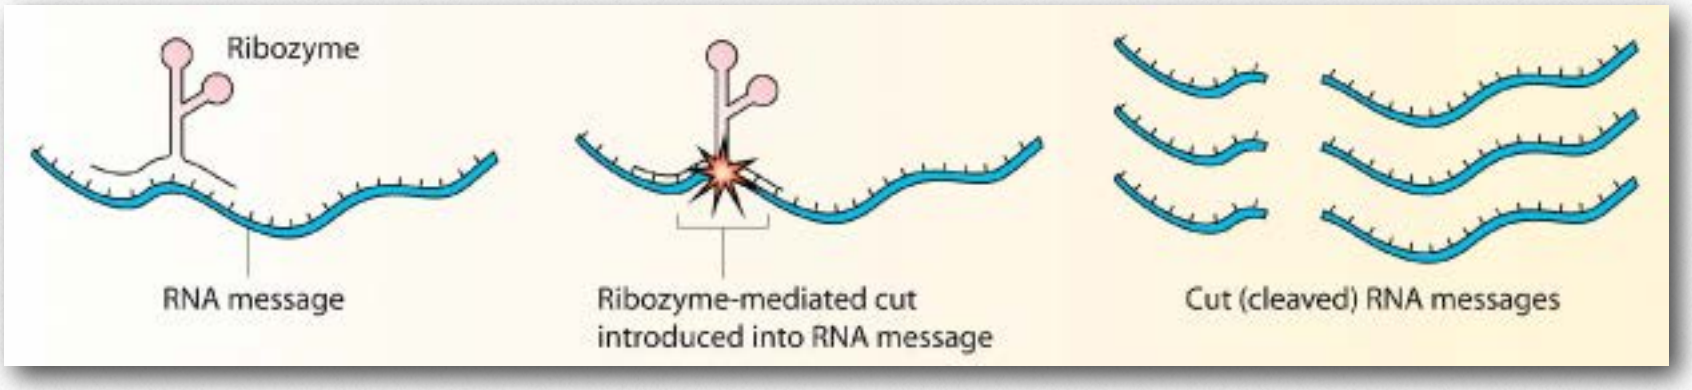

Figure 4.31 - Cleavage of an RNA by a ribozyme

Wikipedia

RNAs have been found. Catalytic RNA molecules are known as ribozymes.

Not unusual

Ribozymes, however, are not rarities of nature. The protein-making ribosomes of cells are essentially giant ribozymes. The 23S rRNA of the prokaryotic ribosome and the 28S rRNA of the eukaryotic ribosome catalyze the formation of peptide bonds.

Ribozymes are also important in our understanding of the evolution of life on Earth. They have been shown to be capable via selection to evolve self-replication. Indeed, ribozymes actually answer a chicken/egg dilemma - which came first, enzymes that do the work of the cell or nucleic acids that carry the information required to produce the enzymes. As both carriers of genetic information and catalysts, ribozymes are likely both the chicken and the egg in the origin of life.

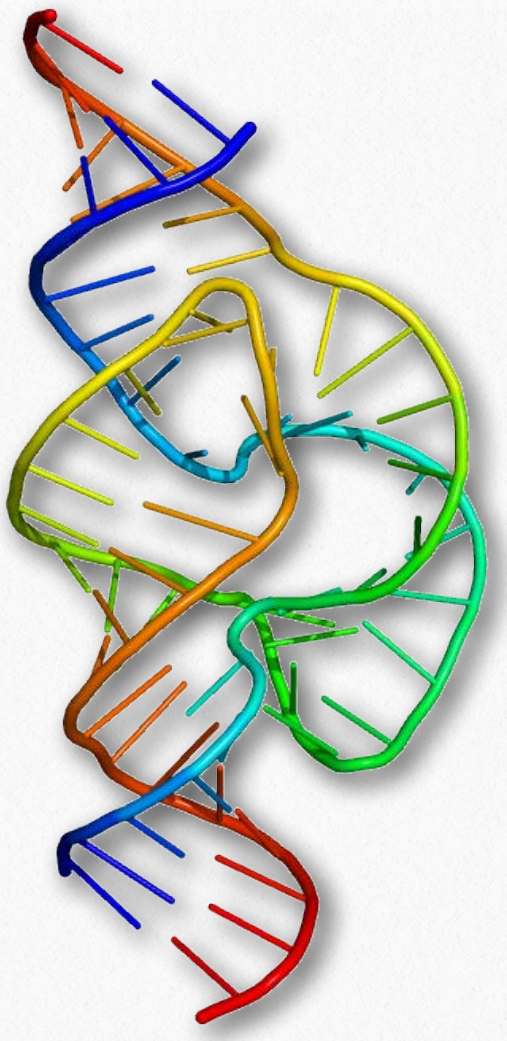

Figure 4.32 - Hammerhead ribozyme

Catalysis: Control of Activity

Regulation of enzyme activity

Apart from their ability to greatly speed the rates of chemical reactions in cells, enzymes have another property that makes them valuable. This property is that their activity can be regulated, allowing them to be activated and inactivated, as necessary. This is tremendously important in maintaining homeostasis, permitting cells to respond in controlled ways to changes in both internal and external conditions.

YouTube Lectures by Kevin
HERE & HERE

Inhibition of specific enzymes by drugs can also be medically useful. Understanding the mechanisms that control enzyme activity is, therefore, of considerable importance.

Inhibition

We will first discuss four types of enzyme inhibition – competitive, non-competitive, uncompetitive, and suicide inhibition. Of these, the first three types are reversible. The last one, suicide inhibition, is not.

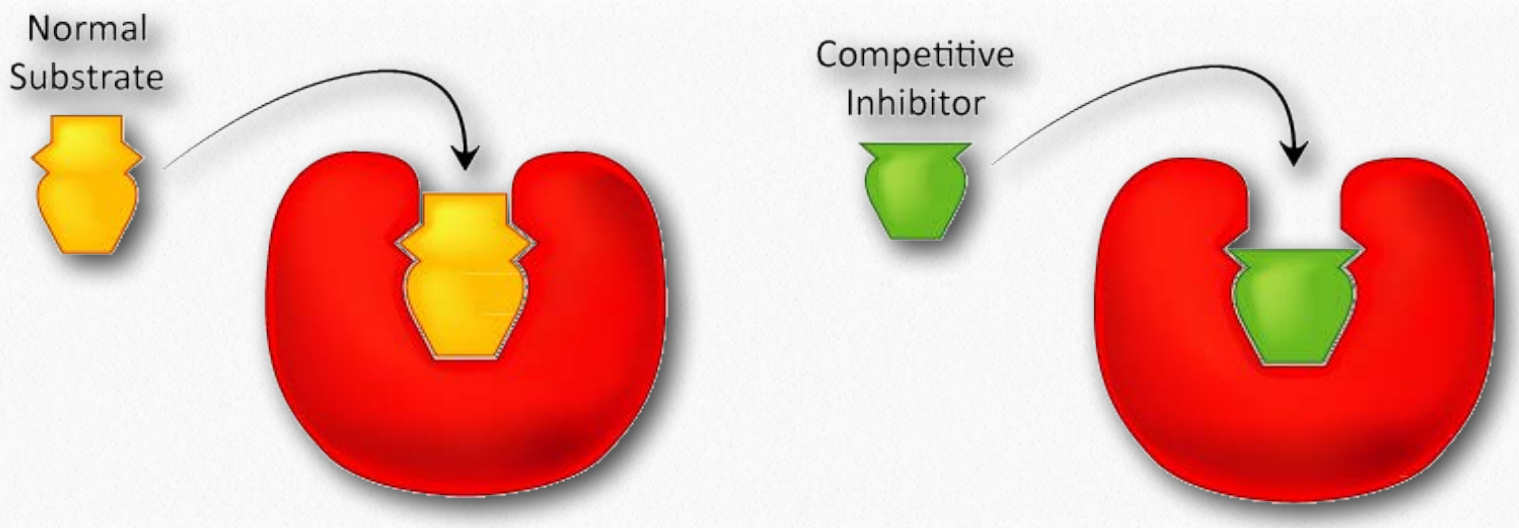

Figure 4.33 - Competitive inhibitors resemble the normal substrate and compete for binding at the active site

Image by Aleia Kim

Competitive inhibition

Probably the easiest type of enzyme inhibition to understand is competitive inhibition and it is the one most commonly exploited pharmaceutically. Molecules that are competitive inhibitors of enzymes resemble one of the normal substrates of an enzyme. An example is methotrexate, which resembles the folate substrate of the enzyme dihydrofolate reductase (DHFR). This enzyme normally catalyzes the reduction of folate, an important reaction in the metabolism of nucleotides.

Inhibitor binding

When the drug methotrexate is present, some of the DHFR enzyme binds to it, instead of to folate, and during the time methotrexate is bound, the enzyme is inactive and unable to bind folate. Thus, the enzyme is inhibited. Notably, the binding site on DHFR for methotrexate is the active site, the same place that folate would normally bind.

As a result, methotrexate 'competes' with folate for binding to the enzyme. The more

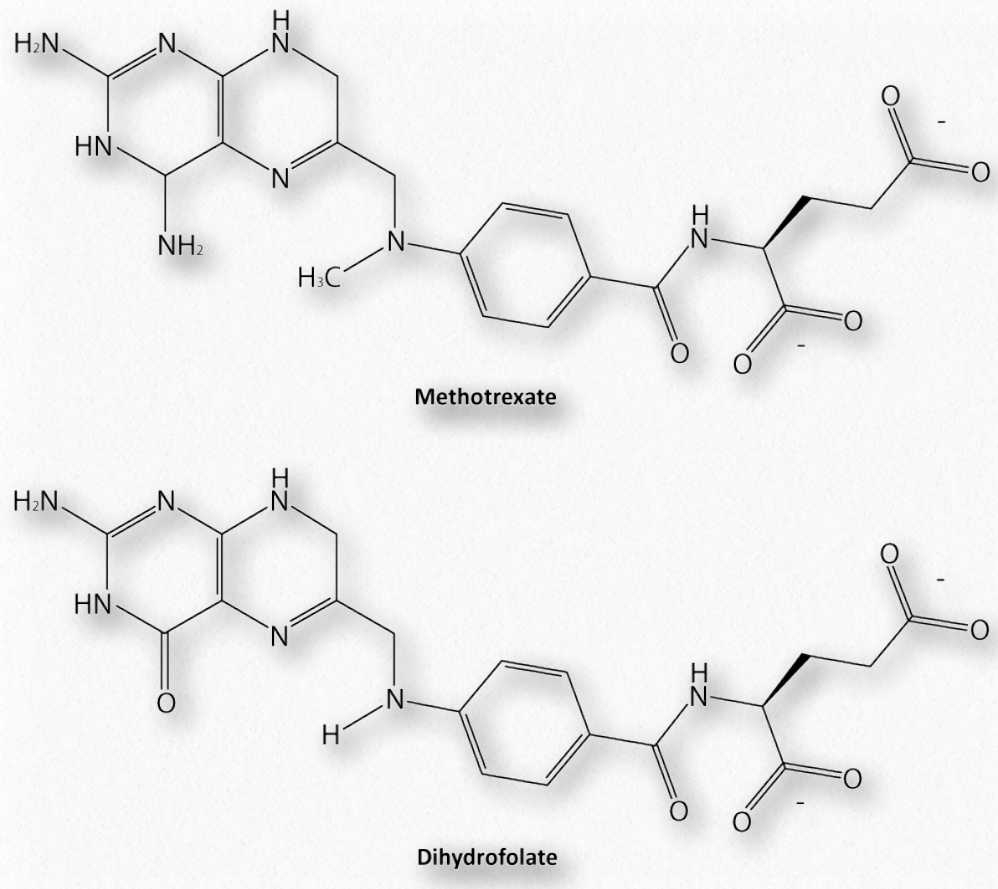

Figure 4.34 - Methotrexate and dihydrofolate

Image by Ben Carson

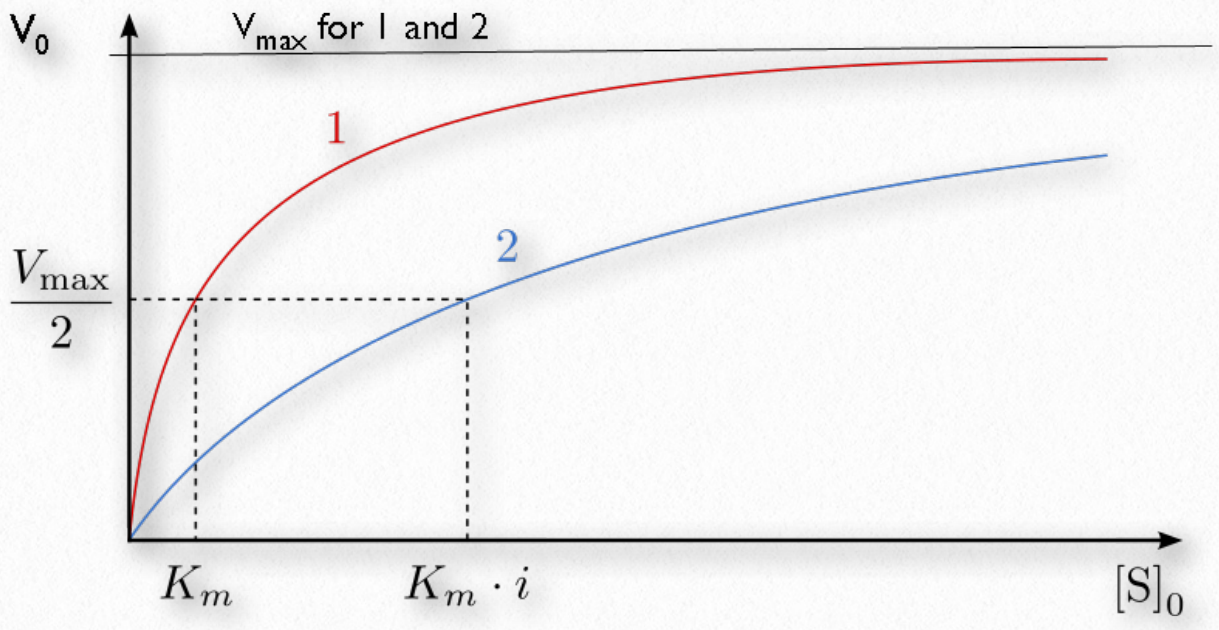

Figure 4.35 V_0 vs [S] Plots for uninhibited reactions (red) and competitively inhibited reactions (blue). Both ultimately have same V_{max}

methotrexate there is, the more effectively it competes with folate for the enzyme's active site. Conversely, the more folate there is, the less of an effect methotrexate has on the enzyme because folate outcompetes it.

Interactive Learning Module HERE

No effect on V_{max}

How do we study competitive inhibition? It is typically done as follows. First, one performs a set of V0 vs. [S] reactions without inhibitor (20 or so tubes, with buffer and constant amounts of enzyme, varying amounts of substrate, equal reaction times). V_0 vs. [S] is plotted (Figure 4.35 red line), as well as $1/V_0$ *vs.* 1/[S] (Figure 4.36 green line). Next, a second set of reactions is performed in the same manner as before, except that a fixed amount of the methotrexate inhibitor is added to each tube. At low concentrations of substrate, the methotrexate competes for the enzyme effectively, but at high concentrations of substrate, the inhibitor will have a much reduced effect, since the substrate outcompetes it, due to its higher concentration (remember that the inhibitor is at fixed concentration).

Graphically, the results of these inhibitor experiments are shown in Figure 4.35 (blue line) and Figure 4.36 (orange line). Notice that at high substrate concentrations, the competitive inhibitor has essentially no effect, causing the V_{max} for the enzyme to remain unchanged. To reiterate, this is due to the fact that at high substrate concentrations, the inhibitor doesn't compete well. However, at lower substrate concentrations, it does.

Increased K_m

In competitively inhibited reactions, the apparent K_m of the enzyme for the substrate increases ($-1/K_m$ gets closer to zero - red line in Figure 4.36) when the inhibitor is present compared to when the inhibitor is absent,

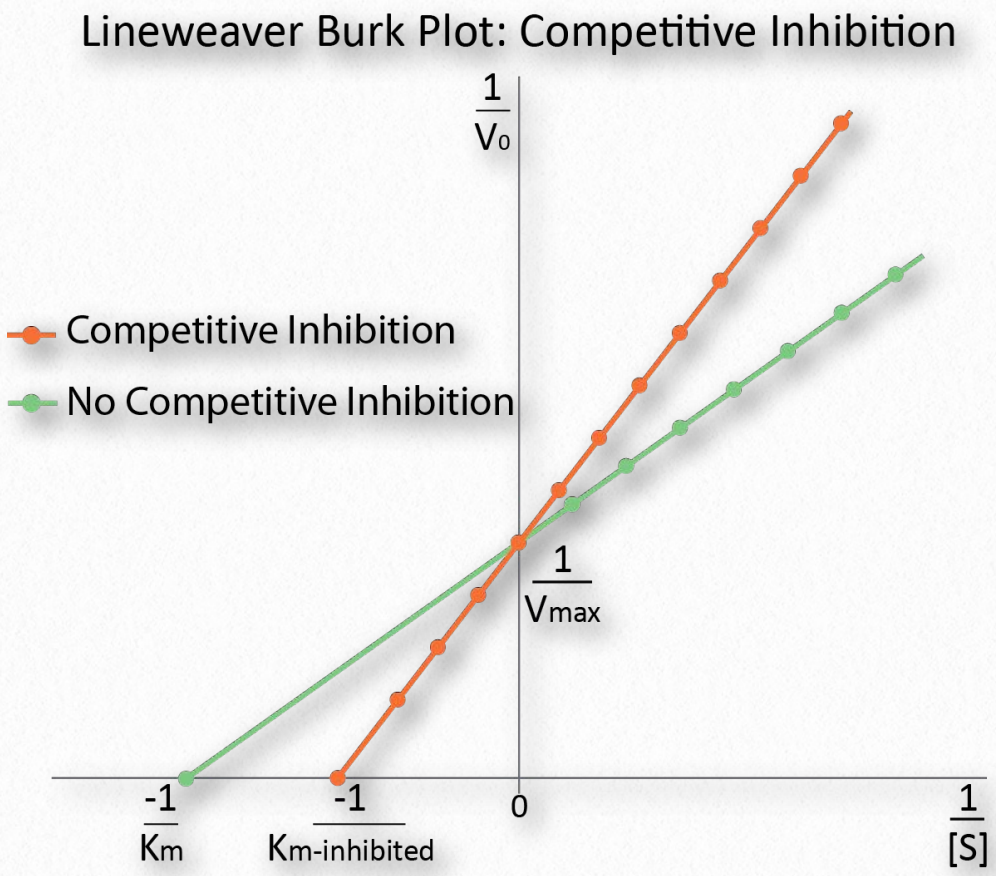

Figure 4.36 - Lineweaver-Burk plots - uninhibited reactions (green). Competitively inhibited reactions (orange). Lines cross on Y-axis at 1/V_{max} Since V_{max} is the same for both reactions

Image by Aleia Kim

thus illustrating the better competition of the inhibitor at lower substrate concentrations.

It may not be obvious why we call the changed K_m the apparent K_m of the enzyme. The reason is that the inhibitor doesn't actually change the enzyme's affinity for the folate substrate. It only appears to do so. This is because of the way that competitive inhibition works. When the competitive inhibitor binds the enzyme, it is effectively 'taken out of action.' Inactive enzymes have NO affinity for substrate and no activity either. We can't measure K_m for an inactive enzyme.

YouTube Lectures by Kevin HERE & HERE

The enzyme molecules that are not bound by methotrexate can, in fact, bind folate and are active. Methotrexate has no effect on them and their K_m values are unchanged. Why then, does K_m appear higher in the presence of a competitive inhibitor? The reason is that the competitive inhibitor is having a greater effect of reducing the amount of active enzyme at lower concentrations of substrate than it does at higher concentrations of substrate. When the amount of enzyme is reduced, one must have more substrate to supply the reduced amount of enzyme sufficiently to get to Vmax/2.

It is worth noting that in competitive inhibition, the percentage of inactive enzyme changes drastically over the range of [S] values used. To start, at low [S] values, the greatest percentage of the enzyme is inhibited. At high [S], no significant percentage of enzyme is inhibited. This is not always the case, as we shall see in non-competitive inhibition.

Non-competitive inhibition

A second type of inhibition employs inhibitors that do not resemble the substrate and bind not to the active site, but rather to a separate site on the enzyme (Figure 4.37). The effect of binding a non-competitive inhibitor is significantly different from

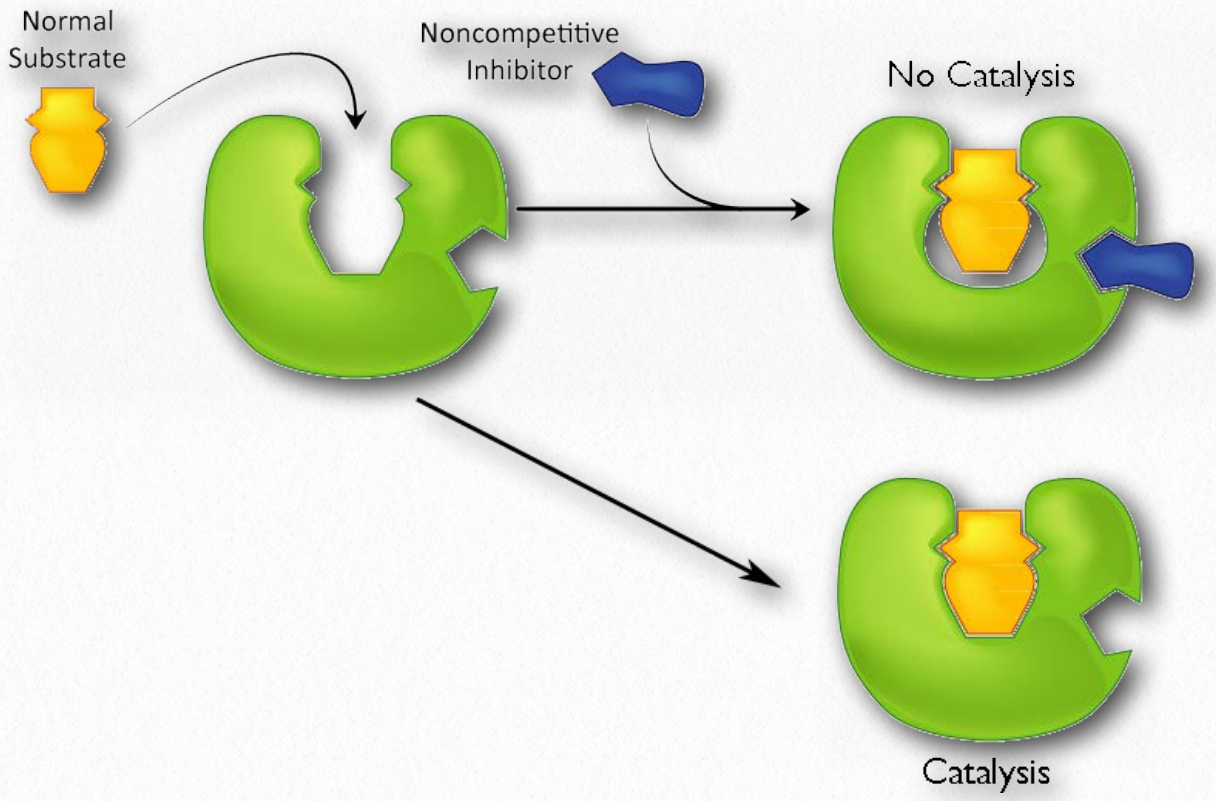

Figure 4.37 - Non-competitive inhibition - inhibitor does not resemble the substrate and binds to a site other than the active site

Image by Aleia Kim

binding a competitive inhibitor because there is no competition. In the case of competitive inhibition, the effect of the inhibitor could be reduced and eventually overwhelmed with increasing amounts of substrate. This was because increasing substrate made increasing percentages of the enzyme active. With non-competitive inhibition, increasing the amount of substrate has no effect on the percentage of enzyme that is active. Indeed, in non-competitive inhibition, the percentage of enzyme inhibited remains the same through all ranges of [S].

This means, then, that non-competitive inhibition effectively reduces the amount of enzyme by the same fixed amount in a typical experiment at every substrate concentration used The effect of this inhibition is shown in Figure 4.38 & 4.39. As you can see, V_{max} is reduced in non-competitive inhibition compared to uninhibited reactions.

This makes sense if we remember that V_{max} is dependent on the amount of enzyme present.

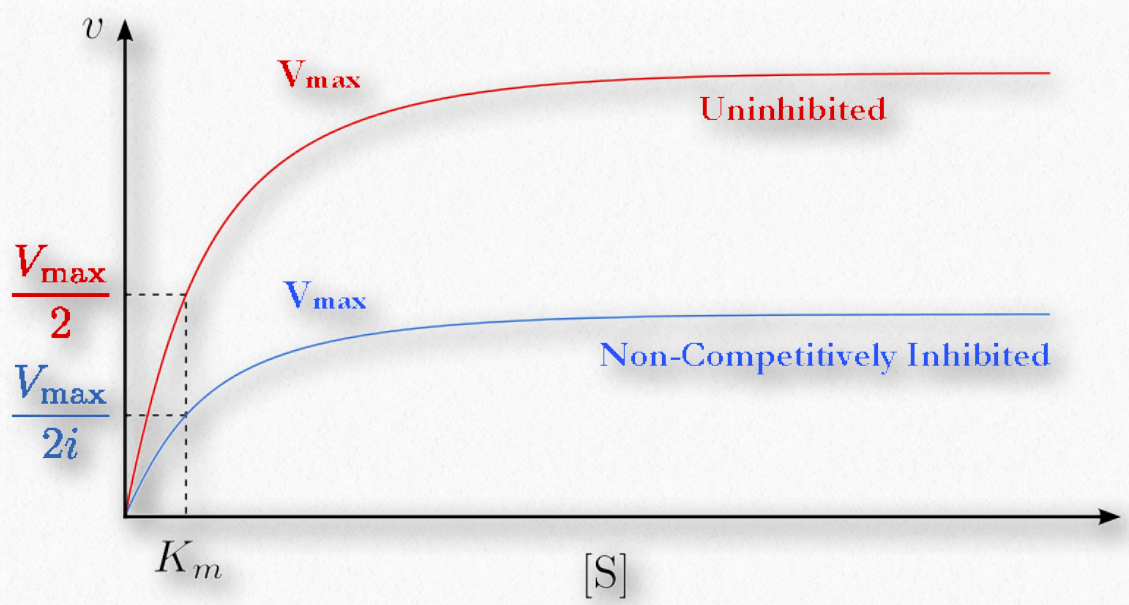

Figure 4.38 - V_0 vs [S] plots of uninhibited reactions (red) and non-competitively inhibited reactions (blue). V_{max} is reduced, but K_m values are unchanged in non-competitively inhibited reactions

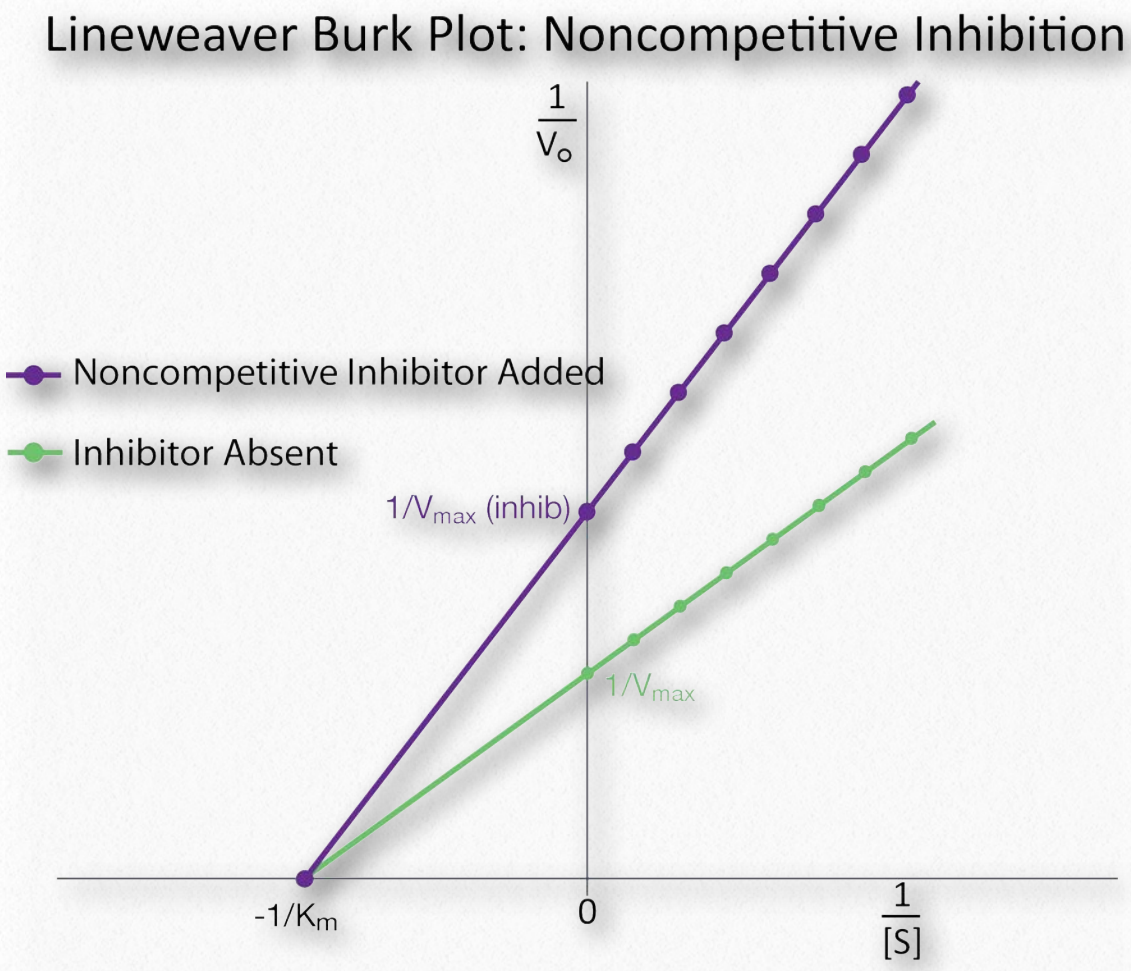

Figure 4.39 - Lineweaver Burk plots of uninhibited reactions (green) and non-competitively inhibited reactions (purple).

Image by Aleia Kim

100% of the enzyme active and the V_{max} appears not to change. Additionally, K_m for non-competitively inhibited reactions does not change from that of uninhibited reactions. This is because, as noted previously, one can only measure the K_m of active enzymes and K_m is a constant for a given enzyme.

Uncompetitive inhibition

A third type of enzymatic inhibition is that of uncompetitive inhibition, which has the odd property of a reduced V_{max} as well as a reduced K_m. The explanation for these seemingly odd results is rooted in the fact that the uncompetitive inhibitor binds only to the enzyme-substrate (ES) complex (Figure 4.40). The inhibitor-bound complex forms mostly under concentrations

Reducing the amount of enzyme present reduces V_{max}. In competitive inhibition, this doesn't occur detectably, because at high substrate concentrations, there is essentially

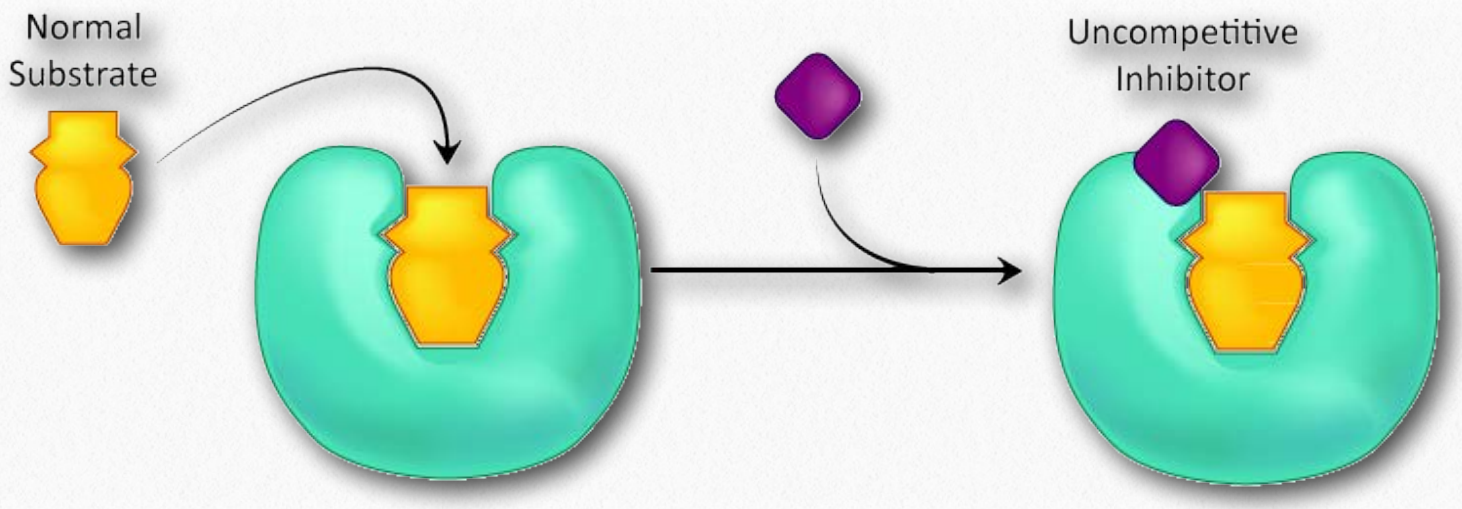

Figure 4.40 - Uncompetitive inhibition

Image by Aleia Kim

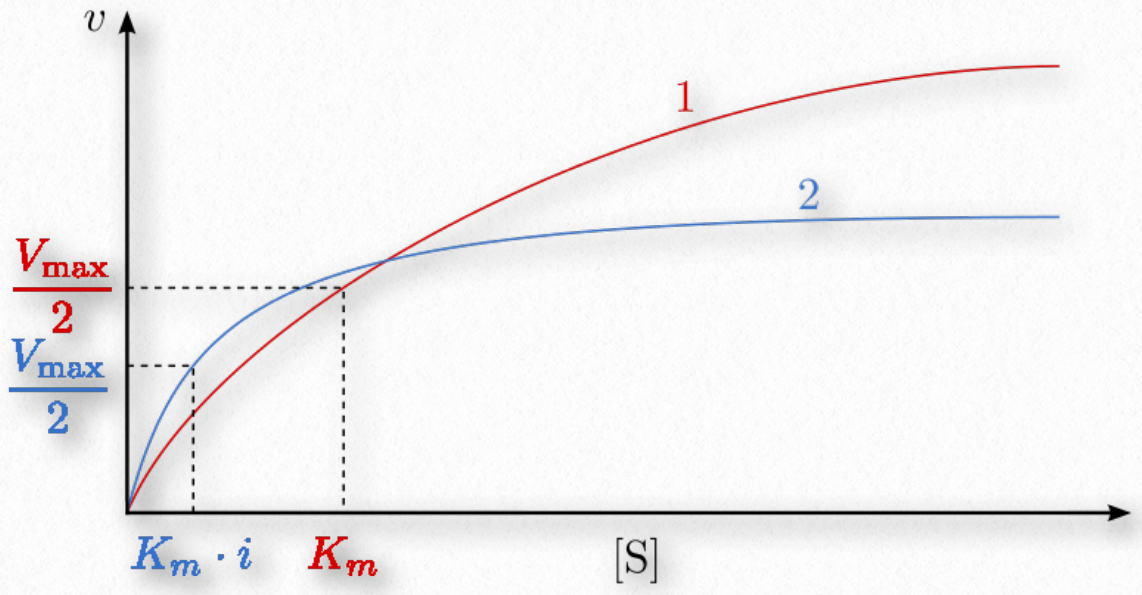

Figure 4.41 - V_0 vs [S] plot for uncompetitive inhibition (blue) and uninhibited reactions (red)

By Le Chatelier's Principle, a shift occurs to form additional ES complex, resulting in less free enzyme and more enzyme in the forms ES and ESI (ES with inhibitor). Decreases in free enzyme correspond to an enzyme with greater affinity for its substrate. Thus, paradoxically, uncompetitive inhibition both decreases V_{max} and increases an enzyme's affinity for its substrate (K_m - Figures 4.41 & 4.42).

Interactive Learning Module HERE

of high substrate and the ES-I complex cannot release product while the inhibitor is bound, thus explaining the reduced V_{max}.

The reduced K_m is a bit harder to conceptualize. The reason is that the inhibitor-bound complex effectively reduces the concentration of the ES complex.

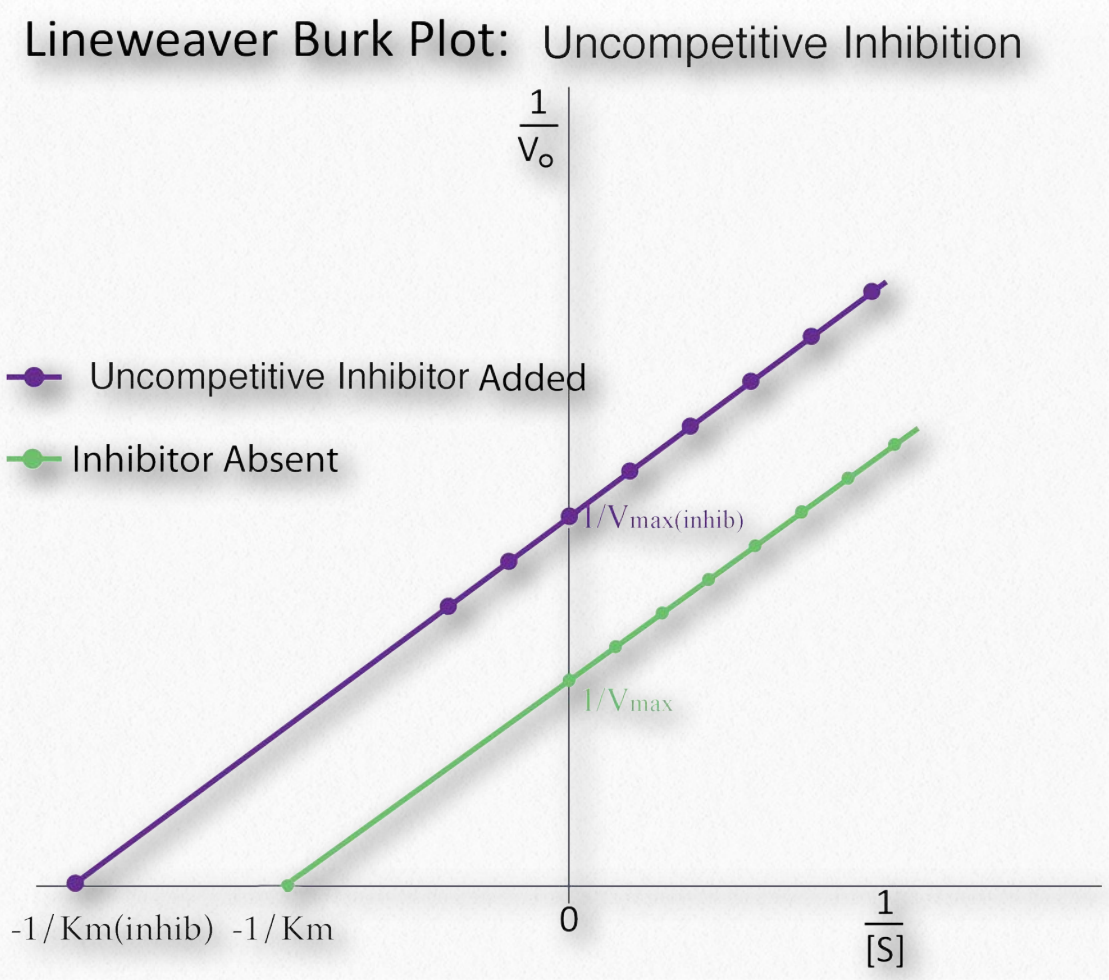

Figure 4.42 - Uncompetitive inhibition (purple) and uninhibited reactions (green)

Image by Aleia Kim

Suicide inhibition

In contrast to the first three types of inhibition, which involve reversible binding of the inhibitor to the enzyme, suicide inhibition is irreversible, because the inhibitor becomes covalently bound to the enzyme during the inhibition. Suicide inhibition rather closely resembles competitive inhibition because the inhibitor generally resembles the substrate and binds to the active site of the enzyme. The primary difference is that the suicide inhibitor is chemically reactive in the active site and makes a bond with it that precludes its removal. Such a mechanism is that employed by penicillin (Figure 4.43), which covalently links to the bacterial enzyme, DD transpeptidase and stops it from functioning. Since the normal function of the enzyme is to make a bond necessary for the peptidoglycan complex of the bacterial cell wall, the cell wall cannot properly form and bacteria cannot reproduce.

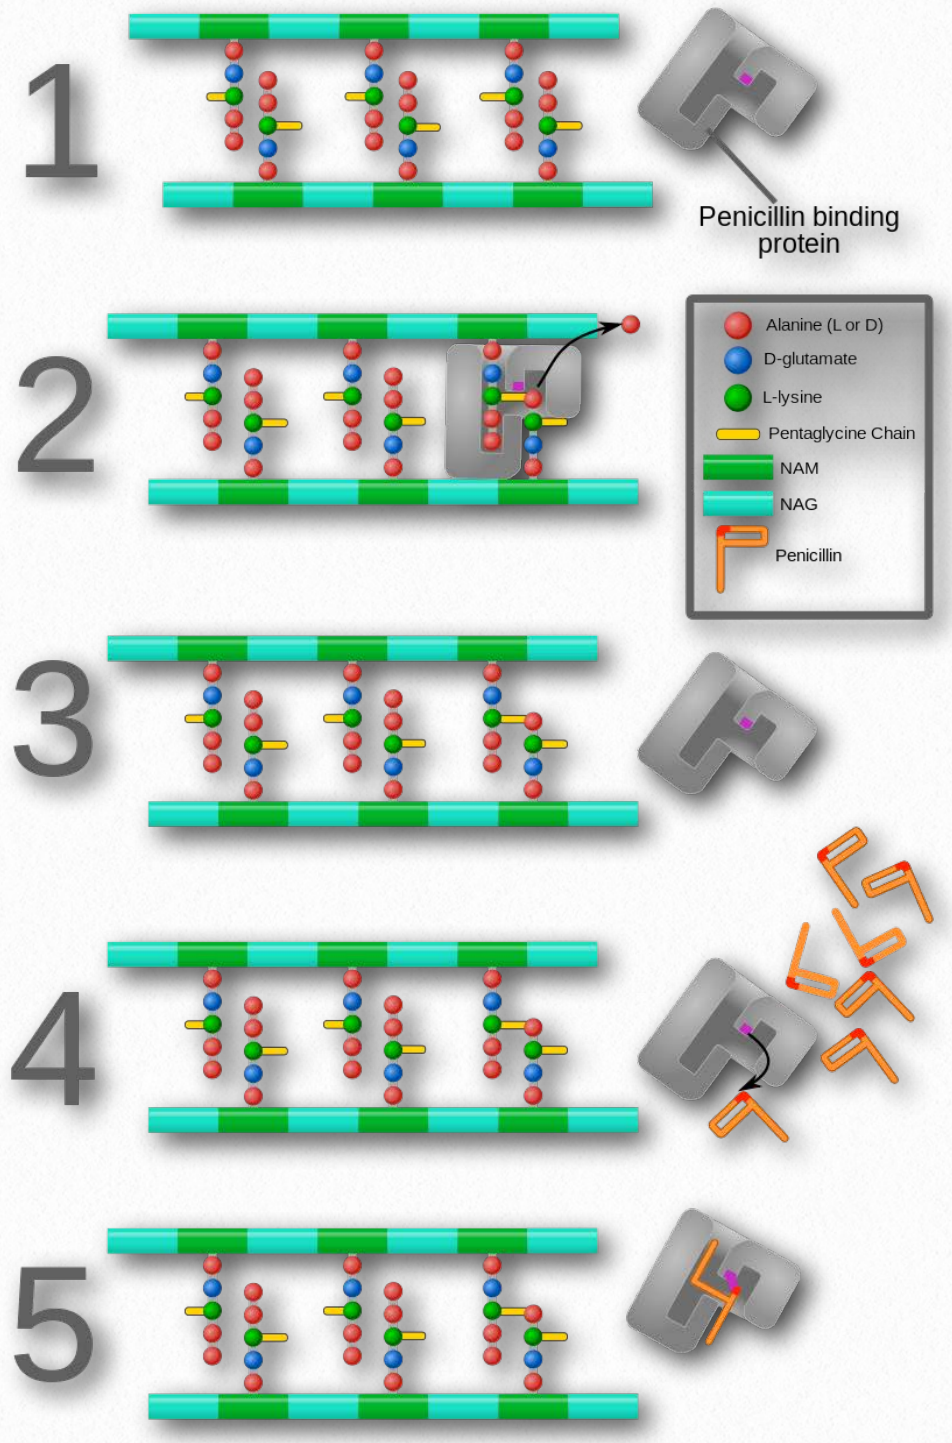

Figure 4.43 - Action of penicillin. DD-transpeptidase builds peptidoglycan layer of bacterial cell wall (1-3). Binding of penicillin by DD-transpeptidase stops peptidoglycan synthesis (4-5)

Wikipedia

For inhibition, here are rules
To give to students in the schools
Non-competers muddy facts
And drop the value of V_{max}
Competers, everyone should know
Will make the K_M values grow
Uncompetition makes them think
Since both K_M and V_{max} shrink
And suicide covalently
Stops enzymes irreversibly

Control of enzymes

It is appropriate to talk at this point about mechanisms cells use to control enzymes. There are four general methods that are employed. They include 1) allosterism; 2) covalent modification; 3) access to substrate;

and 4) control of enzyme synthesis/ breakdown. Some enzymes are controlled by more than one of these methods.

Allosterism

The term allosterism refers to the fact that the activity of certain enzymes can be affected by the binding of small molecules. Molecules causing allosteric effects come in two classifications. Ones that are substrates for the enzymes they affect are called homotropic effectors and those that are not substrates are called heterotropic effectors.

The homotropic effectors usually are activators of the enzymes they bind to and the results of their action can be seen in the conversion of the hyperbolic curve typical of a V_0 vs. [S] plot for an enzyme (Figure 4.18) , being converted to a sigmoidal plot (Figure 4.44). This is due to the conversion of the enzyme from the T-state to the R-state on binding the substrate/homotropic effector.

The V_0 vs. [S] plot of allosteric enzyme reactions resembles the oxygen binding curve of hemoglobin (see Figure 2.83). Even though hemoglobin is not an enzyme and is thus not catalyzing a reaction, the similarity of the plots is not coincidental. In both cases, the binding of an external molecule is being measured – directly, in the hemoglobin plot, and indirectly by the V_0 vs. [S] plot, since substrate binding is a factor in enzyme reaction velocity.

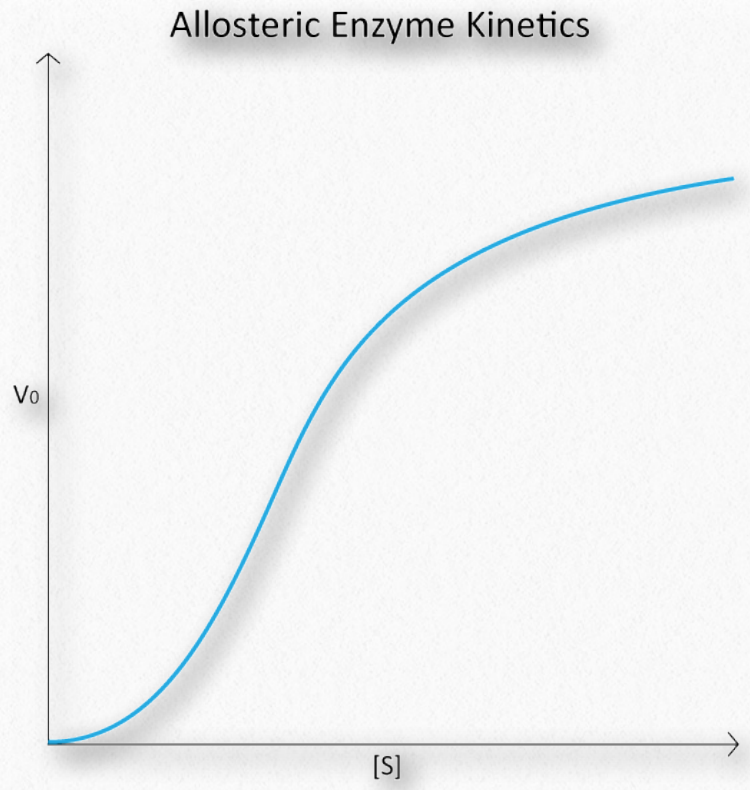

Figure 4.44 - Kinetic profile of an allosteric enzyme whose activity is controlled by a homotropic effector

Image by Aleia Kim

Allosteric inhibition

Allosterically, regulation of these enzymes works by inducing different physical states (shapes, as it were) that affect their ability to bind to substrate. When an enzyme is inhibited by binding an effector, it is converted to the T-state (T=tight), it has a reduced affinity for substrate and it is through this means that the reaction is slowed.

Allosteric activation

On the other hand, when an enzyme is activated by effector binding, it converts to the R-state (R=relaxed) and binds substrate much more readily. When no effector is present, the enzyme may be in a mixture of T- and R-states.

Feedback inhibition

An interesting kind of allosteric control is exhibited by HMG-CoA reductase, which catalyzes an important reaction in the pathway leading to the synthesis of cholesterol. Binding of cholesterol to the enzyme reduces the enzyme's activity significantly. Cholesterol is not a substrate for the enzyme, so it is therefore a heterotropic effector.

Notably, though, cholesterol is the end-product of the pathway that HMG-CoA reductase catalyzes a reaction in. When enzymes are inhibited by an end-product of the pathway in which they participate, they are said to exhibit feedback inhibition.

Feedback inhibition always operates by allosterism and further, provides important and efficient control of an entire pathway. By inhibiting an early enzyme in a pathway, the flow of materials (and ATP hydrolysis required for their processing) for the entire pathway is stopped or reduced, assuming there are not alternate supply methods.

Pathway control

In the cholesterol biosynthesis pathway, stopping this one enzyme has the effect of shutting off (or at least slowing down) the entire pathway. This is significant because after catalysis by HMG-CoA reductase, there are over 20 further reactions necessary to make cholesterol, many of them requiring ATP energy. Shutting down one reactions stops all of them. Another excellent example of allosteric control and feedback inhibition is the enzyme ATCase, discussed below.

ATCase

Another interesting example of allosteric control and feedback inhibition is associated with the enzyme Aspartate Transcarbamoylase (ATCase). This enzyme, which catalyzes a step in the synthesis of pyrimidine nucleotides, has 12 subunits. These include six identical catalytic subunits and six identical regulatory subunits. The catalytic subunits bind to substrate and catalyze a reaction. The regulatory subunits bind to either ATP or CTP. If they bind to ATP, the enzyme

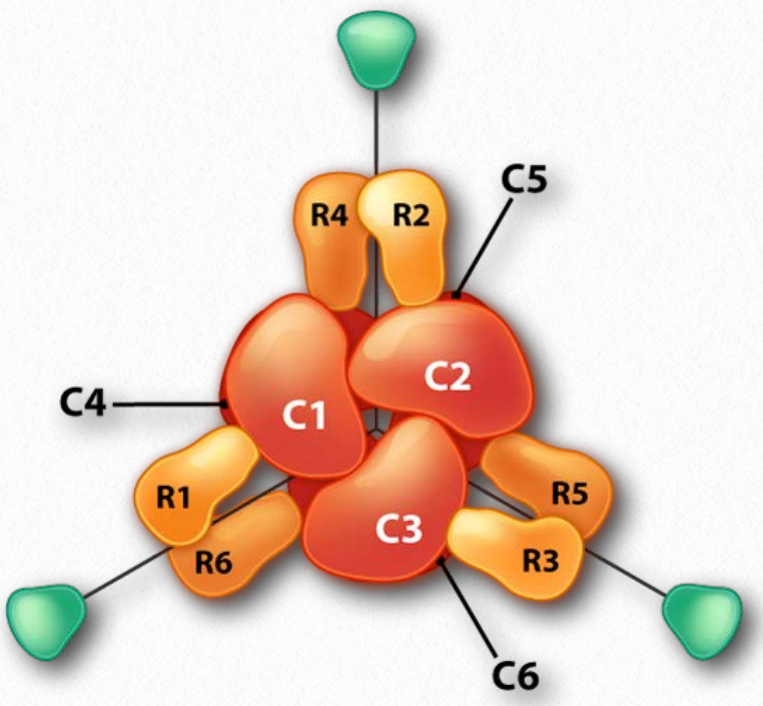

Figure 4.45 - Schematic structure of ATCase. Regulatory Units = R, Catalytic Units = C
Image by Aleia Kim

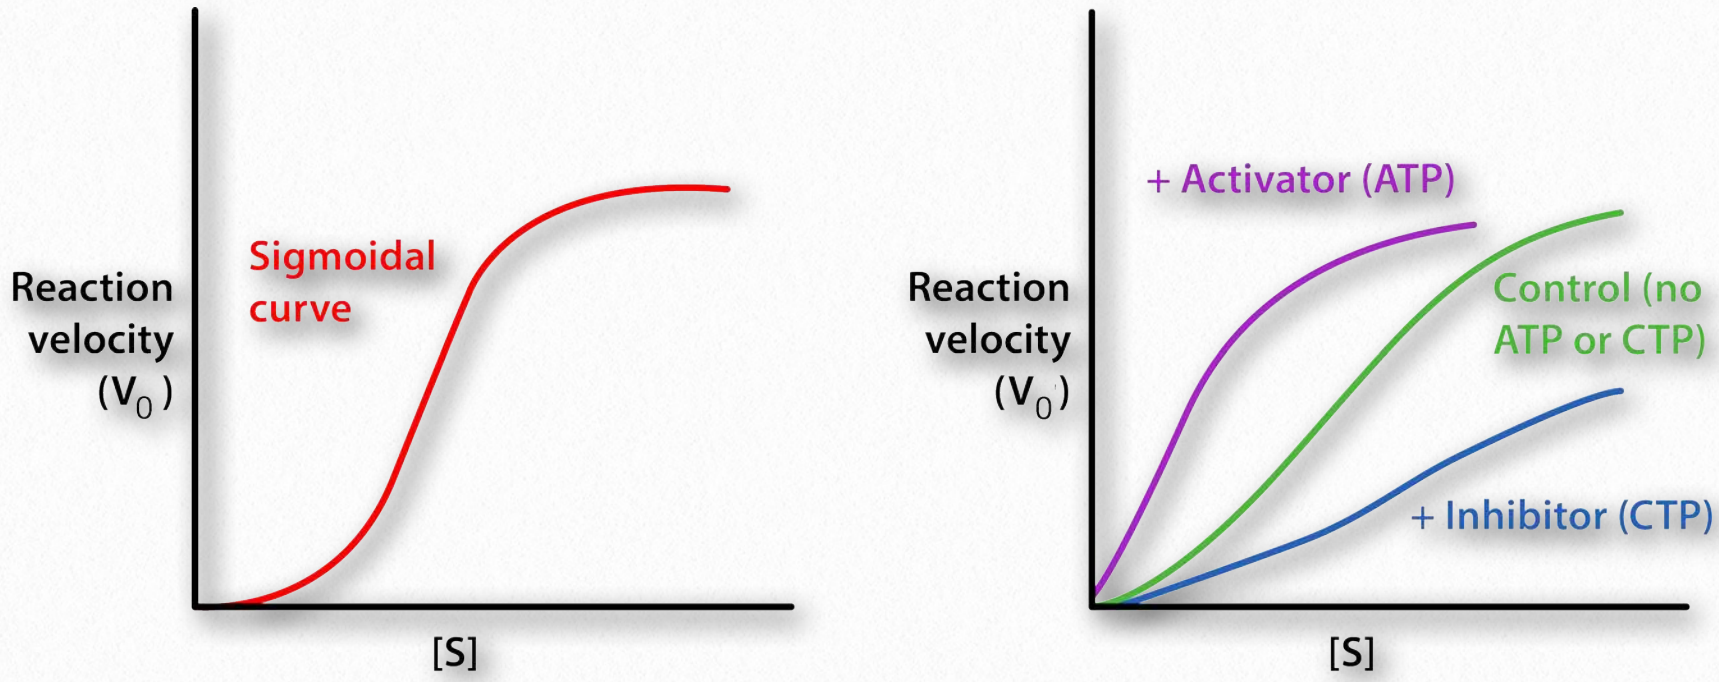

Figure 4.46 - Plots of V_0 vs. [S] for ATCase. Left - Allosteric effect of aspartate. Right - Allosteric effects of ATP (activator) and CTP (inhibitor)

Image by Pehr Jacobson

subunits arrange themselves in the R-state.

R-state

The R-state of ATCase allows the substrate to have easier access to the six active sites and the reaction occurs more rapidly. For the same amount of substrate, an enzyme in the R-state will have a higher velocity than the same enzyme that is not in the R-state.

YouTube Lectures by Kevin HERE & HERE

By contrast, if the enzyme binds to CTP on one of its regulatory subunits, the subunits will arrange in the T-state and in this form, the substrate will not have easy access to the active sites, resulting in a slower velocity for the same concentration of substrate compared to the R-state. ATCase is interesting in that it can also flip into the R-state when one of the substrates (aspartate) binds to an active site within one of the catalytic subunits.

Aspartate has the effect of activating the catalytic action of the enzyme by favoring the R-state. Thus, aspartate, which is a substrate of the enzyme is a homotropic effector and ATP and CTP, which are not substrates of the enzyme are heterotropic effectors of ATCase.

Allosteric models

There are three models commonly used to explain how allosterism regulates multi-subunit enzyme activity. They are known as the Monod-Wyman-Changeux (MWC) model (also known as the concerted model), the sequential model (also known as KNF), and the morpheein model. All models describe a

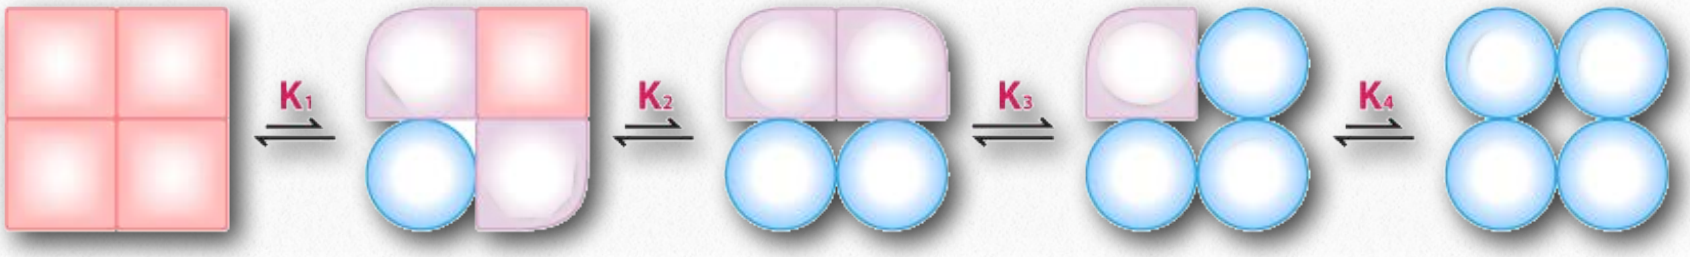

Figure 4.47 - Sequential model of allosteric regulation. Round = R-State. Square = T-state.

Image by Aleia Kim

Tense (T) state that is less catalytically active and a Relaxed (R) state that is more catalytically active. The models differ in how the states change.

Sequential model

In the sequential model, binding of an allosteric effector by one subunit causes it to change from T to R state (or vice versa) and that change makes it easier for adjacent subunits to similarly change state. With this model , there is a cause/effect relationship between binding of an effector by one subunit and change of state by an adjacent subunit.

In hemoglobin, for example, binding of one oxygen by one unit of the complex may induce that unit to flip to the R-state and, through interactions with other subunits, cause them to favor adopting the R configuration before they bind to oxygen. In this way, binding of one subunit favors binding of others and cooperativity can be explained by the change in binding affinity as oxygen concentration changes.

MWC model

The MWC model is less intuitive. In it, the entire complex changes state from T to R (or vice versa) independently of the binding of effectors. Flipping between T-states and R-states is postulated to be in an equilibrium of states in the absence of effector (for example, a 50 to 1 ratio of T/R. This ratio is referred to as L, so L = T/R). Binding of effector by the enzyme complex has the tendency of “locking” the complex in a state. Binding of inhibitors will increase the ratio of T/R whereas binding of activators will increase R and thus decrease the ration of T/R.

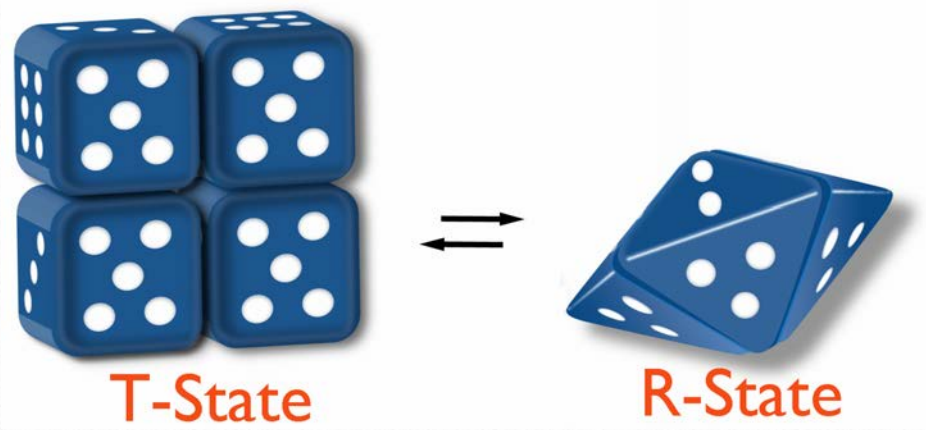

Figure 4.48 - The MWC Model - The multisubunit complex flips as a whole and is in equilibrium

Wikipedia

Morpheein model

The morpheein model is similar to the MWC model, but with an added step of dissociation of the subunits. The MWC model proposes that flipping between R and T states occurs by the complex as a whole and occurs on all units simultaneously.

The morpheein model instead proposes that the multi-subunit enzyme breaks down to individual units which can then flip in structure and re-form the complex. In the morpheein model, only identically shaped units (all R, for example) can come together in the complex, thus explaining the "all-R-" or "all-T-" state found in the MWC model.

A large number of enzymes, including prominent ones like citrate synthase, acetyl-CoA carboxylase, glutamate dehydrogenase, ribonucleotide reductase and lactate dehydrogenase have behavior consistent with the morpheein model.

Covalent control of enzymes

Some enzymes are synthesized in a completely inactive form and their activation requires covalent bonds in them to be cleaved. Such inactive forms of enzymes are called zymogens. Examples include the proteins involved in blood clotting and proteolytic enzymes of the digestive system, such as trypsin, chymotrypsin, pepsin, and others.

Synthesizing some enzymes in an inactive form makes very good sense when an enzyme's activity might be harmful to the tissue where it is being made. For example, the painful condition known as pancreatitis arises when digestive enzymes made in the pancreas are activated too soon and end up attacking the pancreas.

Cascades

For both the blood clotting enzymes and the digestive enzymes, the zymogens are activated in a protease cascade. This occurs when activation of one enzyme activates oth-

Figure 4.49 - Morpheein model of allosterism. States flip as monomers and aggregate only with same monomer.

Wikipedia

ers in a sort of chain reaction. In such a scheme the first enzyme activated proteolytically cleaves the second zymogen, causing it to be activated, which in turn activates a third and this may proceed through several levels of enzymatic action (Figure 4.50).

YouTube Lectures by Kevin HERE & HERE

The advantage of cascades is that they allow a large amount of zymogens to become activated fairly quickly, since there is an amplification of the signal at each level of catalysis.

Zymogens are also abundant in blood. Blood clotting involves polymerization of a protein known as fibrin. Since random formation of fibrin is extremely hazardous because it can block the flow of blood, potentially causing heart attack/stroke, the body synthesizes fibrin as a zymogen (fibrinogen) and its activation results from a "cascade" of activations of proteases that arise when a signal is received from a wound. Similarly, the enzyme catalyzing removal of fibrin clots (plasmin) is also synthesized as a zymogen (plasminogen), since random clot removal would also be hazardous (see below also).

Phosphorylation/ dephosphorylation

Another common mechanism for control of enzyme activity by covalent modification is phosphorylation. The phosphorylation of enzymes (on the side chains of serine, threonine or tyrosine residues) is carried out by protein kinases. Enzymes activated by phos-

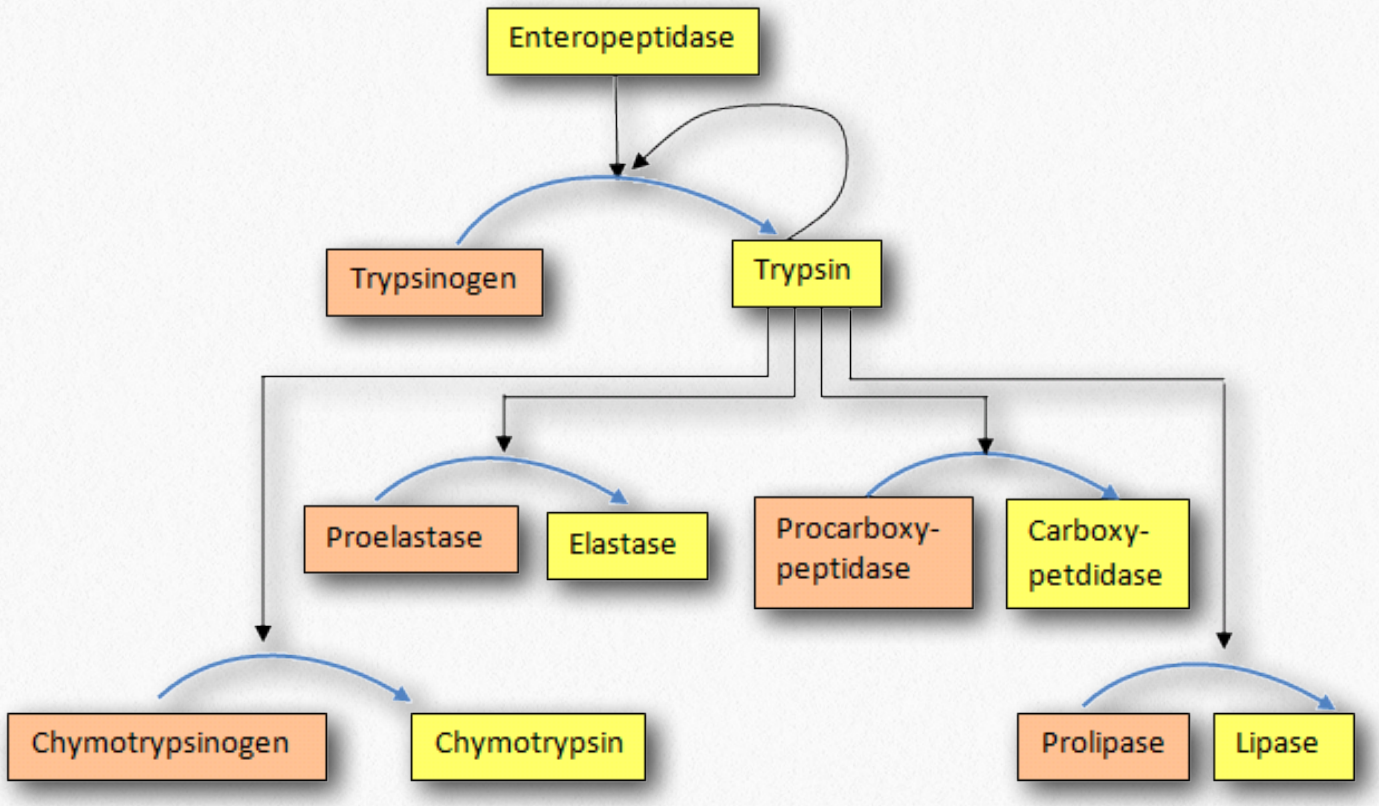

Figure 4.50 - Protease activation scheme

Wikipedia

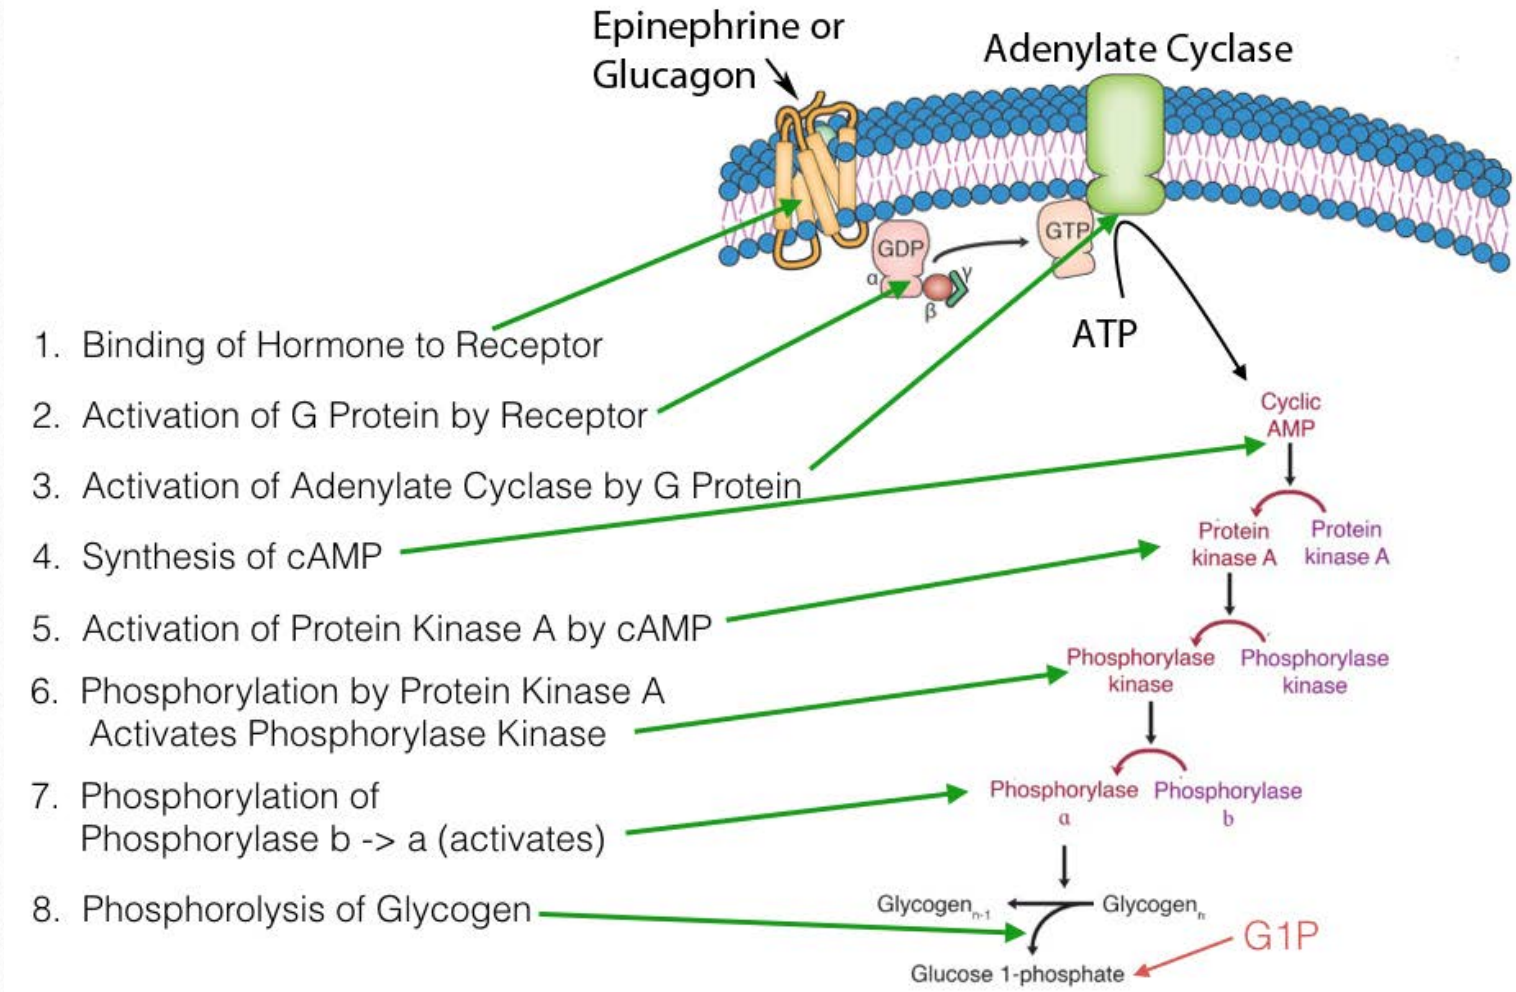

Figure 4.51 - Regulation by covalent modification of glycogen catabolism enzymes

phorylation can be regulated by the addition of phosphate groups by kinases or their removal by phosphatases. Thus, this type of covalent modification is readily reversible, in contrast to proteolytic cleavage.

Reduction/oxidation

An interesting covalent control of enzymes using reduction/oxidation is exhibited in photosynthetic plants. In the light phase of photosynthesis, electrons are excited by light and flow through carriers to $NADP^+$, forming NADPH. Thus, in the light, the NADPH concentration is high. When NADPH concentration is high, the concentration of reduced ferredoxin (a molecule donating electrons to $NADP^+$) is also high.

Reduced ferredoxin can transfer electrons to thioredoxin, reducing it. Reduced thioredoxin can, in turn, transfer electrons to proteins to reduce their disulfide bonds. Four enzymes related to the Calvin cycle can receive electrons from thioredoxin and become activated, as a result.

These include sedoheptulose 1,7-bisphosphatase, ribulose-5-phosphate kinase, fructose 1,6-bisphosphatase, and glyceraldehyde 3-phosphate dehydrogenase. Thus, in the light, electrons flow, causing NADPH to accumulate and ferredoxin to push electrons in the direction of these enzymes above, activating them and favoring the Calvin cycle. In the dark, the concentration of reduced NADPH, reduced ferredoxin, and reduced thioredoxin fall, resulting in loss of electrons by the Calvin cycle enzymes (oxidations that reform disulfide bonds) and the Calvin cycle inactivates.

Other enzyme control mechanisms

Other means of controlling enzymes relate to access to substrate (substrate-level control) and control of enzyme synthesis. Hexokinase is an enzyme that is largely regulated by availability of its substrate, glucose. When glucose concentration is low, the product of the enzyme's catalysis, glucose-6-phosphate, inhibits the enzyme's function.

Regulation of enzymes by controlling their synthesis is covered later in the book in the discussion relating to control of gene expression.

Catalysis: Mechanism

Introduction

The magic of enzymes, as noted, is in their ability to create electronic environments conducive to initiation of a reaction. There are more mechanisms of reaction than we could ever hope to cover in a book like this, and comprehensive discussion of these is not our aim. Instead, we will cite some examples and go into detail on one of them - the mechanism of action of serine proteases.

YouTube Lectures by Kevin HERE & HERE

Chymotrypsin

We will begin with mechanism of action of one enzyme - chymotrypsin. Found in our digestive system, chymotrypsin's catalytic activity is cleaving peptide bonds in proteins and it uses the side chain of a serine in its mechanism of catalysis. Many other protein-cutting enzymes employ a very similar mechanism and they are known collectively as serine proteases (Figure 4.52). These enzymes are found in prokary-

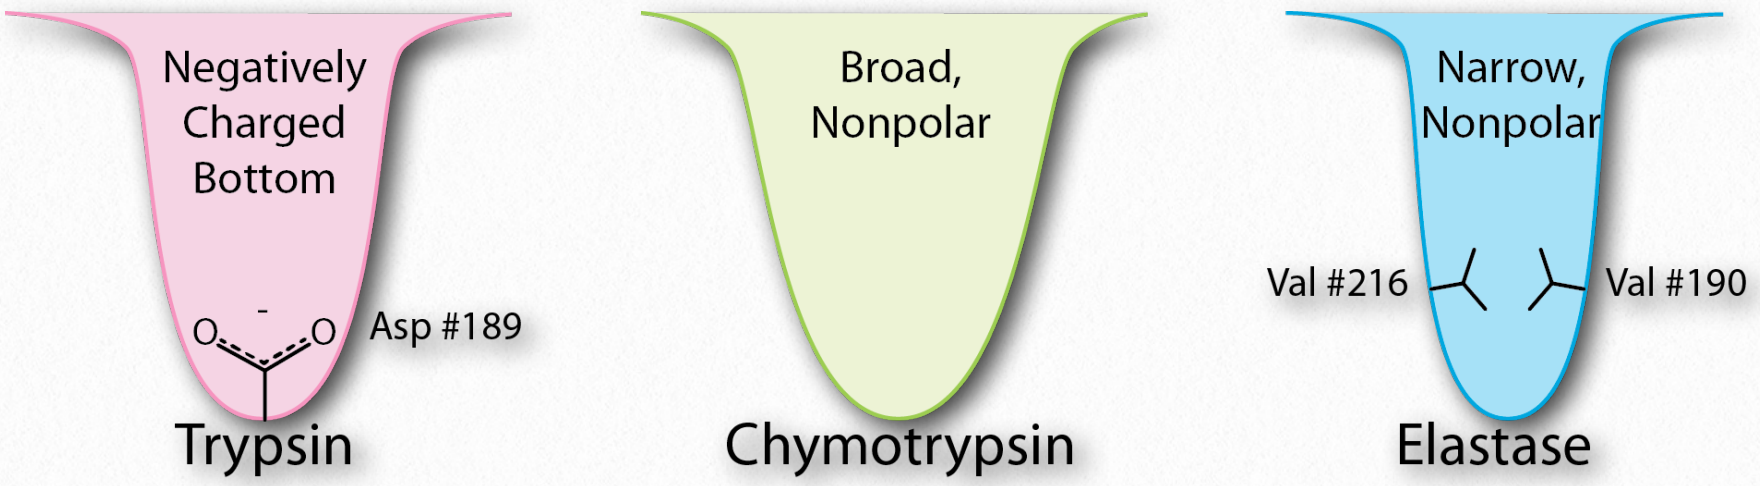

Figure 4.52 - Substrate binding sites (S1 pockets) of three serine proteases

Image by Aleia Kim

otic and eukaryotic cells and all use a common set of three amino acids in the active site called a catalytic triad (Figure 4.53). It consists of aspartic acid, histidine, and serine. The serine is activated in the reaction mechanism to form a nucleophile in these enzymes and gives the class their name. With the exception of the recognition that occurs at the substrate binding site, the mechanism shown here for chymotrypsin would be applicable to any of the serine proteases.

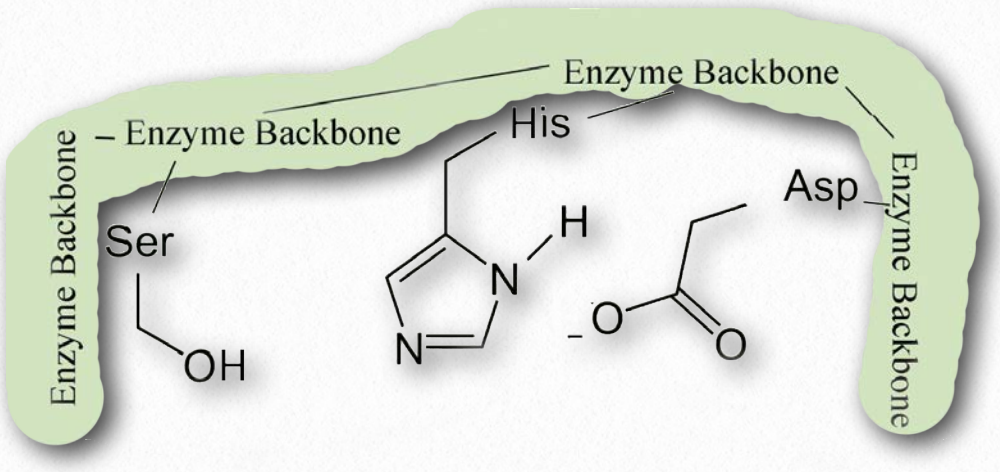

Figure 4.53 - 1. Active site of chymotrypsin showing the catalytic triad of serine - histidine-aspartic acid

Specificity

As a protease, chymotrypsin acts fairly specifically, cutting not all peptide bonds, but only those that are adjacent to relatively nonpolar amino acids in the protein. One of the amino acids it cuts adjacent to is phenylalanine. The enzyme's action occurs in two phases – a fast phase that occurs first and a slower phase that follows. The enzyme has a substrate binding site that includes a region of the enzyme known as the S1 pocket. Let us step through the mechanism by which chymotrypsin cuts adjacent to phenylalanine.

Substrate binding

The process starts with the binding of the substrate in the S1 pocket (Figure 4.54). The S1 pocket in chymotrypsin has a hydrophobic hole in which the substrate is bound. Preferred substrates will include amino acid side

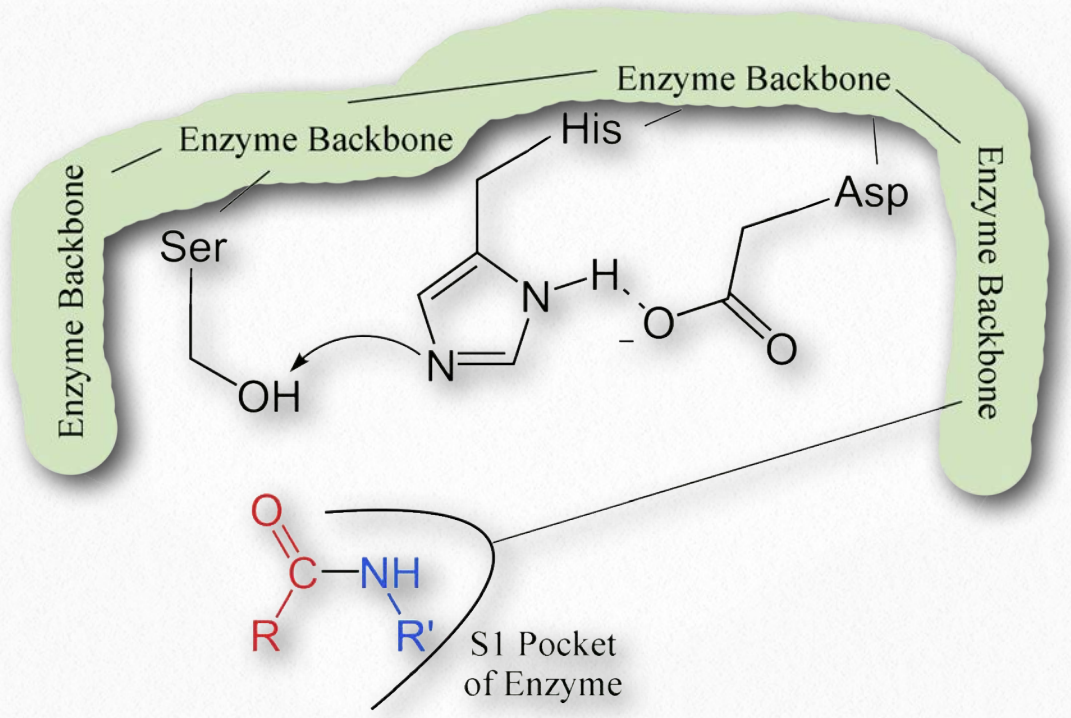

Figure 4.54 - 2. Binding of substrate to S1 pocket in the active site

chains that are bulky and hydrophobic, like phenylalanine. If an ionized side chain, like that of glutamic acid binds in the S1 pocket, it will quickly exit, much like water would avoid an oily interior.

Shape change on binding

When the proper substrate binds in the S1 pocket, its presence induces an ever so slight change in the shape of the enzyme. This subtle shape change on the binding of the proper substrate starts the steps of the catalysis. Since the catalytic process only starts when the proper substrate binds, this is the reason that the enzyme shows specificity for cutting at specific amino acids in the target protein. Only amino acids with the side chains that interact well with the S1 pocket start the catalytic wheels turning.

The slight changes in shape involve changes in the positioning of three amino acids (aspartic acid, histidine, and serine) in the active site known as the catalytic triad.

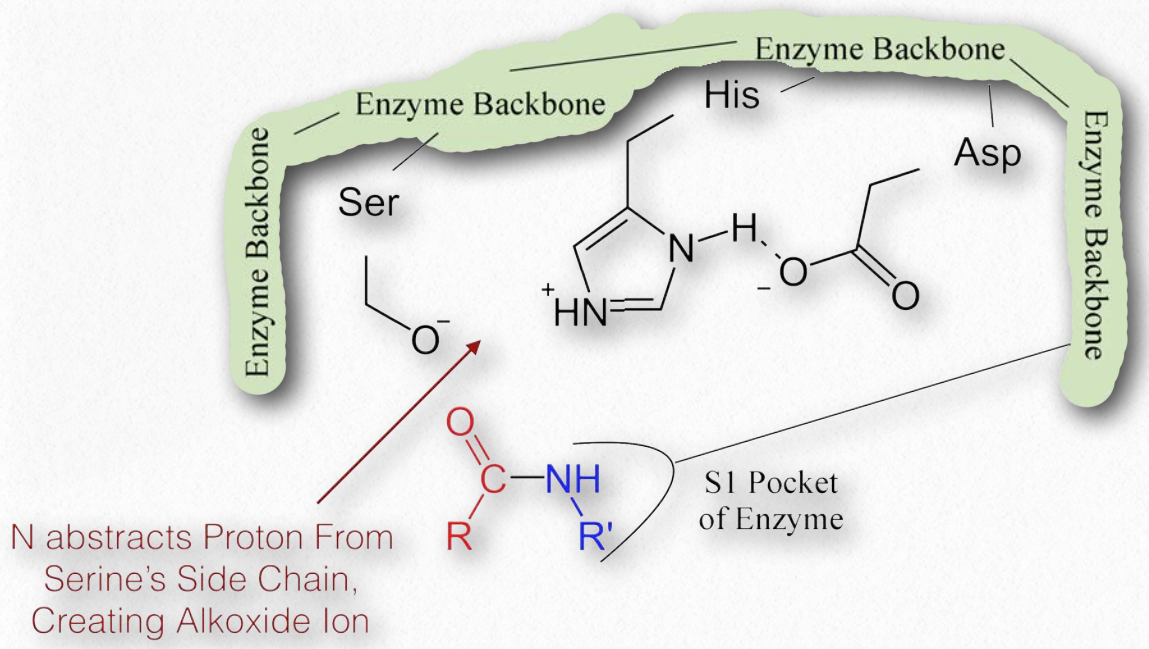

Figure 4.55 - 3. Formation of alkoxide ion

The shift of the negatively charged aspartic acid towards the electron rich histidine ring favors the abstraction of a proton by the histidine from the hydroxyl group on the side chain of serine, resulting in production of a very reactive alkoxide ion in the active site

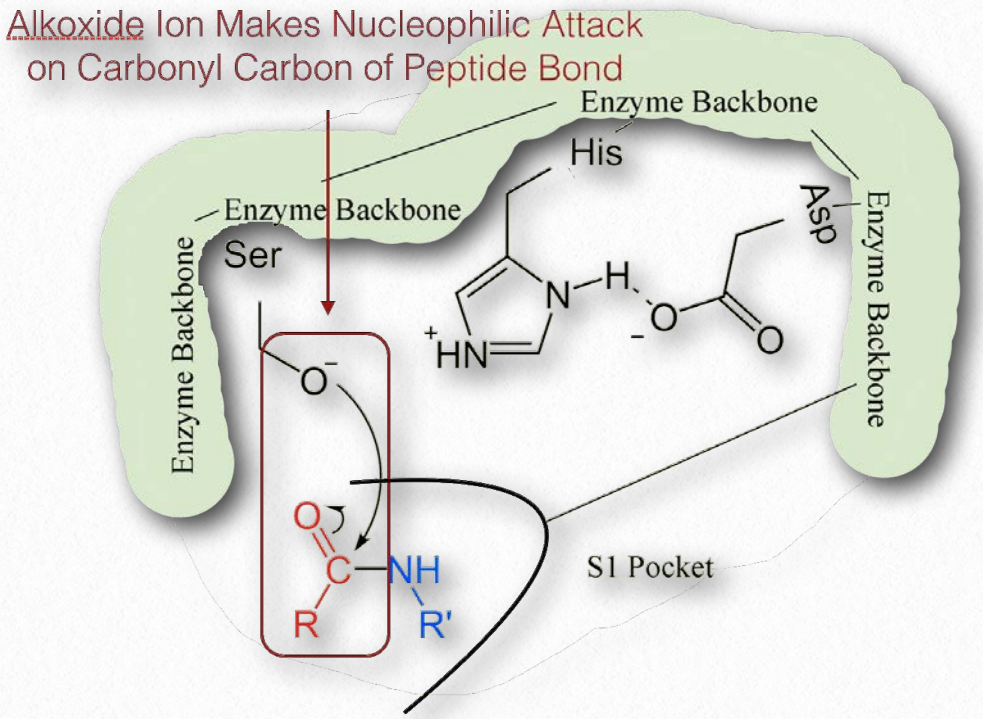

Figure 4.56 - 4. Nucleophilic attack

(Figure 4.55). Since the active site at this point also contains the polypeptide chain positioned with the phenylalanine side chain embedded in the S1 pocket, the alkoxide ion performs a nucleophilic attack on the peptide bond on the carboxyl side of phenylalanine sitting in the S1 pocket (Figure 4.56). This reaction breaks the peptide bond (Figure 4.57) and causes two things to happen.

First, one end of the original polypeptide is freed and exits the active site (Figure 4.58). The second is that the end containing the phenylalanine is covalently linked to the oxygen of the serine side chain. At this point we have completed the first (fast) phase of the catalysis.

Slower second phase

The second phase of the catalysis by chymotrypsin is slower. It requires that the covalent bond between phenylalanine and serine's oxygen be broken so the peptide can be released and the enzyme can return to its original state. The process starts with entry of water into the active site. Water is attacked in a fashion similar to that of the serine side chain in the first phase, creating a reactive hydroxyl group

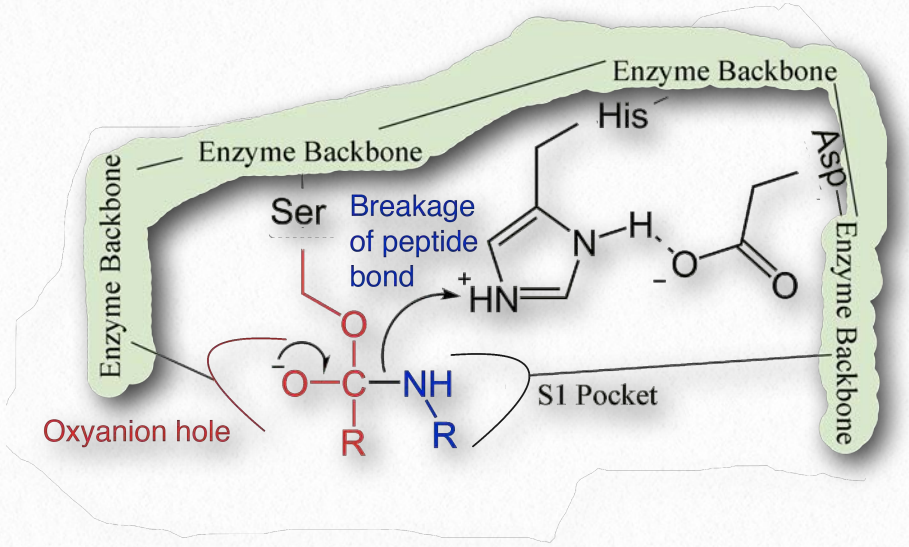

Figure 4.57 - 5. Stabilization by oxyanion hole. Breakage of peptide bond.

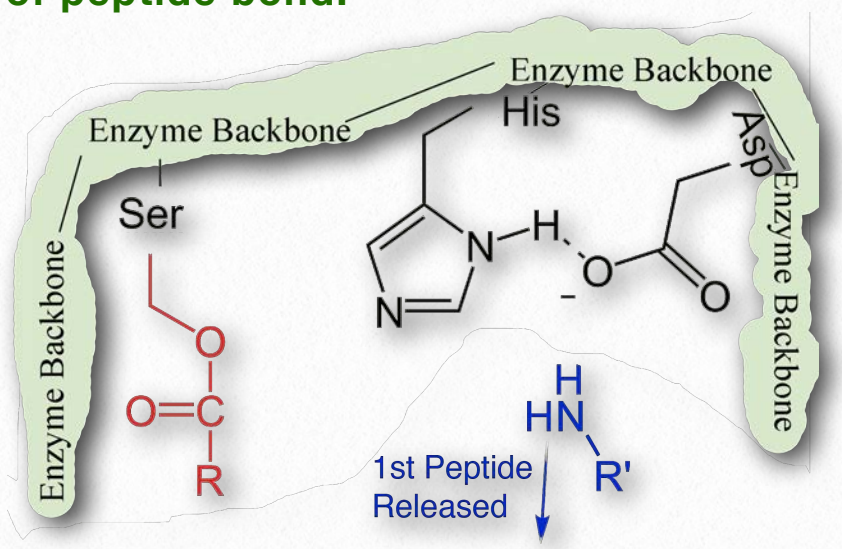

Figure 4.58 - 6. First peptide released. Other half bonded to serine.

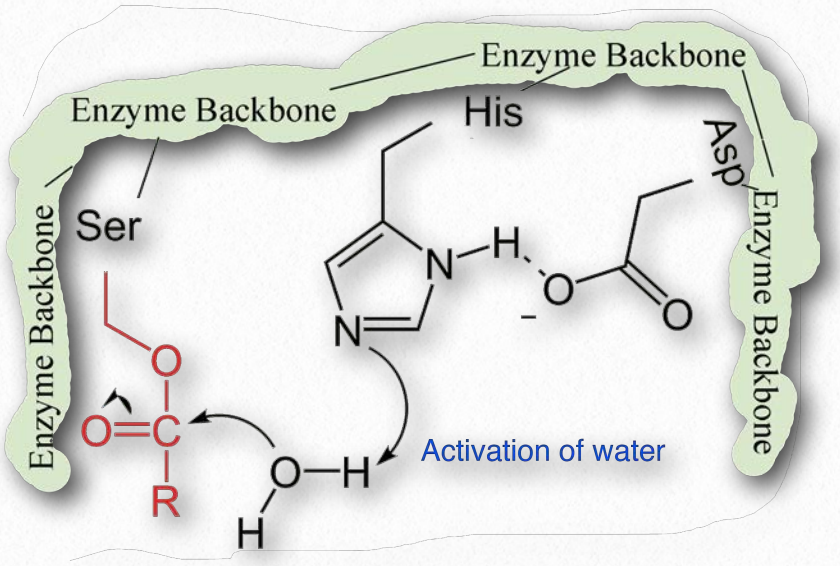

Figure 4.59 - 7. Activation of water by histidine

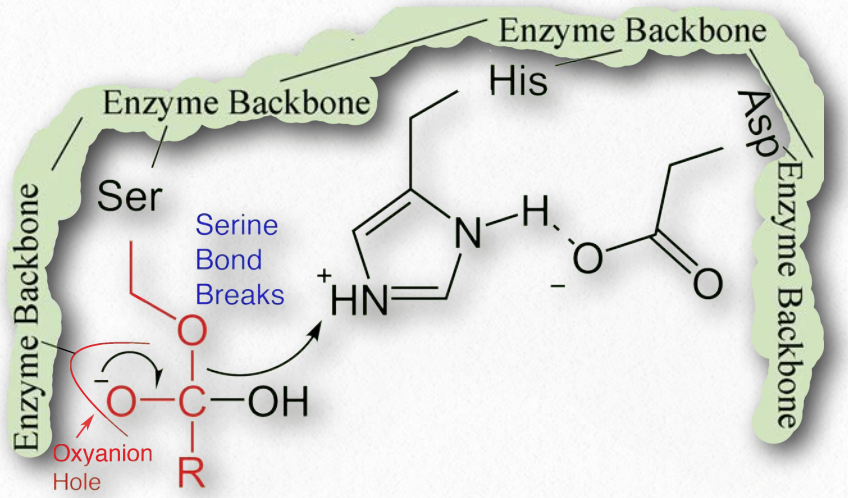

Figure 4.60 - 8. Nucleophile attack by hydroxyl creates tetrahydryl intermediate stabilized by oxyanion hole. Bond to serine breaks.

(Figure 4.59) that performs a nucleophilic attack on the phenylalanine-serine bond (Figure 4.60), releasing it and replacing the proton on serine. The second peptide is released in the process and the reaction is complete with the enzyme back in its original state (Figure 4.61).

Serine proteases

The list of serine proteases is quite long. They are grouped in two broad categories - 1) those that are chymotrypsin-like and 2) those that are subtilisin-like. Though subtilisin-type and chymotrypsin-like enzymes use the same mechanism of action, including the catalytic triad, the enzymes are otherwise not related to each other by sequence and appear to have evolved independently. They are, thus, an example of convergent evolution - a process where evolution of different forms converge on a structure to provide a common function.

The serine protease enzymes cut adjacent to specific amino acids and the specificity is determined by the size/shape/charge of amino acid side chain that fits into the enzyme's S1 binding pocket (Figure 4.52).

Examples of serine proteases include trypsin, chymotrypsin, elastase, subtilisin, signal peptidase I, and nucleoporin. Ser-

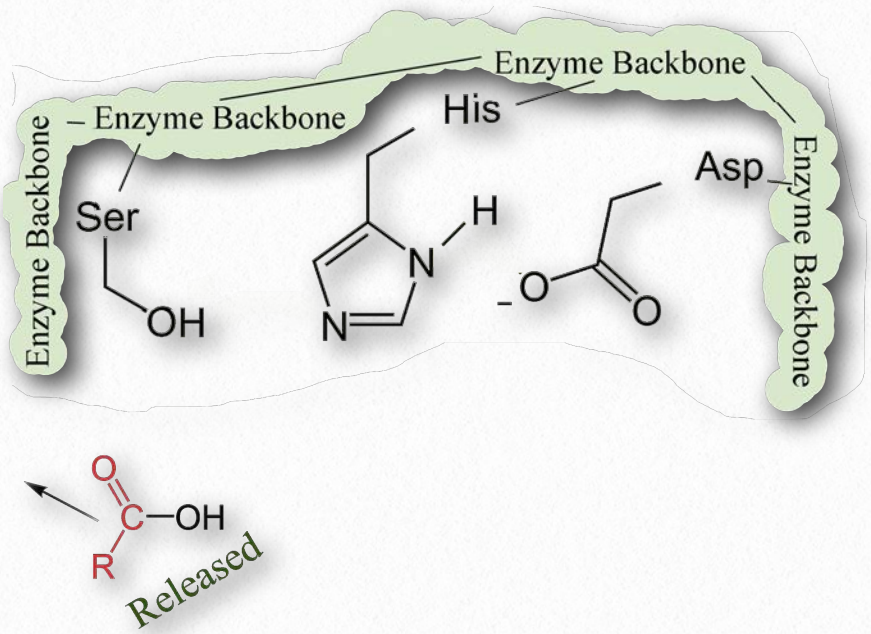

Figure 4.61 - 9. Second half of peptide released. Enzyme active site restored.

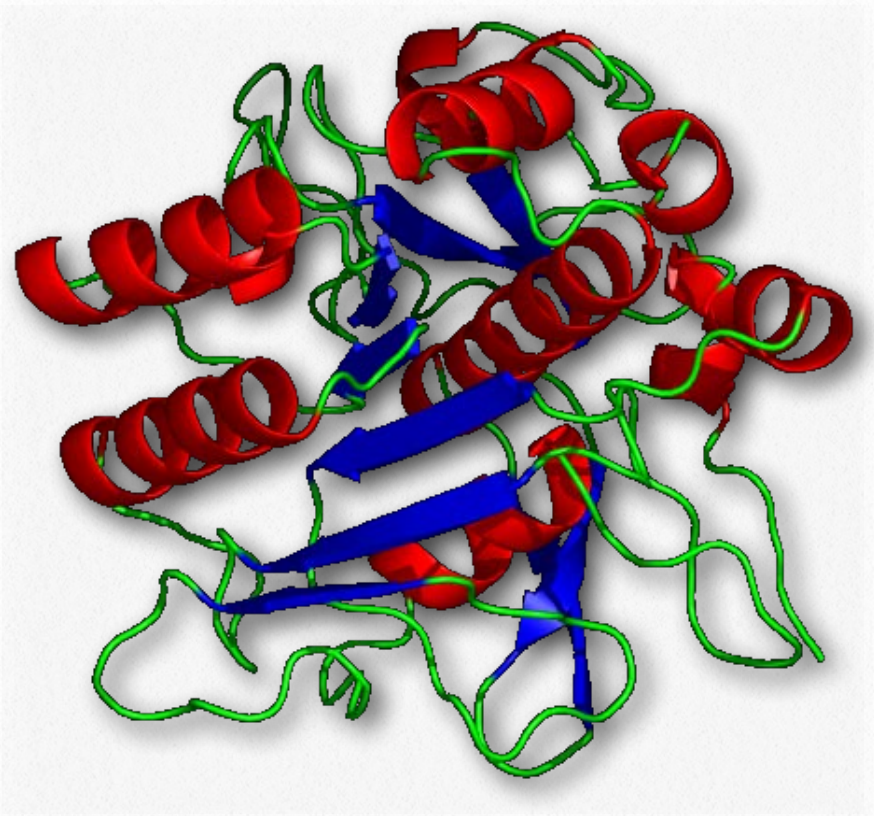

Figure 4.62 - Subtilisin - A serine protease

ine proteases participate in many physiological processes, including blood coagulation, digestion, reproduction, and the immune response.

Cysteine proteases

Cysteine proteases (also known as thiol proteases) catalyze the breakdown of proteins by cleaving peptide bonds using a nucleophilic thiol from a cysteine (Figure 4.63). The cysteine is typically found in a catalytic dyad or triad also involving histidine and (sometimes) aspartic acid (very much like serine proteases). The sulfhydryl group of cysteine proteases is more acidic than the hydroxyl of serine proteases, so the aspartic acid of the triad is not always needed.

The mechanism of action is very similar to that of serine proteases. Binding of proper substrate results in activation of the thiol (removal of the proton by the histidine group). The activated thiol acts as a nucleophile, attacking the peptide bond and causing it break. One peptide is released and the other peptide becomes covalently linked to the sulfur. Hydrolysis by water releases the second peptide and completes the cycle. Examples of cysteine proteases include papain, caspases, hedgehog protein, calpain, and cathepsin K.

YouTube Lectures by Kevin HERE & HERE

Caspases

Caspases (Cysteine-ASPartic ProteASEs) are a family of cysteine proteases that play important roles in the body. At the cellular level they function in apoptosis and necrosis and in the body, they are involved in inflammation and the immune system. Maturation of lymphocytes is one such role. They are best known, however, for their role in apoptosis, which has given rise to descriptions of them as “executioner” proteins or “suicide proteases” that dismantle cells in programmed cell death.

There are 12 known human caspases. The enzymes are synthesized as pro-caspase zymogens with a prodomain and two other

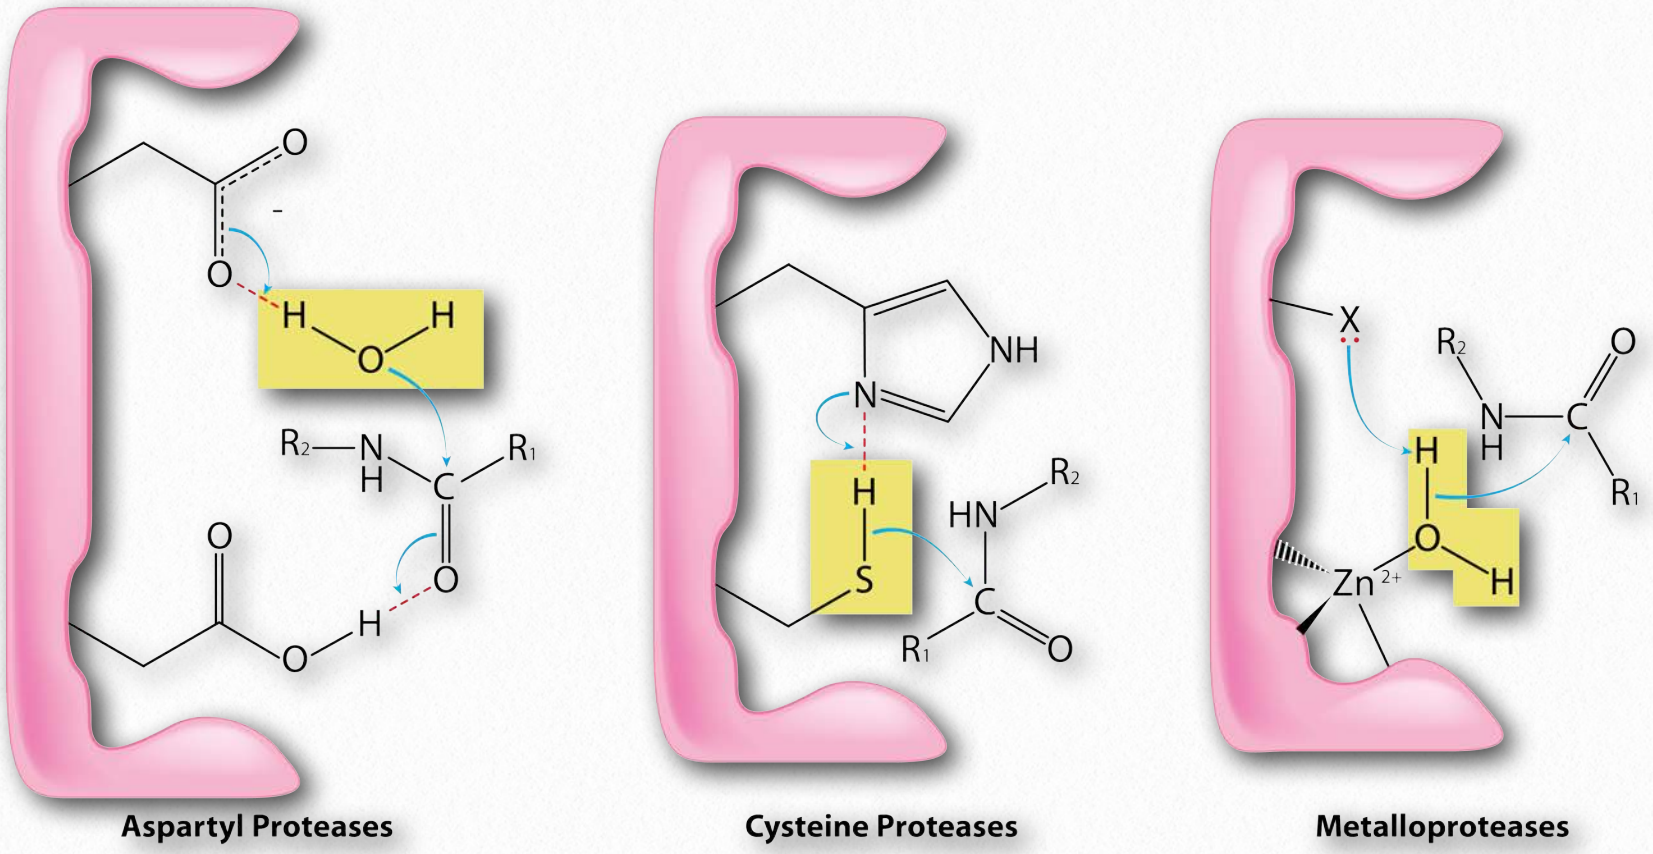

Figure 4.63 - Mechanism of action of proteases. In each case, a nucleophile is created - hydroxyl (aspartyl proteases), thiol (cysteine proteases), and hydroxyl (metalloproteases)

Image by Aleia Kim

subunits. The prodomain contains regions that allow it to interact with other molecules that regulate the enzyme's activity. The caspases come in two forms. The initiator caspases, when activated, activate the effector caspases. The effector caspases cleave other proteins in the cell. Targets for effector caspase cleavage action include the nuclear lamins (fibrous proteins providing structural integrity to the nucleus), ICAD/DFF45 (an inhibitor of DNAse), PARP (flags areas where DNA repair needed), and PAK_2 (apoptotic regulation).

The caspase activation cascade can itself be activated by granzyme B (a serine protease secreted by natural killer cells and cytotoxic T-cells), cellular death receptors, and the apoptosome (large protein structure in apoptotic cells stimulated by release of cytochrome C from the mitochondria). Each of these activators is responsible for activating different groups of caspases.

Metalloproteases

Metalloproteases (Figure 4.63) are enzymes whose catalytic mechanism for breaking peptide bonds involves a metal. Most metalloproteases use zinc as their metal, but a few use cobalt, coordinated to the protein by three amino acid residues with a labile water at the fourth position. A variety of side chains are

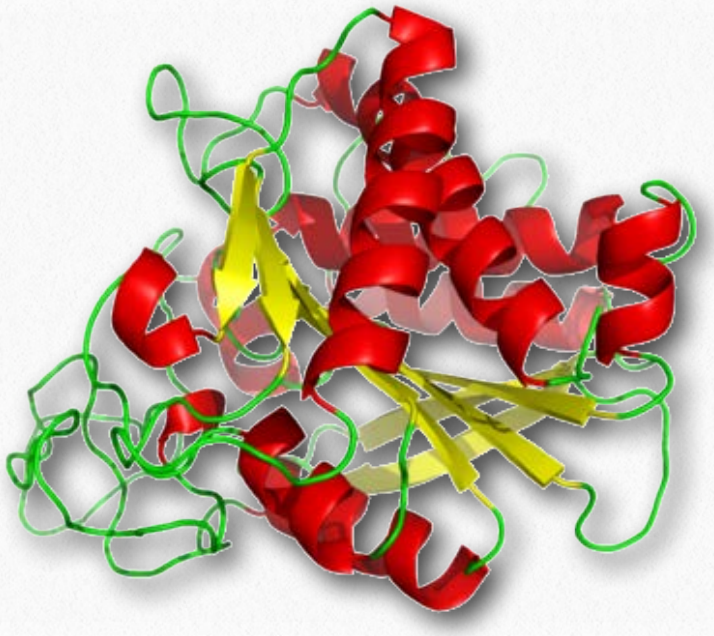

Figure 4.64 - Carboxypeptidase - A metalloprotease

used - histidine, aspartate, glutamate, arginine, and lysine. The water is the target of action of the metal which, upon binding of the proper substrate, abstracts a proton to create a nucleophilic hydroxyl group that attacks the peptide bond, cleaving it (Figure 4.63). Since the nucleophile here is not attached covalently to the enzyme, neither of the cleaved peptides ends up attached to the enzyme during the catalytic process. Examples of metalloproteases include carboxypeptidases, aminopeptidases, insulinases and thermolysin.

Aspartyl proteases

As the name suggests, aspartyl proteases use aspartic acid in their catalytic mechanism (Figures 4.63 & 4.65). Like the metalloproteases, aspartyl proteases activate a water to create a nucleophile for catalysis (Figure 4.65). The activated water attacks the pep-

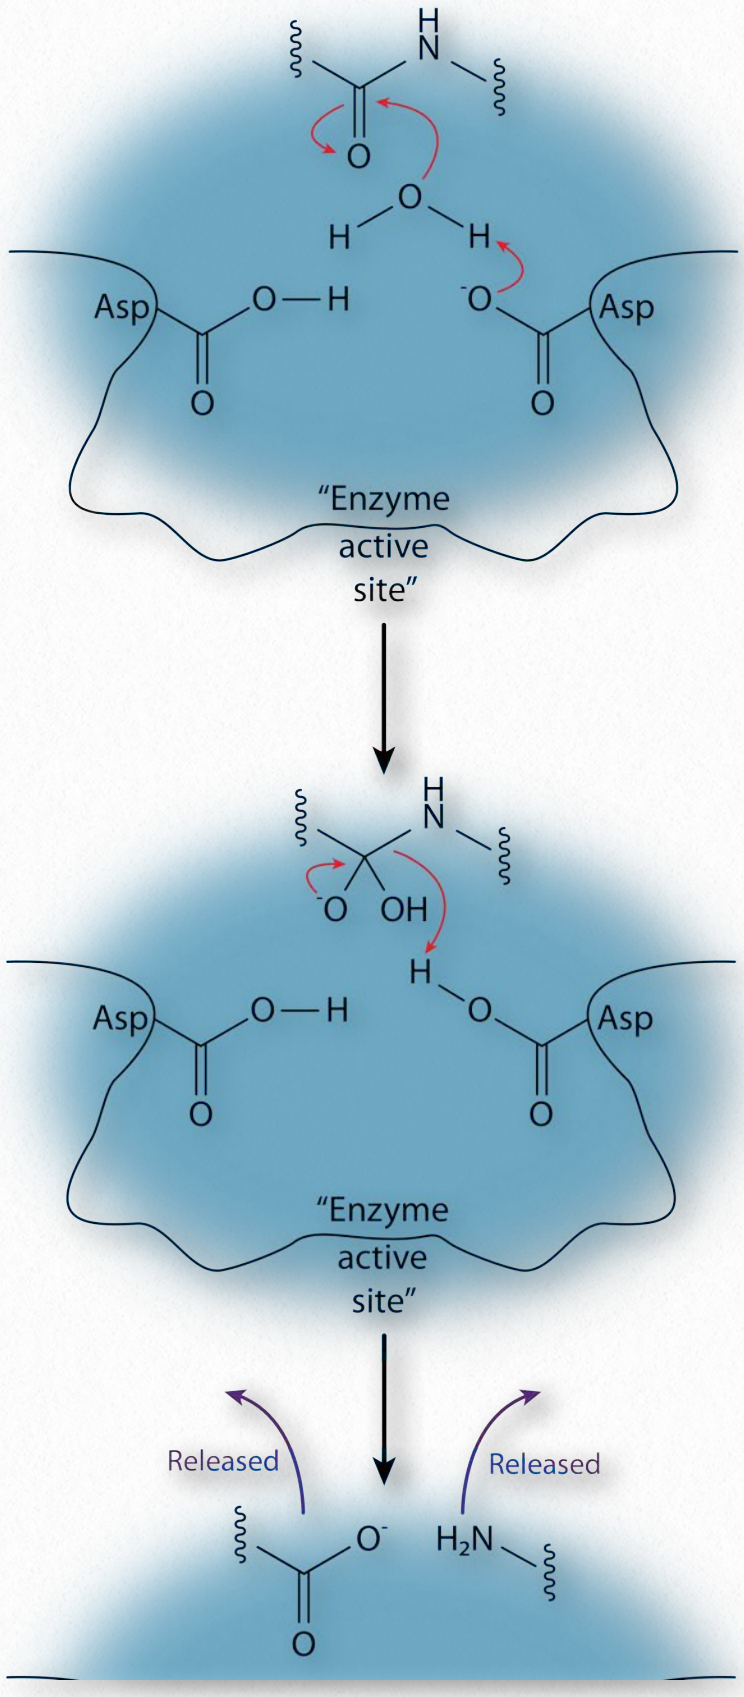

Figure 4.65 - Activation of an aspartyl protease - aspartate side chain abstracts proton (top). Hydroxyl attacks peptide bond (middle). Broken peptide pieces released (bottom)

Image by Pehr Jacobson

tide bond of the bound substrate and releases the two pieces without the need to release a bound intermediate, since water is not covalently attached to the enzyme. Common aspartyl proteases include pepsin, signal peptidase II, and HIV-1 protease.

Threonine proteases

Though threonine has an R-group with a hydroxyl like serine, the mechanism of action of this class of proteases differs somewhat from the serine proteases. There are some similarities. First, the threonine's hydroxyl plays a role in catalysis and that is to act as a nucleophile. The nucleophile is created, however, not by a catalytic triad, but rather as a result of threonine's own α-amine group abstracting a proton.

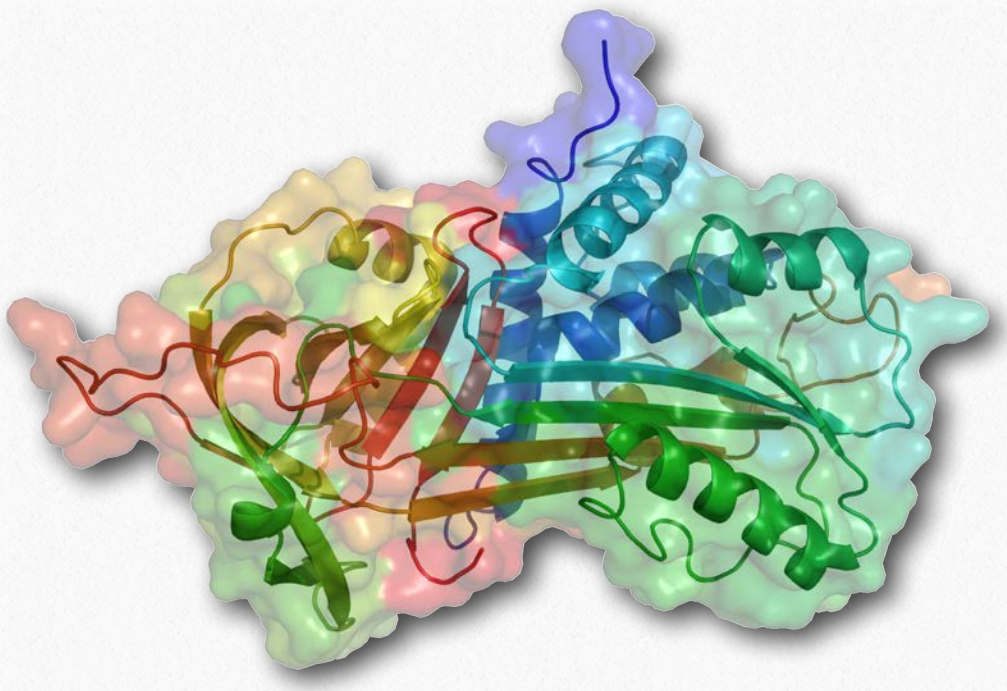

Figure 4.66 - α-1-antitrypsin

Because of this, the nucleophilic threonine in a threonine protease must be at the n-terminus of the enzyme. Nucleophilic attack of the peptide bond in the target protease results in breakage of the bond to release one peptide and the other is covalently attached to serine, like the serine proteases. Also, as with the serine proteases, water must come in to release the covalently linked second peptide to conclude the catalytic mechanism.

Examples

Examples of threonine proteases include the catalytic subunits of the proteasome. Some acyl transferases (such as ornithine acyltransferase) have evolved the same catalytic mechanism by convergent evolution. The latter enzymes use ornithine instead of water to break the enzyme-substrate covalent bond, with the result that the acyl-group becomes attached to ornithine, instead of water.

Protease inhibitors

Molecules which inhibit the catalytic action of proteases are known as protease inhibitors. These come in a variety of forms and have biological and medicinal uses. Many biological inhibitors are proteins themselves. Protease inhibitors can act in several ways, including as a suicide inhibitor, a transition state inhibitor, a denaturant, and as a chelating agent. Some work only on specific classes of enzymes. For example,

most known aspartyl proteases are inhibited by pepstatin. Metalloproteases are sensitive to anything that removes the metal they require for catalysis. Zinc-containing metalloproteases, for example, are very sensitive to EDTA, which chelates the zinc ion.

One category of proteinaceous protease inhibitors is known as the serpins. Serpins inhibit serine proteases that act like chymotrypsin. 36 of them are known in humans.

YouTube Lectures by Kevin HERE & HERE

Serpins are unusual in acting by binding to a target protease irreversibly and undergoing a conformational change to alter the active site of its target. Other protease inhibitors act as competitive inhibitors that block the active site.

Serpins can be broad in their specificity. Some, for example, can block the activity of cysteine proteases. One of the best known biological serpins is α-1-anti-trypsin (A1AT - Figure 4.66) because of its role in lungs, where it functions to inhibit the elastase protease. Deficiency of A1AT leads to emphysema. This can arise as a result of genetic deficiency or by cigarette smoking. Reactive oxygen species produced by cigarette smoking can oxidize a critical methionine residue (#358 of the processed form) in A1AT, rendering it unable to inhibit elastase. Uninhibited, elastase can attack lung tissue and cause emphysema. Most serpins work extracellularly. In blood, for example, serpins like antithrombin can help to regulate the clotting process.

Anti-viral Agents

Protease inhibitors are used as anti-viral agents to prohibit maturation of viral proteins - commonly viral coat proteins.

They are part of drug "cocktails" used to inhibit the spread of HIV in the body and are also used to treat other viral infections, including hepatitis C. They have also been investigated for use in treatment of malaria and may have some application in anti-cancer therapies as well.

I Lost a Lung

To the tune of "*I Left My Heart in San Francisco*"

Metabolic Melodies Website HERE

You've gone and left me breathless, so especially today
An absence from my body makes it hard to say
I'm so horribly upset and reminded evermore
I'll not forget - how you took my breath away

I lost a lung from smoking Camels
Emphysema kills, it seems to me
You see those nicotines and tars
Leave alveolar scars
My raspy throat will often choke, from the smoke

I've no respect for RJ Reynolds
And its cor---por-a-toc-rac-y
Now when I hear the name, RJ Reynolds
I only think malignancy

Recording by David Simmons

The New Serine Protease Song

To the tune of "*Rudolph the Red-Nosed Reindeer*"

Metabolic Melodies Website HERE

All serine proteases
Work almost identically
Using amino acid
Triads catalytically

First they bind peptide substrates
Holding onto them so tight
Changing their structure when they
Get them in the S1 site

Then there are electron shifts
At the active site
Serine gives up its proton
As the RE-ac-tion goes on

Next the alkoxide ion
Being so electron rich
Grabs peptide's carbonyl group
Breaks its bond without a hitch

So one piece is bound to it
The other gets set free
Water has to act next to
Let the final fragment loose

Then it's back where it started
Waiting for a peptide chain
That it can bind itself to

Go and o'er

start all again

Catalysis: Blood Clotting

Blood clotting

Clotting is a process in which liquid blood is converted into a gelatinous substance that eventually hardens. The aim is to stop the flow of blood from a vessel. The formation of a clot is the result of a series of enzymatic reactions that are triggered upon injury. The process involves 1) a step of activation (wounding) followed by 2) a cellular response (aggregation of blood platelets) and 3) a molecular response (polymerization of the protein called fibrin to create a meshwork that hardens). Factors released in the cellular response help activate the molecular response. The process is highly conserved across species.

YouTube Lectures by Kevin
HERE & HERE

Cellular response

Injury to the epithelial lining of a blood vessel begins the process of coagulation almost instantly. The cellular response has an initial action followed by an amplification step. In the cellular response (Figure 4.68), the platelets bind directly to collagen using Ia/IIa collagen-

binding surface receptors and glycoprotein VI to form a plug. The signal to the platelets to take this action is exposure of the underlying collagen, something that would not happen in the absence of a wound. Upon injury, platelet integrins get activated and bind tightly to the extracellular matrix to anchor them to the site of the wound.

The von Willebrand factor (see below also) assists by forming additional links between the platelets' glycoprotein Ib/IX/V and the fibrils of the collagen.

Amplification

In the amplification part of the cellular response, the activated platelets release a large number of factors, including platelet factor 4 (a cytokine stimulating inflammation and moderating action of the heparin anticoagulant) and thromboxane A2, The latter has the effect of increasing the "stickiness" of platelets, favoring their aggregation. In addition, a a Gq-protein linked receptor cascade is activated, resulting in release of calcium from intracellular stores. This will play a role in the molecular response.

Molecular response

The molecular response results in the creation of a web comprised of polymers of fibrin protein. Like the cellular pathway, the molecular pathway begins with an initiation phase and continues with an amplification phase. Polymerization of fibrin results from convergence of two cascading catalytic pathways. They are the intrinsic pathway (also called the contact activation pathway) and the extrinsic pathway (also referred to as the tissue factor pathway). Of the two pathways, the tissue factor pathway has recently been shown to be the more important.

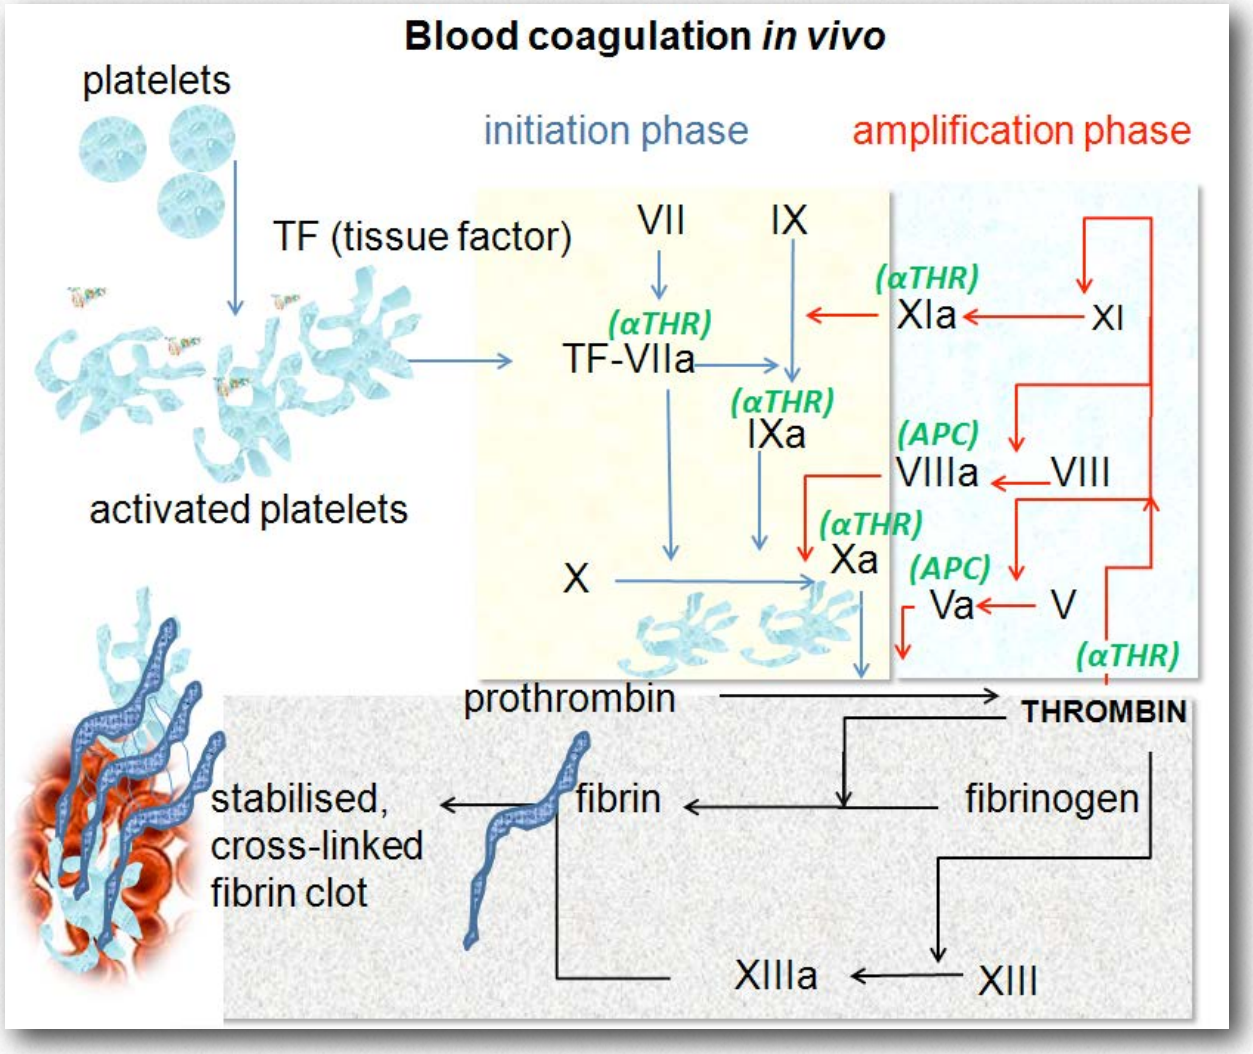

Figure 4.68 - Blood coagulation scheme. The cellular response is shown in white on upper left. Everything else is part of the molecular response

Wikipedia

Serine protease cascade

In both pathways, a series of zymogens of serine proteases are sequentially activated in rapid succession. The advantage of such a cascading system is tremendous amplification of a small signal. At each step of the cascade, activation of a zymogen causes the production of a considerable amount of an active serine protease, which is then able to activate the next zymogen which, in turn, activates an even larger amount of the next zymogen in the system. This results in the ultimate activation of a tremendous amount more fibrin than could be achieved if there were only a single step where an enzyme activated fibrinogen to fibrin.

Nomenclature

A note about nomenclature - the zymogen factors in the molecular response are generally labeled with Roman numerals. A lowercase, subscripted 'a' is used to designate an activated form.

The tissue factor pathway functions to create a thrombin burst, a process in which thrombin is activated very quickly. This is the initiation phase. It is fairly straightforward because it has one focus - activation of throm-

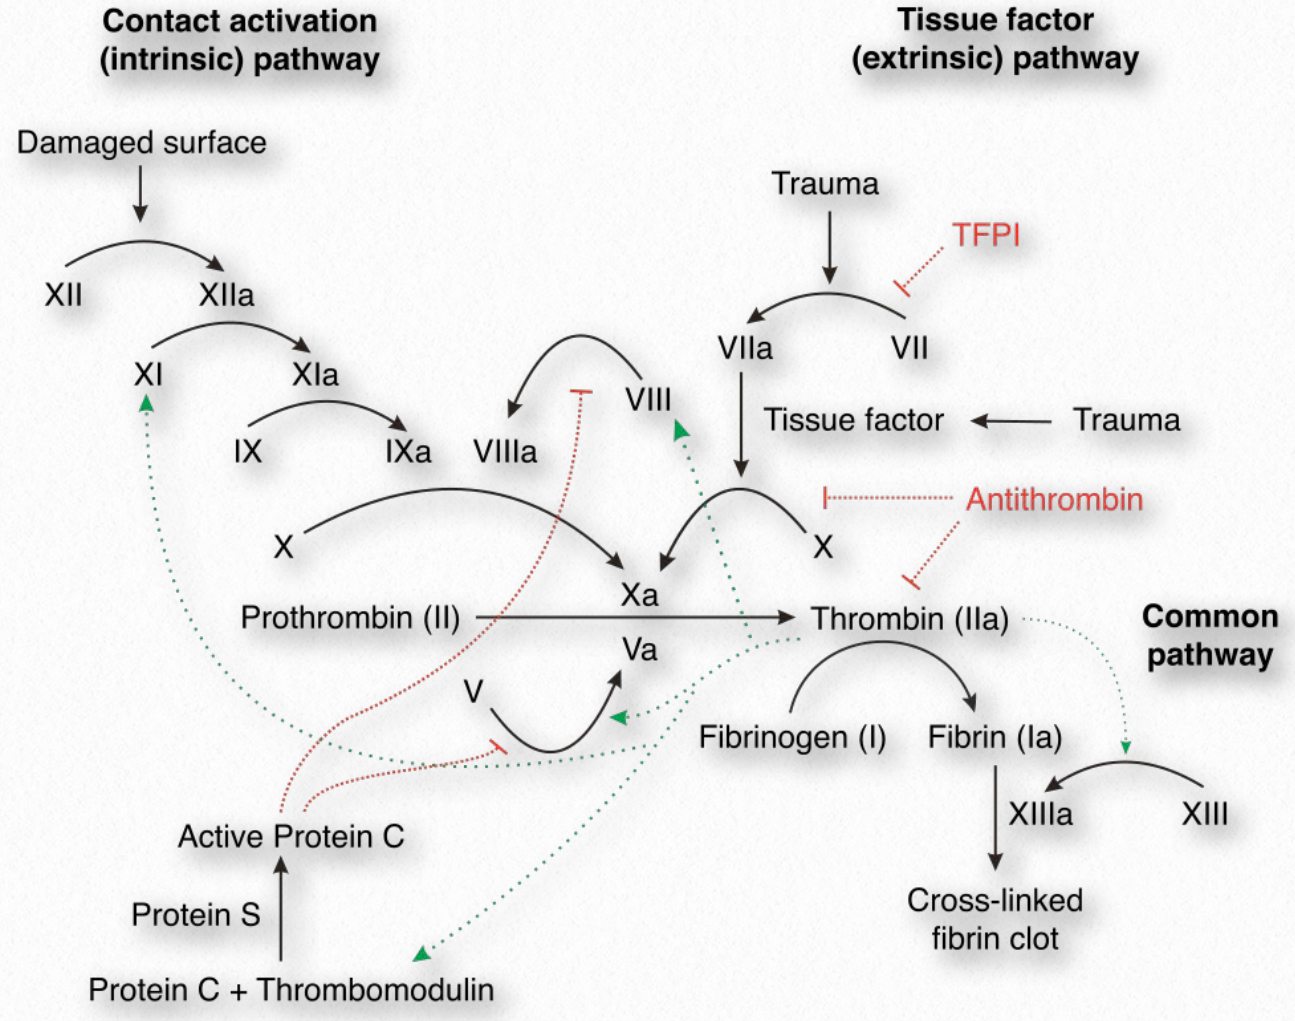

Figure 4.69 - Intrinsic and extrinsic pathways of blood coagulation. The aim is making a fibrin clot (lower right)

Wikipedia

bin. Thrombin, which converts fibrinogen into the fibrin of the clot, is central also to the amplification phase, because it activates some of the factors that activate it, creating an enormous increase in signal and making a lot of thrombin active at once.

Initiation phase

The initiation phase of the molecular response begins when Factor VII (the letter 'F' before the Roman numeral is often used as an abbreviation for 'factor') gets activated to FVIIa after damage to the blood vessel (Figure 4.69 & 4.70). This happens as a result of its interaction with Tissue Factor (TF, also called coagulation Factor III) to make a TF-FVIIa complex. The combined efforts of TF-FVIIa, FIXa, and calcium (from the cellular response) inefficiently convert FX to FXa. FXa, FV, and calcium inefficiently convert prothrombin (zymogen) to thrombin (active). A tiny amount of thrombin has been activated at the end of the initiation phase.

YouTube Lectures by Kevin HERE & HERE

Amplification phase

To make sufficient thrombin to convert enough fibrinogen to fibrin to make a clot, thrombin activates other factors (FV, FXI, FVIII) that help to make more thrombin. This is the amplification phase of the molecular process and is shown in the light blue portion in the upper right part of Figure 4.68. The amplification phase includes factors in both the intrinsic and extrinsic path-

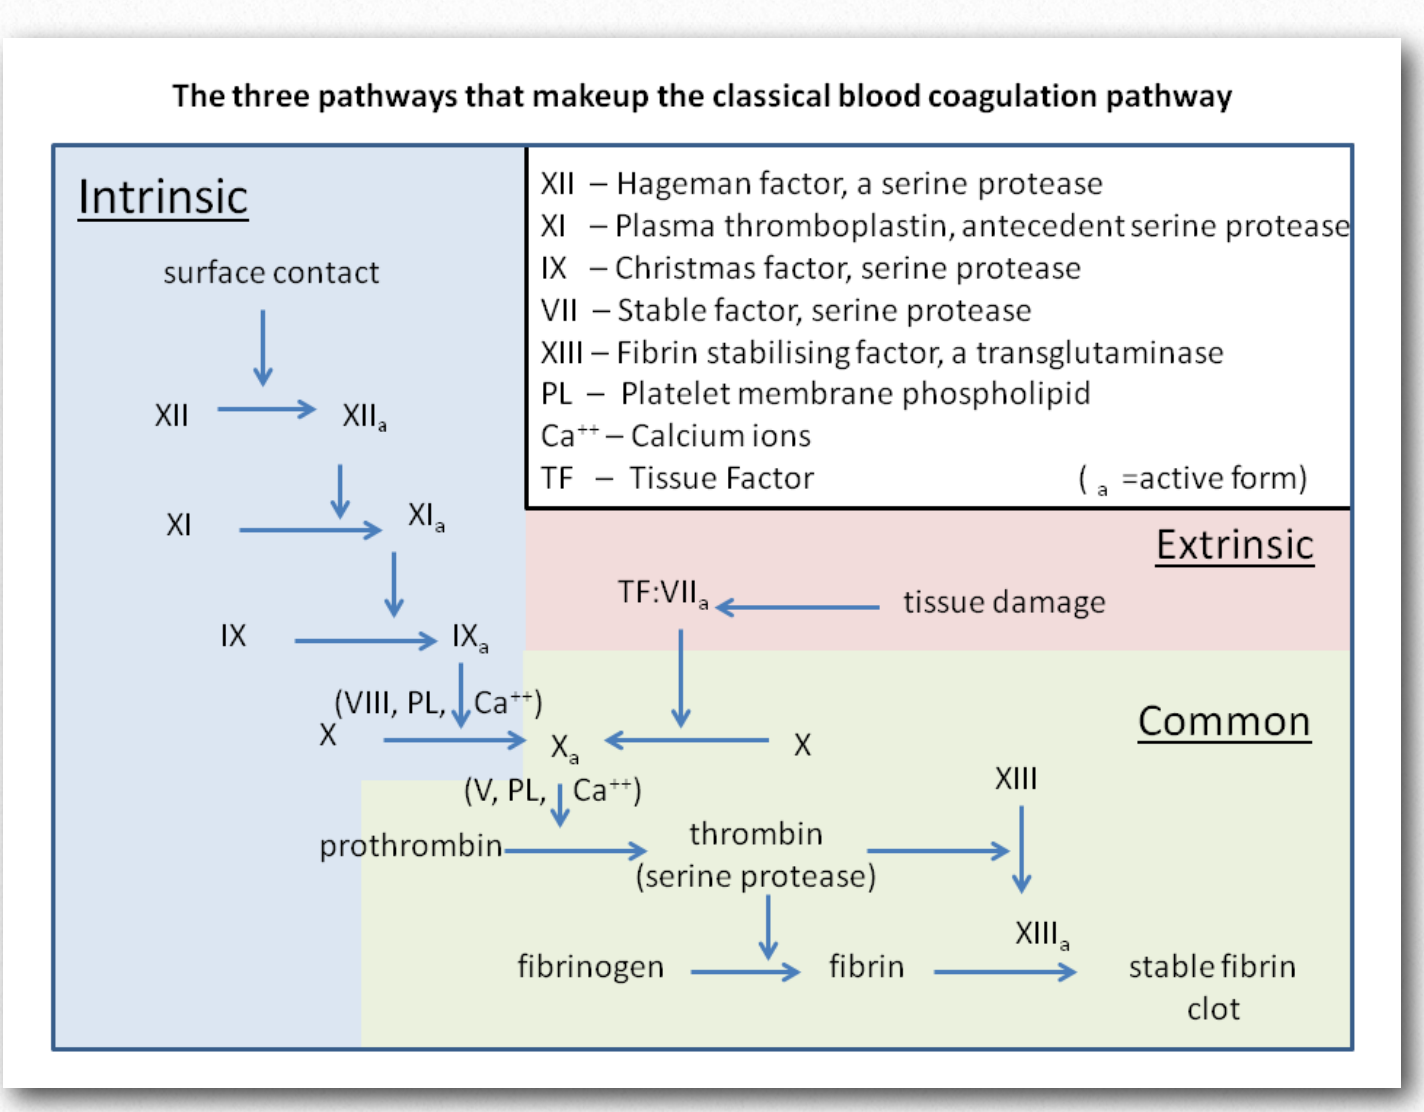

Figure 4.70 - Another view of the molecular response of the blood clotting pathway

Wikipedia

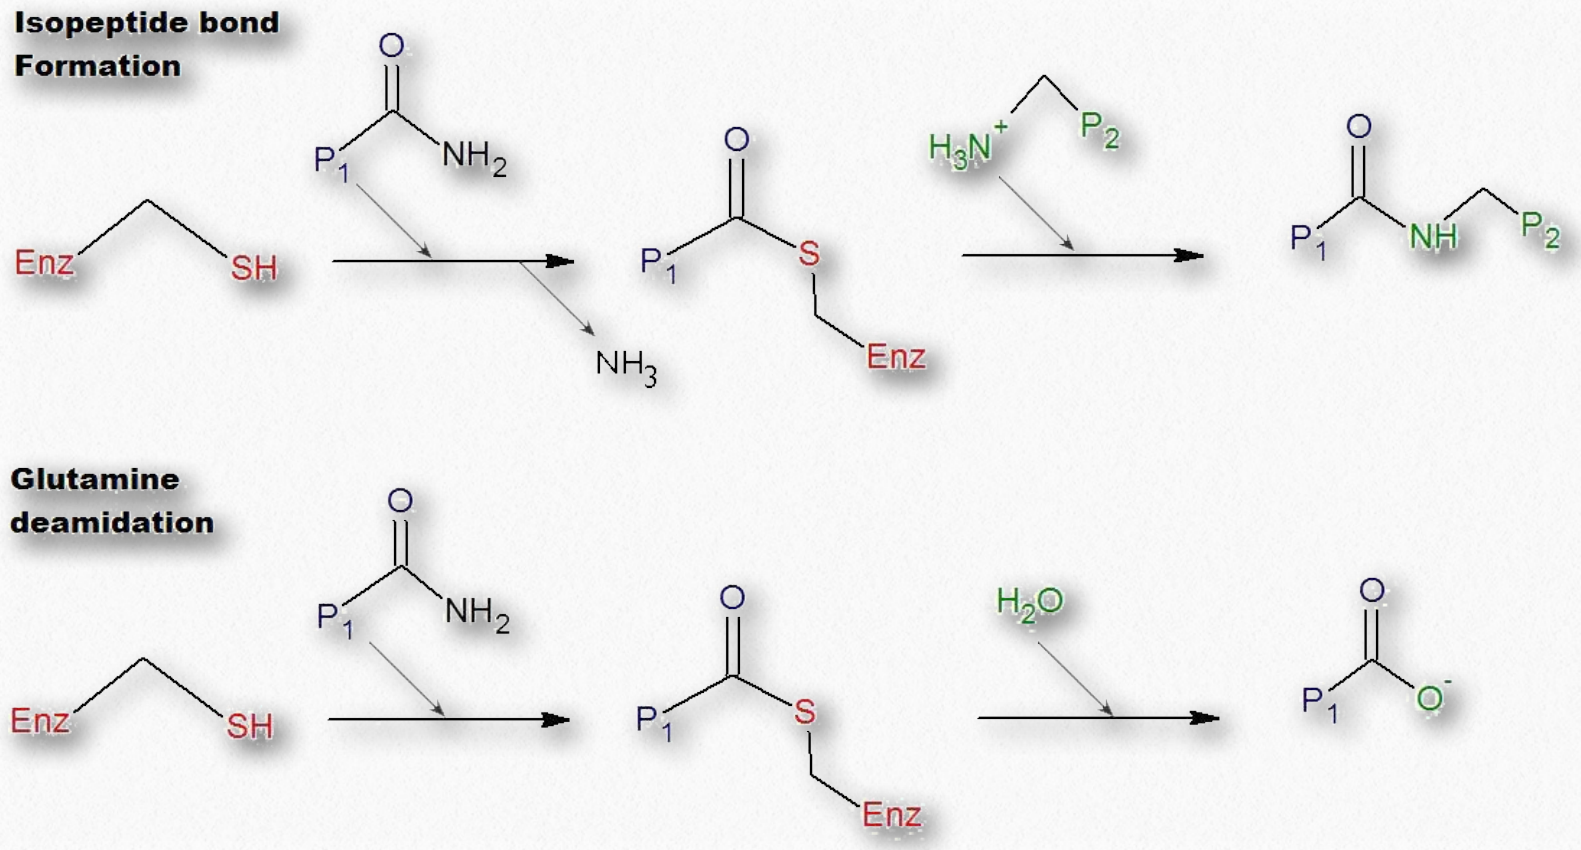

Figure 4.71 - Catalytic action of transglutaminase (top) and breaking of transglutamide bonds by hydrolysis (bottom)

ways. FVIII is normally bound in a complex with the von Willebrand factor and is inactive until it is released by action of thrombin. Activation of FXI to FXIa helps favor production of more FIXa. FIXa plus FVIIIa stimulate production of a considerable amount of FXa. FVa joins FXa and calcium to make a much larger amount of thrombin. Factors FVa and FVIIIa are critical to the amplification process. FVIIIa stimulates FIXa's production of FXa by 3-4 orders of magnitude. FVa helps to stimulate FXa's production of thrombin by about the same magnitude. Thus, thrombin stimulates activation of factors that, in turn, stimulate activation of more thrombin.

Transglutaminase

In addition to helping to amplify product of itself and conversion of fibrinogen to fibrin, thrombin catalyzes the activation of FXIII to FXIIIa. FXIIIa is a transglutami-

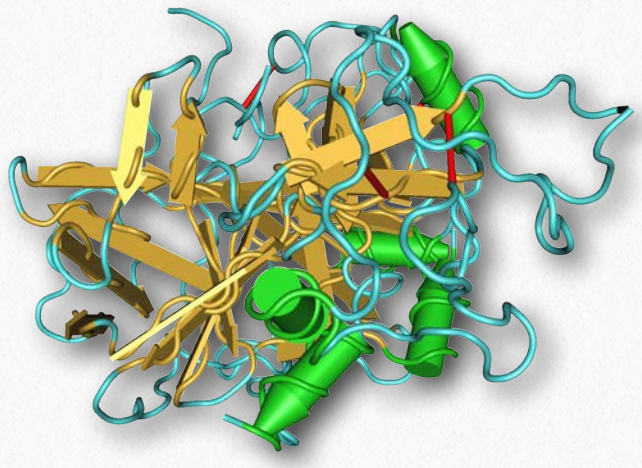

Figure 4.72 - α-thrombin

Wikipedia

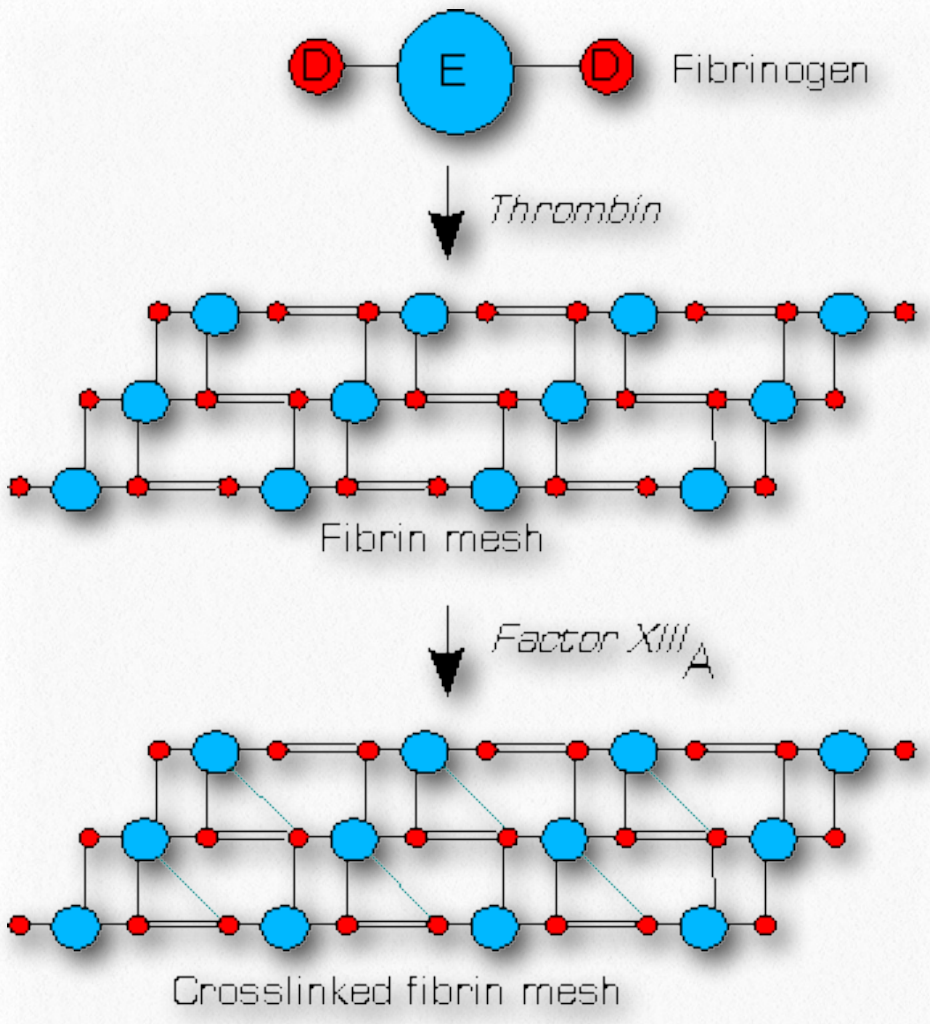

Figure 4.73 - Product of transglutaminase action - cross links

Wikipedia

nase that helps to “harden” the clot (Figure 4.71 & 4.73). It accomplishes this by catalyzing formation of a covalent bond between adjacent glutamine and lysine side chains in the fibrin polymers.

Not all of the factors involved in the clotting process are activated by the pathway, nor are all factors serine proteases. This includes FVIII and FV which are glycoproteins, and FXIII, which is the transglutaminase described above.

The blood clotting process must be tightly regulated. Formation of clots in places where no damage has occurred can lead to internal clots (thrombosis) cutting off the flow of blood to critical regions of the body, such as heart or brain. Conversely, lack of clotting can lead to internal bleeding or, in severe cases, death due to unregulated external bleeding. Such is a danger for people suffering from hemophilia.

Hemophilia

Hemophilia is a hereditary genetic disorder affecting the blood clotting process in afflicted individuals. The disease is X-linked and thus occurs much more commonly in males. Deficiency of FVIII leads to Hemophilia A (about 1 in 5000 to 10,000 male births) and deficiency of FIX produces Hemophilia B (about 1 in 20,000 to 35,000 male births).

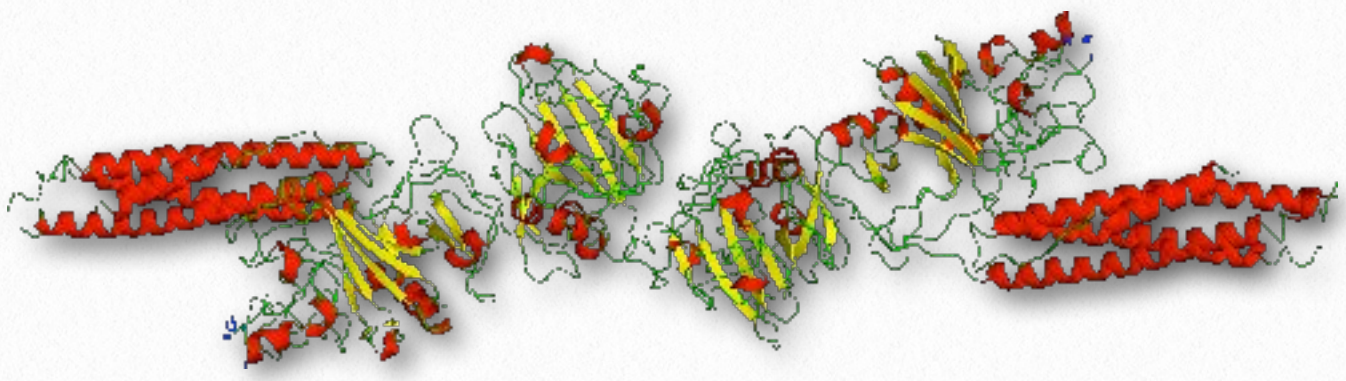

Figure 4.74 - Fibrin dimer - basic unit of a fibrin clot

Wikipedia

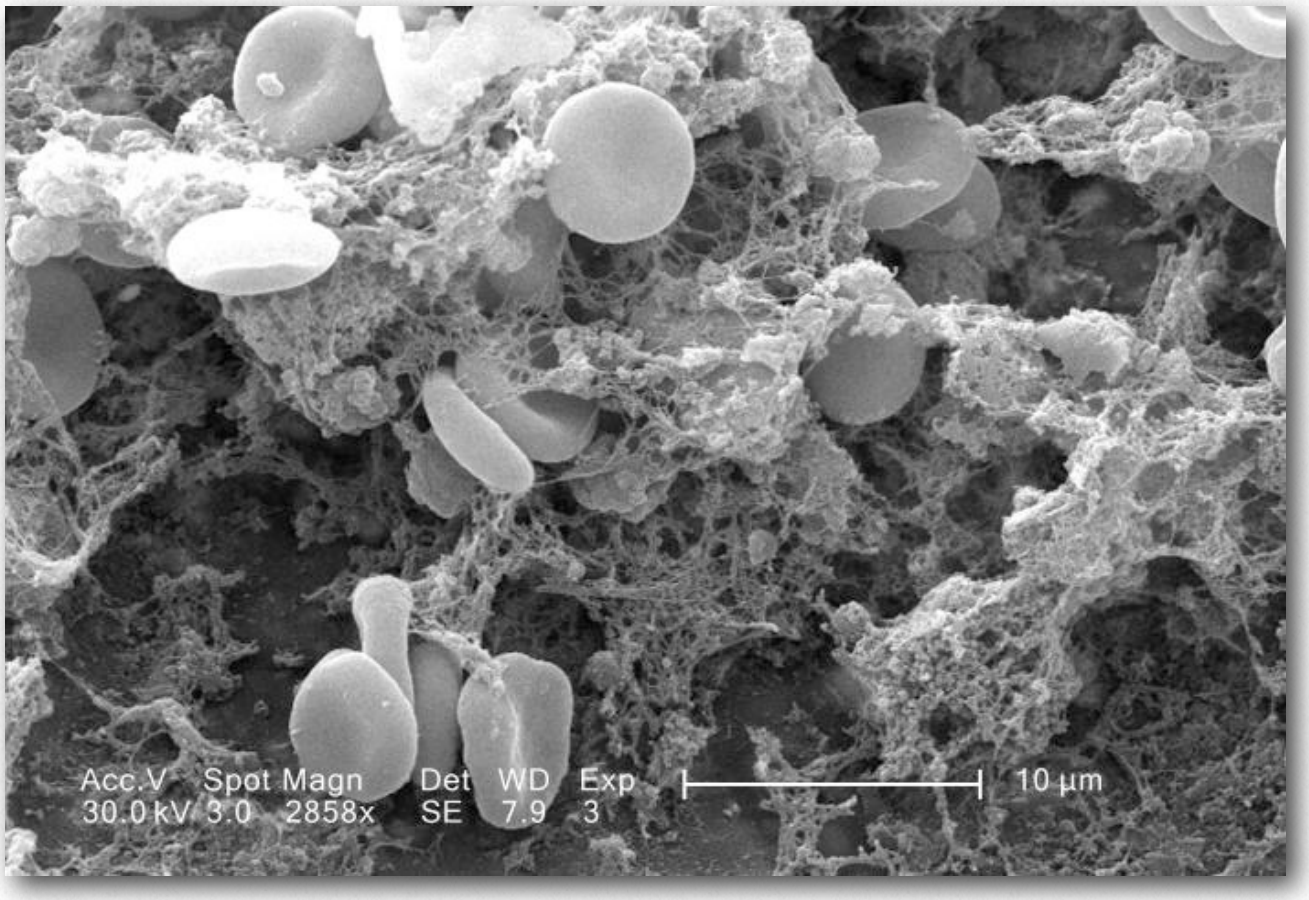

Figure 4.75 - Blood cells enmeshed in a fibrin clot

Hemophilia B spread through the royal families of Europe, beginning with Queen Victoria's son, Leopold. Three of the queen's grandsons and six of her great-grandsons suffered from the disease. Hemophilia is treated by exogenous provision of missing clotting factors and has improved life expectancy dramatically. In 1960, the life expectancy of a hemophiliac was about 11 years. Today, it is over 60.

Figure 4.76 - Queen Victoria, whose descendants suffered from hemophilia B

von Willebrand's disease

A related disease to hemophilia that is also genetically linked is von Willebrand's Disease. The von Willebrand factor plays a role in both the cellular and the molecular responses in blood clotting. First, the factor is a large multimeric glycoprotein present in blood plasma and also is produced in the endothelium lining blood vessels.

The von Willebrand factor helps to anchor platelets near the site of the wound in the cellular response. It binds to several things. First, it binds to platelets' Ib glycoprotein. Second, it binds to heparin and helps moderate its action. Third, it binds to collagen and fourth, the factor binds to FVIII in the molecular response, playing a protective role for it. In the absence of the von Wille-

brand factor, FVIII is destroyed. Fifth, the von Willebrand factor binds to integrin of platelets, helping them to adhere together and form a plug. Defects of the von Willebrand factor lead to various various bleeding disorders.

Blood "thinners"

The clotting of blood is essential for surviving wounds that cause blood loss. However, some people have conditions that predispose them to the formation of clots that can lead to stroke, heart attack, or other problems, like pulmonary embolism. For these people, anti-clotting agents (commonly called blood thinners) are used to reduce the likelihood of undesired clotting.

The first, and more common of these is aspirin. Aspirin is an inhibitor of the production of prostaglandins. Prostaglandins are molecules with 20 carbons derived from arachidonic acid that have numerous physiological effects. Metabolically, the prostaglandins are precursors of a class of molecules called the thromboxanes. Thromboxanes play roles in helping platelets to stick together in the cellular response to clotting. By inhibiting the production of prostaglandins, aspirin reduces the production of thromboxanes and reduces platelet stickiness and the likelihood of clotting.

Vitamin K action

Another approach to preventing blood clotting is one that interferes with an important molecular action of Vitamin K. A pro-clotting factor found in the blood, vitamin K is necessary for an important modification to prothrombin and other blood clotting proteins. Vitamin K serves as an enzyme cofactor that helps to catalyze addition of an extra carboxyl group onto the side chain of glutamic acid residues of several clotting enzymes (see HERE). This modification gives them the ability to bind to calcium (Figure 4.77), which is important for activating the serine protease cascade. During the reaction that adds carboxyl groups to glutamate, the reduced form of vitamin K becomes oxidized. In

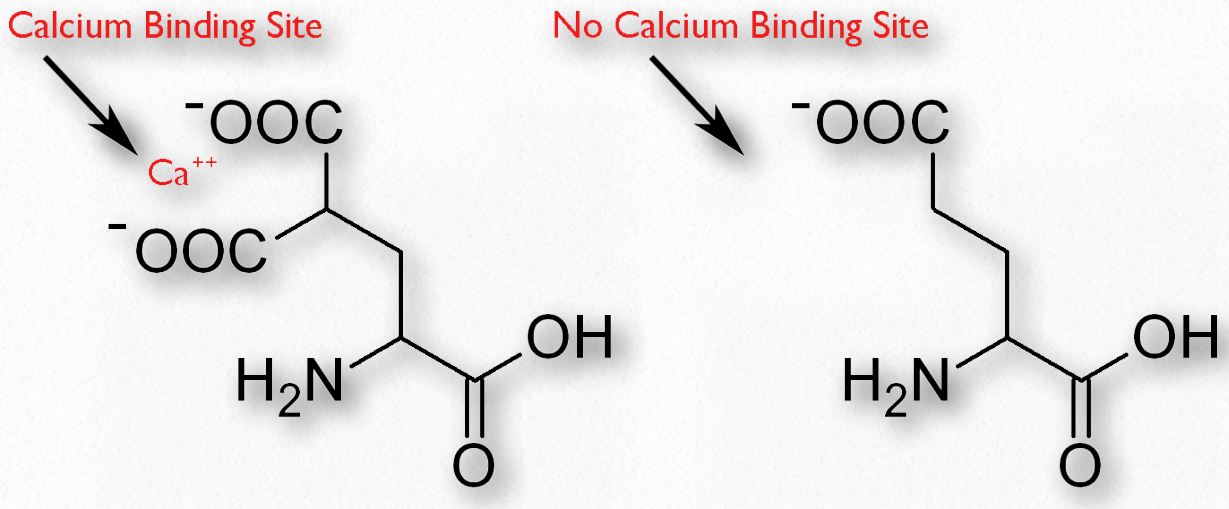

Figure 4.77 - γ-carboxylglutamic acid (left) has a calcium binding Site. Unmodified glutamic acid (right) does not.

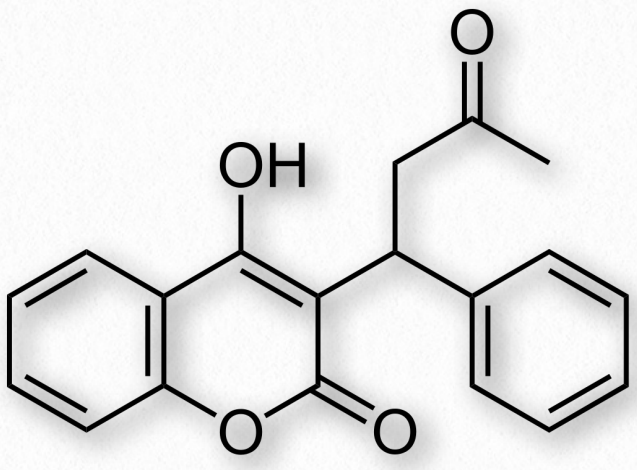

Figure 4.78 - Warfarin

order for vitamin K to stimulate additional carboxylation reactions to occur, the oxidized form of vitamin K must be reduced by the enzyme vitamin K epoxide reductase.

Warfarin blocks reduction

The compound known as warfarin (brand name = coumadin - Figure 4.78) interferes with the action of vitamin K epoxide reductase and thus, blocks recycling of vitamin K. As a consequence, fewer prothrombins (and other blood clotting proteins) get carboxylated, and less clotting occurs.

Vitamin K-mediated carboxylation of glutamate occurs on the γ carbon of the amino acid's side chain, for 16 different proteins, 7 of which are involved in blood clotting, including prothrombin. When the carboxyl group is added as described, the side chain is able to efficiently bind to calcium ions. In the absence of the carboxyl group, the side chain will not bind to calcium. Calcium released near the site of the wound in the cellular response to clotting helps to stimulate activation of proteins in the serine protease cascade of the molecular response.

Vitamin K comes in several forms. It is best described chemically as a group of 2-methyl-1,4-naphthoquinone derivatives. There are five different forms recognized as vitamin Ks (K_1, K_2, K_3, K_4, and K_5). Of these, vitamins K_1 and K_2 come from natural sources and the others are synthetic. Vitamin K_2, which is made from vitamin K_1 by gut microorganisms, has several forms, with differing lengths of of isoprenoid side-chains. The various forms are commonly named as MK-X, where X is a number, and MK stands for menaquinone, which is the name given to this form of vitamin K. Figure 4.79 shows a common form known as MK-4 (menatetrenone).

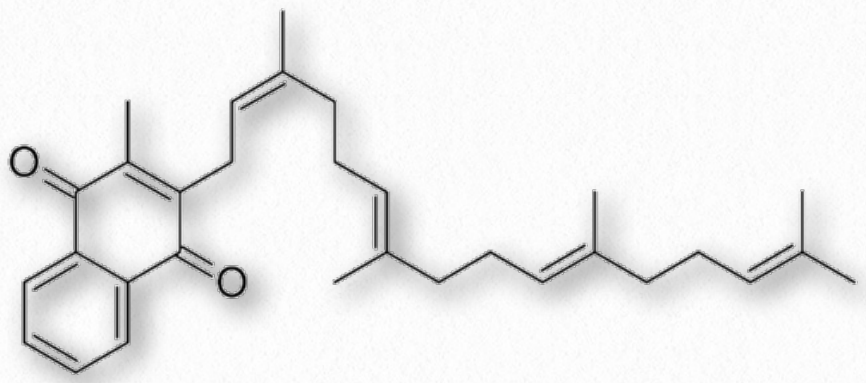

Figure 4.79 - MK-4 (menatetrenone)

Hemorrhaging danger

It is very critical that the proper amount of warfarin be given to patients. Too much can result in hemorrhaging. Patients must have

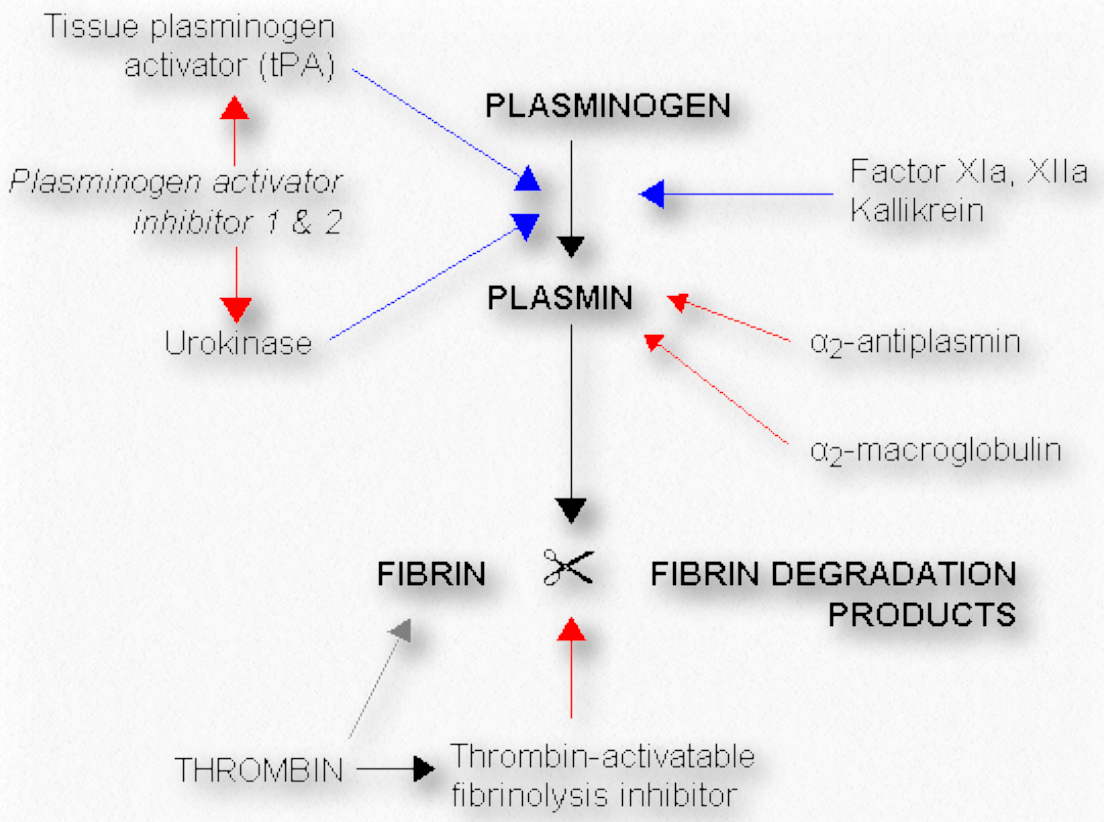

Figure 4.80 - Regulation of fibrin breakdown. Activators in blue. Inhibitors in red.

Wikipedia

their clotting times checked regularly to ensure that they are taking the right dose of anti-coagulant medication. Diet and the metabolism of Vitamin K in the body can affect the amount of warfarin needed. Vitamin K is synthesized in plants and plays a role in photosynthesis. It can be found in the highest quantities in vegetables that are green and leafy. Patients whose diet is high in these vegetables may require a different dose than those who rarely eat greens. Dietary vitamin K is also, as mentioned earlier, metabolized by bacteria in the large intestine, where they convert vitamin K_1 into vitamin K_2.

Plasmin

Clots, once made in the body, do not remain there forever. Instead, a tightly regulated enzyme known as plasmin is activated, when appropriate, to break down the fibrin-entangled clot. Like many of the enzymes in the blood clotting cascade, plasmin is a serine protease. It is capable of cleaving a wide range of proteins. They include polymerized fibrin clots, fibronectin, thrombospondin, laminin, and the von Willebrand factor.

Plasmin plays a role in activating collagenases and in the process of ovulation by weakening the wall of the Graafian follicle in the ovary. Plasmin is made in the liver as the zymogen known as plasminogen. Several different enzymes can activate it.

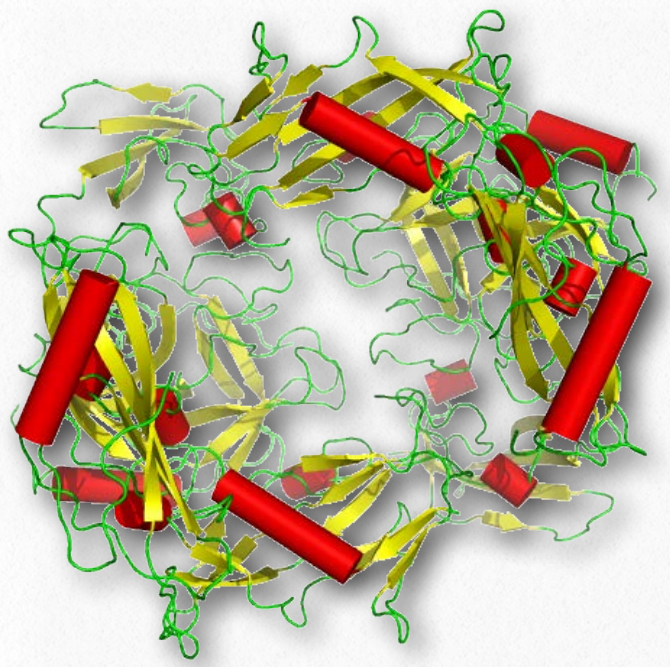

Figure 4.81 - Plasmin

Tissue plasminogen activator (tPA), using fibrin as a co-factor, is one. Others include urokinase plasminogen activator (using urokinase plasminogen activator receptor as a co-factor), kallikrein (plasma serine protease with many forms and blood functions), and FXIa and FXIIa from the clotting cascade.

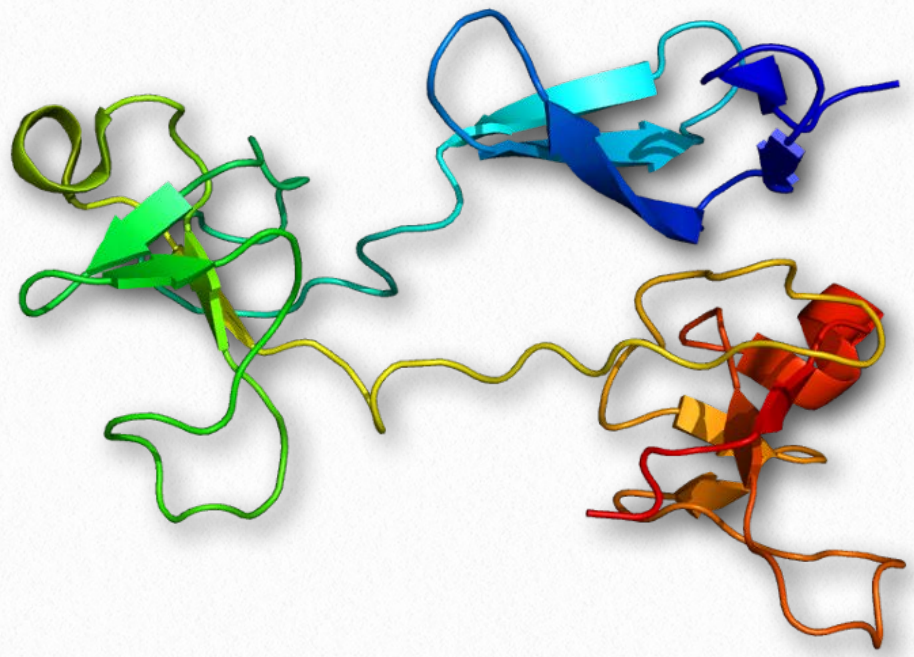

Figure 4.82 - Fibronectin 1

Wikipedia

Plasmin inhibition

Plasmin's activity can also be inhibited. Plasminogen activator inhibitor, for example, can inactivate tPA and urokinase. After plasmin has been activated, it can also be inhibited by α_2-antiplasmin and α_2-macroglobulin (Figure 4.80).

Thrombin also plays a role in plasmin's inactivation, stimulating activity of thrombin activatable fibrinolysis inhibitor. Angiostatin is a sub-domain of plasmin produced by auto-proteolytic cleavage. It blocks the growth of new blood vessels and is being investigated for its anti-cancer properties.

YouTube Lectures by Kevin HERE & HERE

Fibronectin

Fibronectin is a large (440 kDa) glycoprotein found in the extracellular matrix that binds to integral cellular proteins called integrins and to extracellular proteins, including collagen, fibrin, and heparan sulfate. It comes in two forms. The soluble form is found in blood plasma and is made by the liver. It is found in high concentration in the blood stream (300 µg/ml). The insoluble form is found abundantly in the extracellular matrix.

The protein is assembled in the extracellular matrix and plays roles in cellular growth, adhesion, migration, and differentiation. It is very important in wound healing.

Assists in blood clot formation

Fibronectin from the blood plasma is localized to the site of the wound, assisting in formation of the blood clot to stop bleeding. In the initial stages of wound healing, plasma fibronectin interacts with fibrin in clot formation. It also protects tissue sur-

rounding the wound. Later in the repair process, remodeling of the damaged area begins with the action of fibroblasts and endothelial cells at the wound site. Their task is to degrade proteins of the blood clot matrix, replacing them with a new matrix like the undamaged, surrounding tissue.

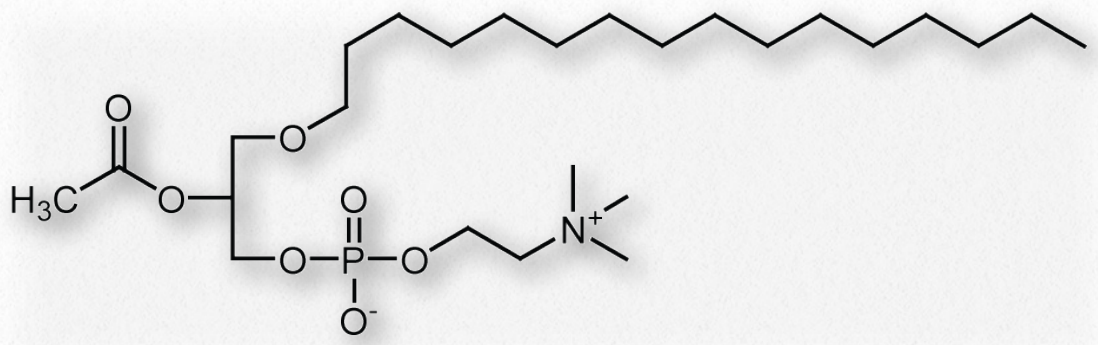

Figure 4.83 - Platelet Activating Factor

Wikipedia

Fibroblasts act on the temporary fibronectin-fibrin matrix, remodeling it to replace the plasma fibronectin with cellular fibronectin. This may cause the phenomenon of wound contraction, one of the steps in wound healing. Secretion of cellular fibronectin by fibroblasts is followed by fibronectin assembly and integration with the extracellular matrix.

Embryogenesis

Fibronectin is essential for embryogenesis. Deleting the gene in mice causes lethality before birth. This is likely due to its role in migration and guiding the attachment of cells as the embryo develops. Fibronectin also has a role in the mouth. It is found in saliva and is thought to inhibit colonization of the mouth by pathogenic bacteria.

Platelet activating factor

Platelet Activating Factor (PAF) is a compound (Figure 4.82) produced primarily in cells involved in host defense. These include platelets, macrophages, neutrophils, and monocytes, among others. It is produced in greater quantities in inflammatory cells upon proper stimulation. The compound acts like a hormone and mediates platelet aggregation/degranulation, inflammation, and anaphylaxis. It can transmit signals between cells to trigger and amplify inflammatory and clotting cascades.

When unregulated, signaling by PAF can cause severe inflammation resulting in sepsis and injury. Inflammation in allergic reactions arises partly as a result of PAF and is an important factor in bronchoconstriction in asthma. In fact, at a concentration of only 10 picomolar, PAF can cause asthmatic inflammation of the airways that is life threatening.

Thank Goodness My Blood is Clotting

To the tune of "*Don't Sleep in the Subway Darling*"

Metabolic Melodies Website HERE

I'm feeling so sad
'Cuz I cut . . . . myself bad
Now I'm all worried 'bout . . . . consequences

It's starting to bleed
There's some clo . . . . sure I need
So the body kicks . . . . in its defenses

It's happened all so many times before
The blood flows out and then it shuts the door

Thank goodness my blood is clotting
Enmeshing the fibrin chains
Thank goodness my blood is clotting
The zymogens
Are activating and all is well
So I'll stop bleeding again

The vitamin K's
Help to . . . . bind to cee-ays
Adding C-O-. . . . O-H to amend things
Um-m-um-um-um-um

It hardens and stays
When a glu. . . . taminase
Creates co. . . . valent bonds . . . . for cementing

In just a moment, things are good to go
The clot's in place and it has stopped the flow

But what about clot dissolving?
Untangling fibrin chains?
This calls for some problem solving
There is a way
Just activate up some t-PA
Get plasmin active in veins

Oh, oh, oh.
And thanks to the dis-enclotting'
As part of repairin' veins
It's part of my body's plotting
The wound is gone
I'm back where I started and
Nothing's wrong
My blood flow is normal again.

Energy

"Getting over a painful experience is much like crossing monkey bars. You have to let go at some point in order to move forward."

-C.S Lewis

We know that energy can neither be created or destroyed, so cells must merely convert energy, from one form to another. The two principal organelles that carry out these transformations in eukaryotic cells are mitochondria and chloroplasts, ancient endosymbionts that have now become part of their host cells. In this chapter we examine the energy transformations carried out by these organelles.

Energy: Basics

Introduction

Living organisms are made up of cells, and cells contain a horde of biochemical components. Living cells, though, are not random collections of these molecules. They are extraordinarily organized or "ordered". By contrast, in the nonliving world, there is a universal tendency to increasing disorder. Maintaining and creating order in cells takes the input of energy. Without energy, life is not possible.

YouTube Lectures by Kevin HERE & HERE

Oxidative energy

The primary mechanism used by non-photosynthetic organisms to obtain energy is oxidation and carbon is the most commonly oxidized energy source. The energy released during the oxidative steps is “captured” in ATP and can be used later for energy coupling (see HERE). The more reduced a carbon atom is, the more energy can be realized from its oxidation. Fatty acids are highly reduced, whereas carbohy-

drates are moderately so. Complete oxidation of both leads to carbon dioxide, which has the lowest energy state. Conversely, the more oxidized a carbon atom is, the more energy it takes to reduce it.

In the series shown in Figure 5.1, the most reduced form of carbon is on the left. The energy of oxidation of each form is shown above

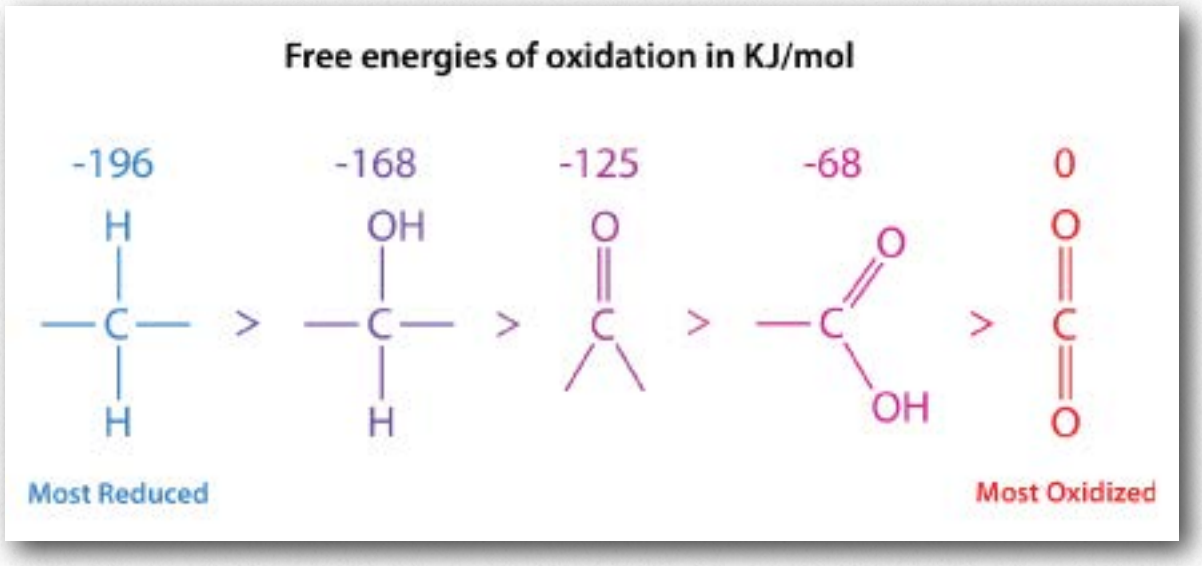

Figure 5.1 - Five oxidation states of carbon
Image by Pehr Jacobson

it. The reduction states of fatty acids and carbohydrates can be seen by their formulas.

Palmitic acid = $C_{16}H_{34}O_2$

Glucose = $C_6H_{12}O_6$

Palmitic acid only contains two oxygens per sixteen carbons, whereas glucose has six oxygen atoms per six carbons. Consequently, when palmitic acid is fully oxidized, it generates more ATP per carbon (128/16) than glucose (38/6). It is because of this that we use fat (contains fatty acids) as our primary energy storage material.

Oxidation vs. reduction in metabolism

Biochemical processes that break things down from larger to smaller are called catabolic processes. Catabolic processes are often oxidative in nature and energy releasing. Some, but not all, of that energy is captured as ATP. If not all of the energy is captured as ATP, what happens to the rest of it? The answer is simple. It is released as heat and it is for this reason we get hot when we exercise.

By contrast, synthesizing large molecules from smaller ones (for example, making proteins from amino acids) is referred to as anabolism. Anabolic processes are often reductive in nature (Figures 5.3 & 5.4) and require energy input. By themselves, they would not occur, as they are reversing oxidation and decreasing entropy (making many small things into a larger one). To overcome this energy barrier, cells must expend energy. For example, if one wishes to reduce CO_2 to carbohydrate, energy must be used to do so. Plants do this during the dark reactions of photosynthesis (Figure 5.3). The energy source for the reduction is ultimately the sun. The electrons for the reduction come from water, and the CO_2 is removed

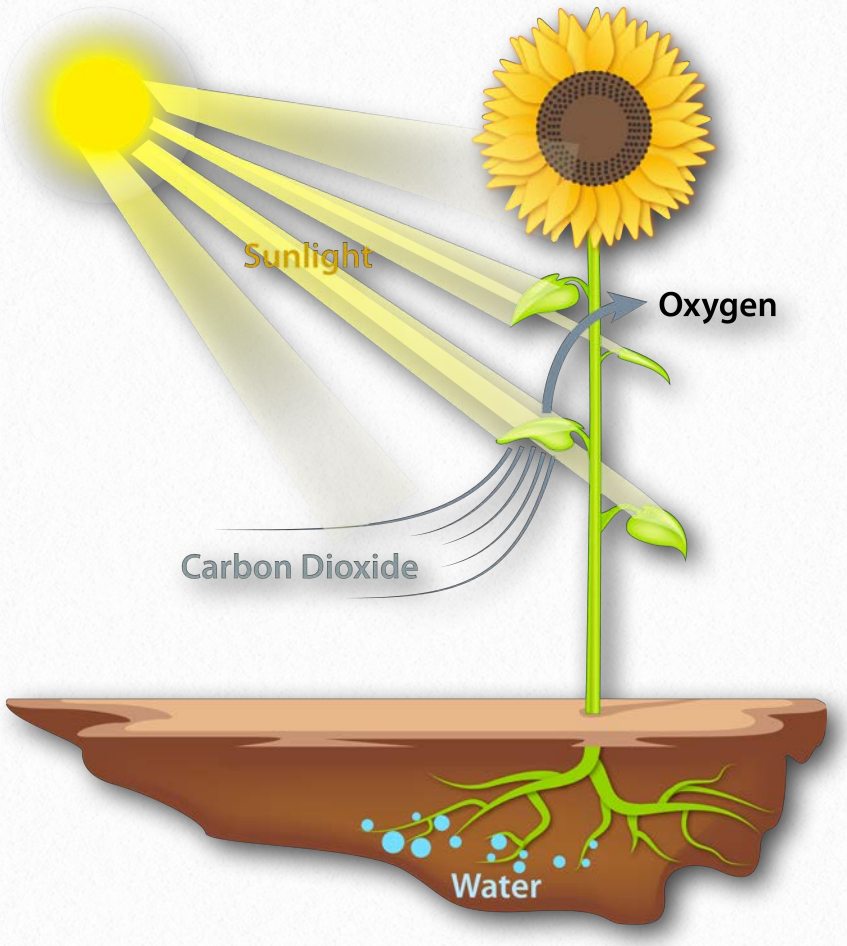

Figure 5.2 - Photosynthesis - The primary source of biological energy

Image by Aleia Kim

from the atmosphere and gets incorporated into a sugar.

Energy coupling

The synthesis of the many molecules needed by cells needs the input of energy to occur. Cells overcome this energy obstacle by using ATP to "drive" the reaction (Figure 5.6). The energy needed to drive reactions is harvested in very controlled conditions in enzymes. This involves a process called 'coupling'. Coupled reactions rely on linking an energetically favorable reaction (i.e., one with a negative $\Delta G°'$) with the reaction requiring an energy input, which has a positive $\Delta G°'$. As long as the overall $\Delta G°'$ of the two reactions together is negative, the reaction can proceed. Hydrolysis of ATP is a very energetically favorable reaction that is commonly linked to many energy requiring reactions in cells. Without the hydrolysis of ATP (or GTP, in some cases), the reaction would not be feasible.

Entropy and energy

Most students who have had some chemistry know about the Second Law of Ther-

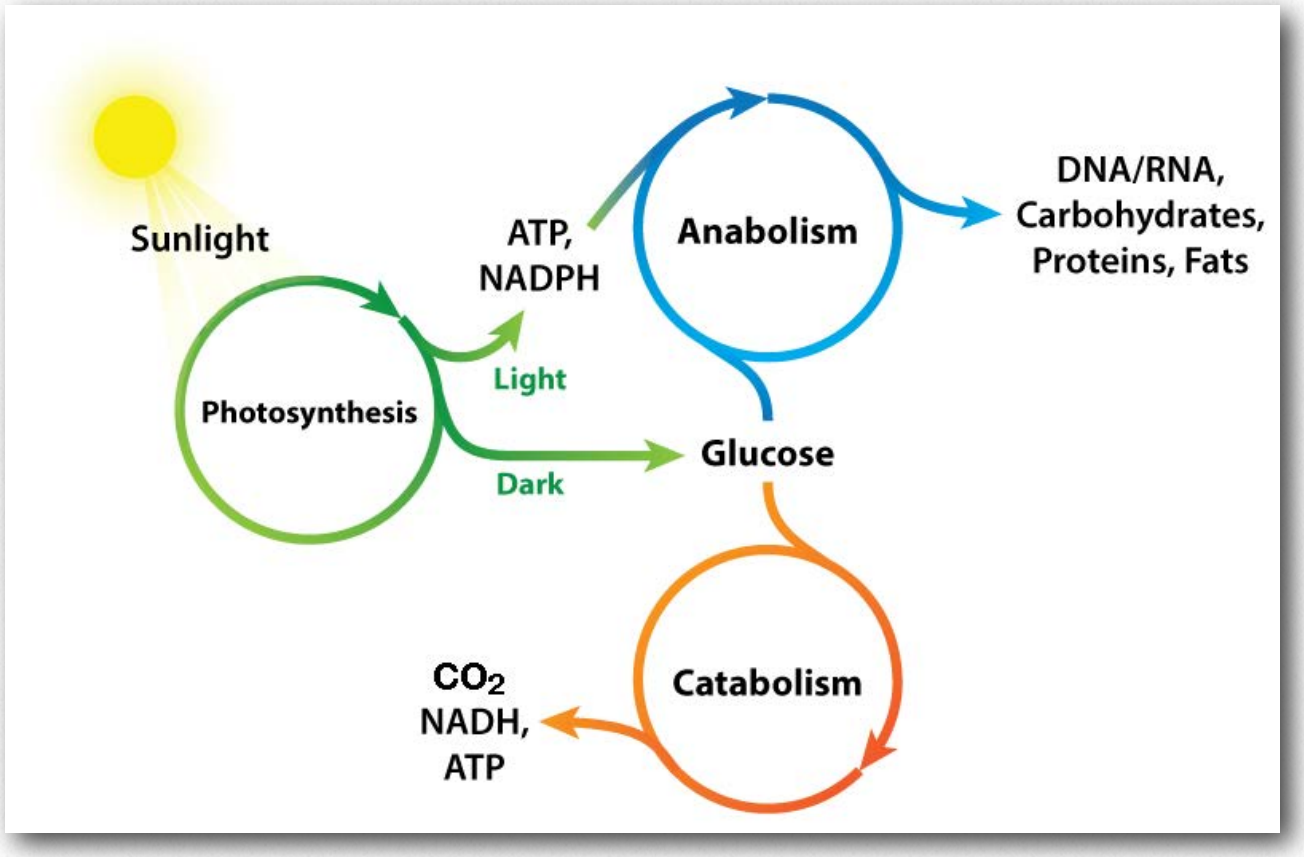

Figure 5.3 - Movement of biological energy

Image by Aleia Kim

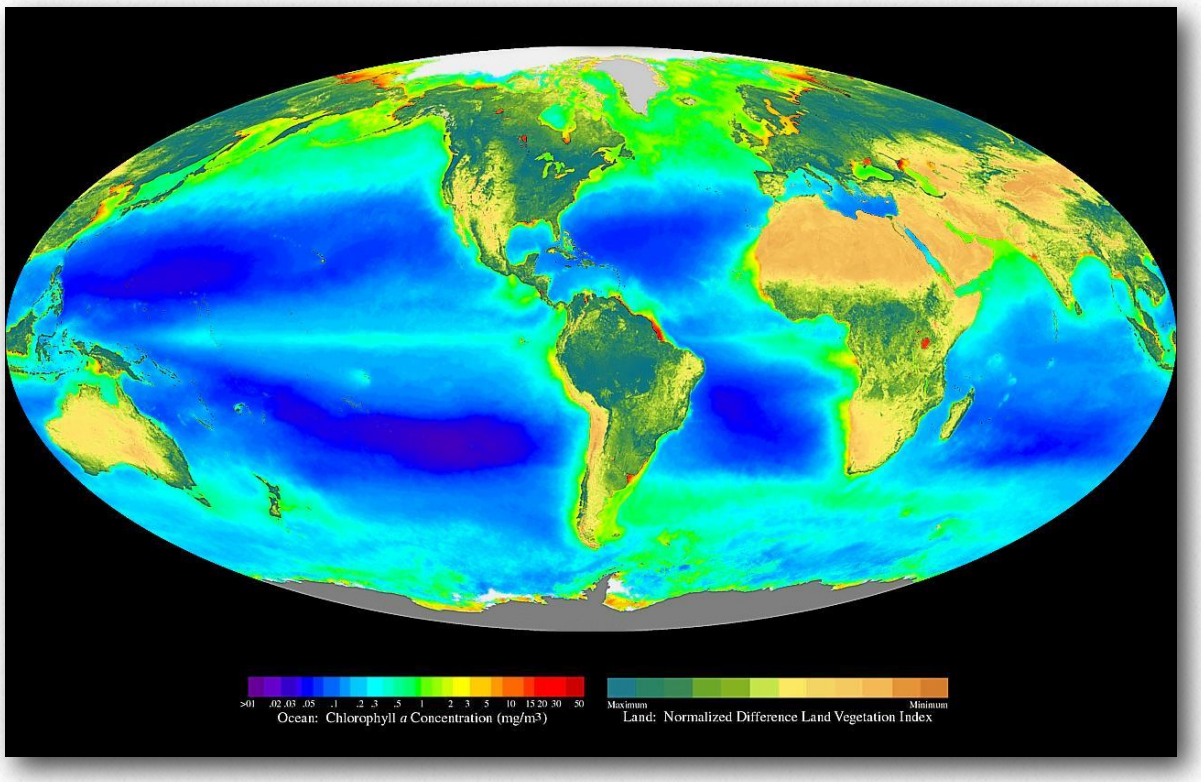

Figure 5.4 - Photosynthesis as measured by chlorophyll concentration

modynamics with respect to increasing disorder of a system. Cells are very organized or ordered structures, leading some to mistakenly conclude that life somehow violates the second law. In fact, that notion is incorrect. The second law doesn't say that entropy always increases, just that, left alone, it tends to do so, in an isolated system. Cells are not isolated systems, though, in that they obtain energy, either from the sun, if they are autotrophic, or food, if they are heterotrophic.

To counter the universal tendency towards disorder on a local scale requires energy. As an example, take a fresh deck of cards which is neatly aligned with Ace-King-Queen . . . . 4,3,2 for each suit. Throw the deck into the air, letting the cards scatter. When you pick them up, they will be

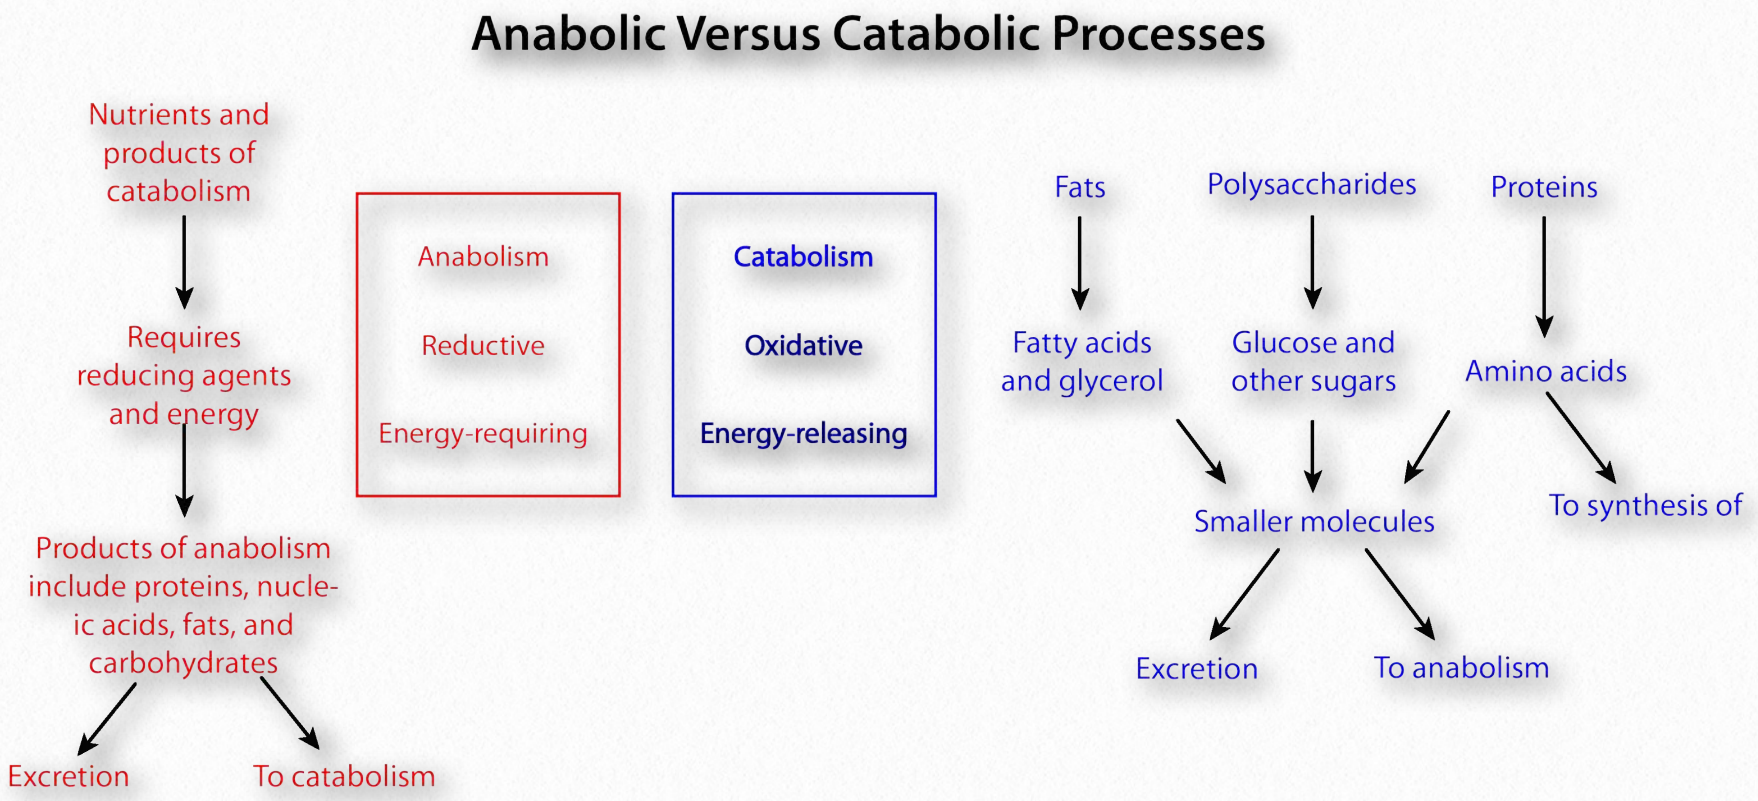

Figure 5.5 - Synthesis and breakdown pathways in metabolism

Image by Pehr Jacobson

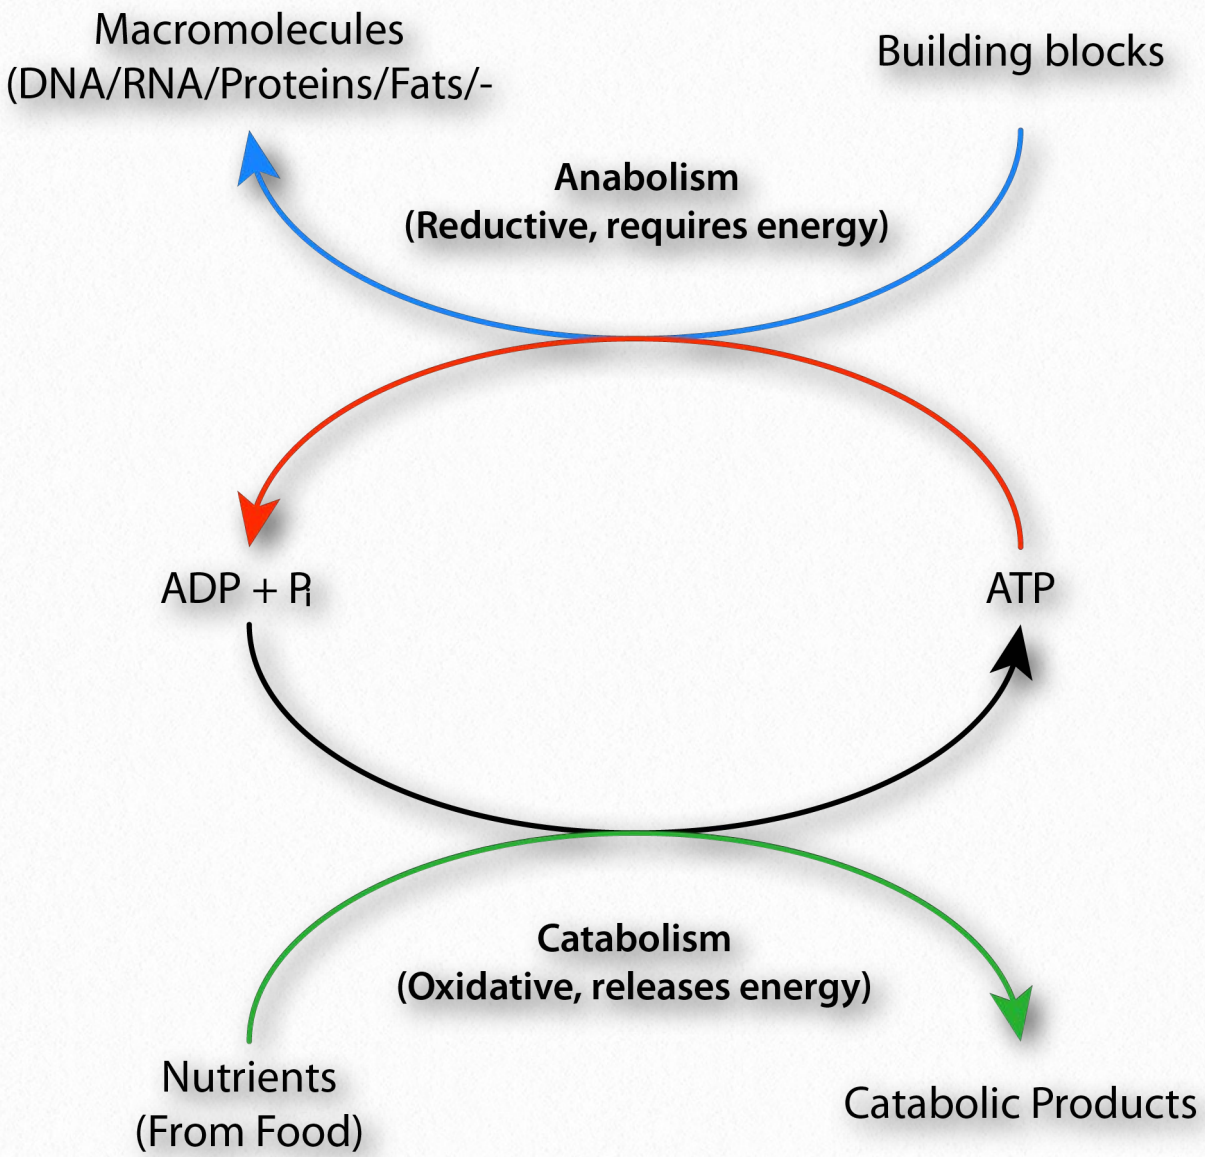

Figure 5.6 - Cycling of biological energy via ADP and ATP
Image by Pehr Jacobson

more disordered than when they started. However, if you spend a few minutes (and expend a bit of energy), you can reorganize the same deck back to its previous, organized state. If entropy always increased everywhere, you could not do this. However, with the input of energy, you overcame the disorder. This illustrates an important concept - the cost of fighting disorder is energy.

YouTube Lectures by Kevin HERE & HERE

Biological energy

There are, of course, other reasons that organisms need energy. Muscular contraction, synthesis of molecules, neurotransmission, signaling, thermoregulation, and subcellular movements are examples. Where does this energy come from? The currencies of energy are generally high-energy phosphate-containing molecules. ATP is the best known and most abundant, but GTP is also an important energy source (energy source for protein synthesis). CTP is involved in synthesis of glycerophospholipids and UTP is used for synthesis of glycogen and other sugar compounds. In each of these cases, the energy is in the form of potential chemical energy stored in the multi-phosphate bonds. Hydrolyzing those bonds releases the energy in them.

Of the triphosphates, ATP is the primary energy source, acting to facilitate the synthesis of the others by action of the enzyme NDPK. ATP is made by three distinct types of phosphorylation – oxidative phosphorylation (in mitochondria), photophosphorylation (in chloroplasts of

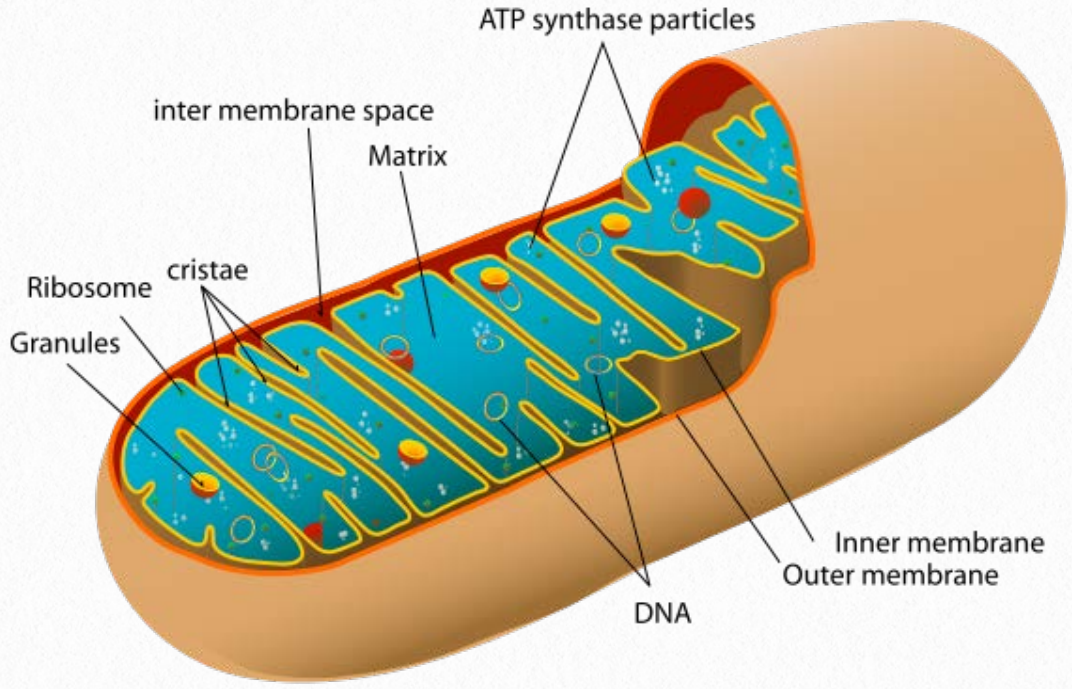

Figure 5.7 A mitochondrion

plants), and substrate level phosphorylation (in enzymatically catalyzed reactions).

Gibbs free energy in biology

ATP is generally considered the "storage battery" of cells (See also 'Molecular Battery Backups for Muscles HERE). In order to understand how energy is captured, we must first understand Gibbs free energy and in doing so, we begin to see the role of energy in determining the directions chemical reactions take.

Gibbs free energy may be thought of as the energy available to do work in a thermodynamic system at constant temperature and pressure.

Mathematically, the Gibbs free energy is given as:

$$G = H - TS$$

where H is the enthalpy, T is the temperature in Kelvin, and S is the entropy.

At standard temperature and pressure, every system seeks to achieve a minimum of free energy. Thus, increasing entropy, S, will reduce Gibbs free energy. Similarly, if excess heat is available (reducing the enthalpy, H), the free energy can also be reduced.

Cells must work within the laws of thermodynamics, as noted, so all of their biochemical reactions, too, are ruled by these laws. Now we shall consider energy in the cell. The change in Gibbs free energy (ΔG) for a reaction is crucial, for it, and it alone, determines whether or not a reaction goes forward.

$\Delta G = \Delta H - T\Delta S$,

There are three cases

One reason we need ATP
Is the high cost of living, you see
'Cause the chaotic entity
Known as the entropy
Requires cells to burn energy

$\Delta G < 0$ - the reaction proceeds as written

$\Delta G = 0$ - the reaction is at equilibrium

$\Delta G > 0$ - the reaction runs in reverse

For a reaction

$$aA \rightleftarrows bB$$

(where 'a' and 'b' are integers and A and B are molecules) at pH 7, ΔG can be determined by the following equation,

$$\Delta G = \Delta G^{\circ\prime} + RT\ln([B]^b/[A]^a)$$

For multiple substrate reactions, such as $aA + cC \rightleftarrows bB + dD$

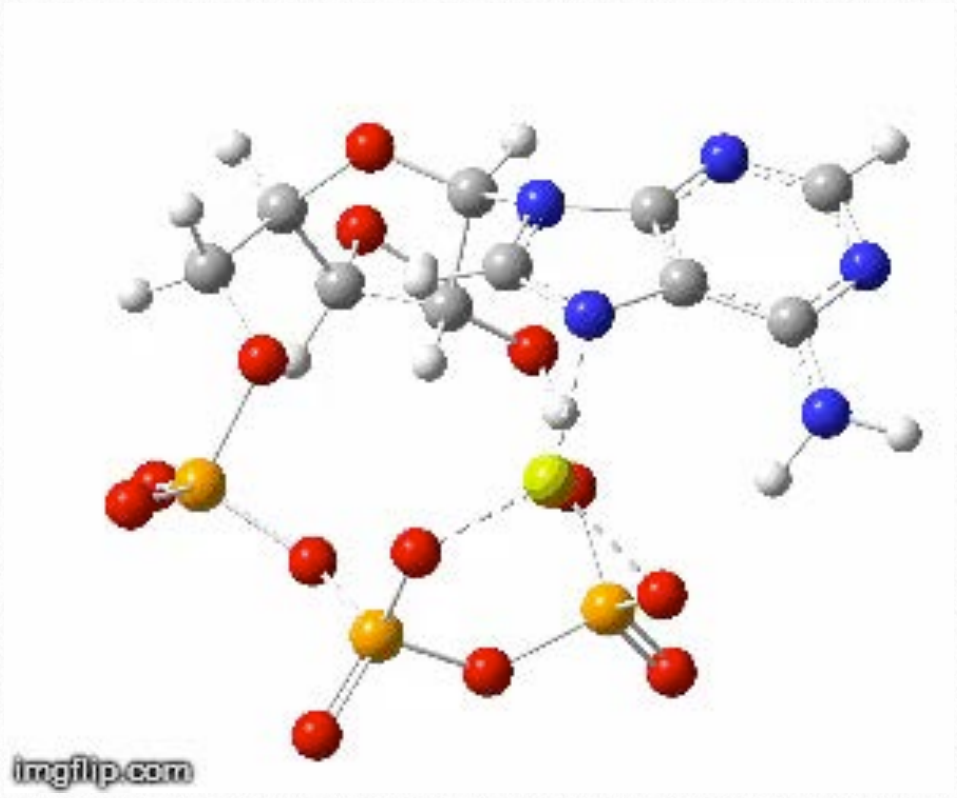
$$\Delta G = \Delta G^{\circ\prime} + RT\ln\{([B]^b[D]^d)/([A]^a[C]^c)\}$$

The $\Delta G^{\circ\prime}$ term is called the change in Standard Gibbs Free energy, which is the change in energy that occurs when all of the products and reactants are at standard conditions and the pH is 7.0. It is a constant for a given reaction.

In simple terms, we can collect all of the terms of the numerator together and call them {Products} and all of the terms of the denominator together and call them {Reactants},

$$\Delta G = \Delta G^{\circ\prime} + RT\ln(\{Products\}/\{Reactants\})$$

For most biological systems, the temperature, T, is a constant for a given reaction. Since $\Delta G^{\circ\prime}$ is also a constant for a given reaction, the ΔG is changed almost exclusively as the ratio of {Products}/{Reactants} changes.



Movie 5.1 - ATP - The fuel of the cell

Wikipedia

Importance of $\Delta G^{\circ\prime}$

If one starts out at standard conditions, where everything except protons is at 1M, the RTln({Products}/{Reactants}) term is zero, so the $\Delta G^{\circ\prime}$ term equals the ΔG, and the $\Delta G^{\circ\prime}$ determines the direction the reaction will take (*only* under those conditions). This is why people say that a negative $\Delta G^{\circ\prime}$ indicates an energetically favorable reaction, whereas a positive $\Delta G^{\circ\prime}$ corresponds to an unfavorable one.

Increasing the ratio of {Products}/{Reactants} causes the value of the natural log (ln) term to become more positive (less negative), thus making the value of ΔG more positive. Conversely, as the ratio of {Products}/{Reactants} decreases, the value of the natural log term becomes less positive (more negative), thus making the value of ΔG more negative.

System response to stress

Intuitively, this makes sense and is consistent with Le Chatelier's Principle – a system responds to stress by acting to alleviate the stress. If we examine the ΔG for a reaction in a closed system, we see that it will always move to a value of zero (equilibrium), no matter whether it starts with a positive or negative value.

Another type of free energy available to cells is that generated by electrical potential. For example, mitochondria and chloroplasts partly use Coulombic energy (based on charge) from a proton gradient across their membranes to provide the necessary energy for the synthesis of ATP. Similar energies drive the transmission of nerve signals (sodium and potassium gradients) and the movement of some molecules in secondary active transport processes across membranes (e.g., H^+ differential driving the movement of lactose). From the Gibbs free energy change equation,

When reactions have product largesse
They will act to address the excess
Henry Le Chatelier
Showed conversion's the way
To suppress the excess by redress

$$\Delta G = \Delta H - T\Delta S$$

it should be noted that an increase in entropy will help contribute to a decrease in ΔG. This happens, for example when a large molecule is being broken into smaller pieces or when the rearrangement of a molecule increases the disorder of molecules around it. The latter situation arises in the hydrophobic effect, which helps drive the folding of proteins.

Chemical and electrical potential

It is said that absence makes the heart grow fonder. We won't tackle that philosophical issue here, but we will say that separation provides potential energy that cells can and do harvest. The lipid bilayer of cell and (in eukaryotic cells) organelle membranes provide the necessary barrier for separation.

Impermeable to most ions and polar compounds, biological membranes are essential for processes that generate cellular energy. Consider Figure 5.8. A lipid bilayer separates two solutions with different concentrations of a solute. There is a greater concentration of negative ions in the bottom and a

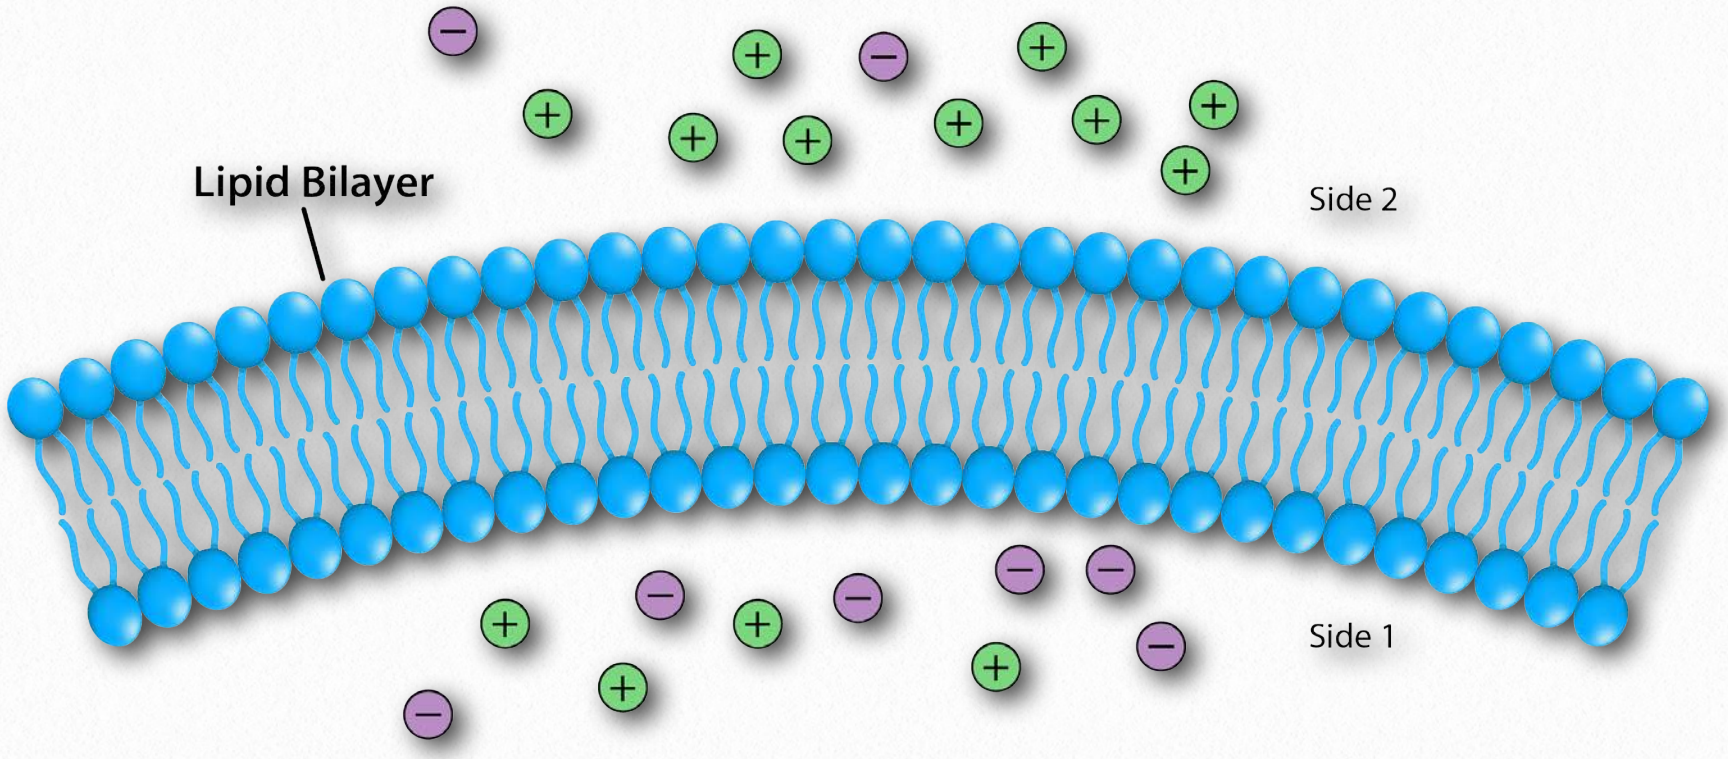


Figure 5.8 - Differences in ion concentration across a membrane give rise to chemical and electrical gradients

Image by Pehr Jacobson

greater concentration of positive ions on the top.

Whenever there is a difference in concentration of molecules across a membrane, there is said to be a concentration gradient across it. A difference in concentration of ions across a membrane also creates a charge (or electrical) gradient. Because there is a difference in both the chemical concentration of the ions and in the charge on the two sides of the membrane, this is described as an electrochemical gradient (Figures 5.8 -5.10).

Potential energy

Such gradients function like batteries and contain potential energy. When the potential energy is harvested by cells, they can create ATP, transmit nerve signals, pump molecules across membranes, and more. It is important, therefore, to understand how to calculate the potential energy of electrochemical gradients.

First, we consider chemical (solute) gradients. In Figure 5.9, two concentrations of glucose are separated by a lipid bilayer. Let's assume C_2 be the concentration of glucose inside the cell (bottom) and C_1 be the glucose concentration outside (top). The Gibbs free energy associated with moving glucose in the direction of C_2 (into the cell) is given by

$$\Delta G = RT\ln[C_2/C_1]$$

To move it in the direction of C_1 (to the outside of the cell) the expression would be

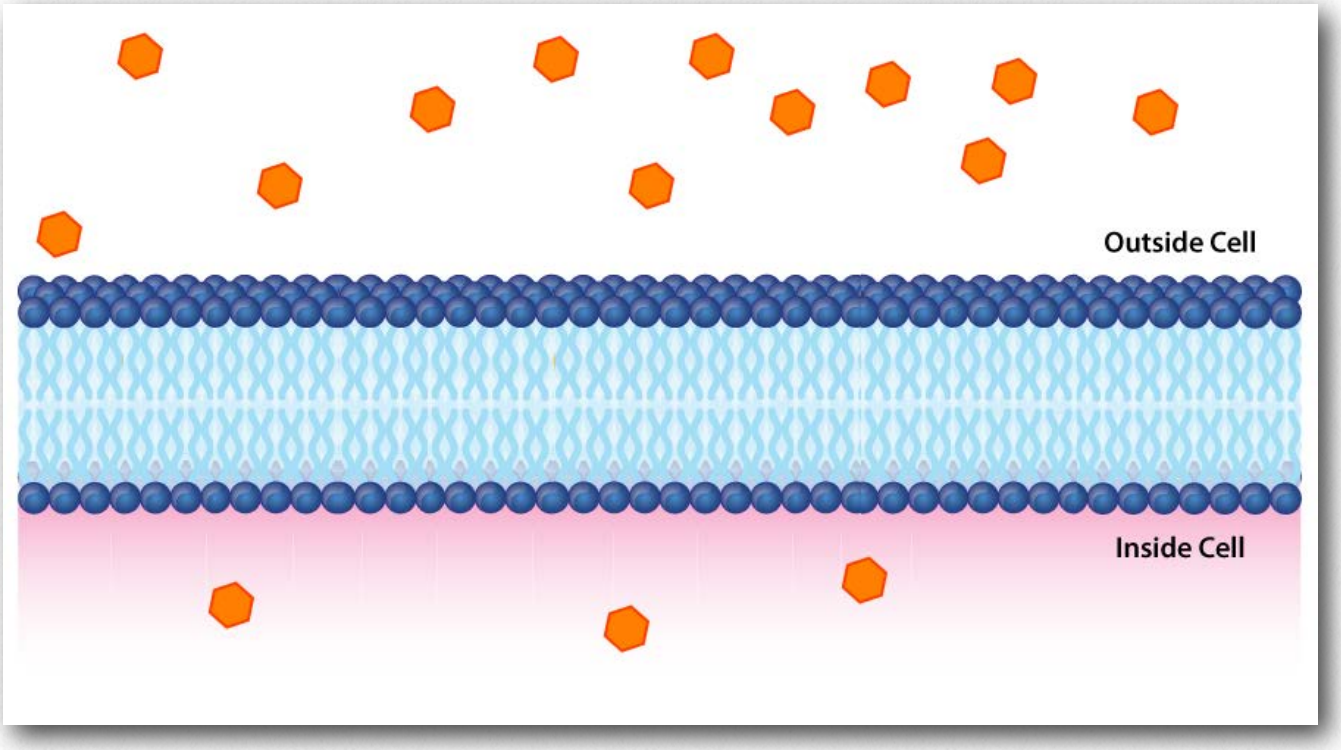

Figure 5.9 - A chemical gradient

Image by Aleia Kim

In the example above, we considered glucose, which is an uncharged molecule. When ions are involved, their charges must also be taken into consideration. Figure 5.10 depicts a similar situation across a lipid bilayer. In this case, a difference of concentration and charge exists. There are more positive charges inside the cell than outside.

$$\Delta G = RT\ln[C_1/C_2]$$

Since C_2 is smaller than C_1 (i.e., there are fewer glucose molecules inside the cell) then the ΔG is negative and diffusion would be favored into the cell, if the glucose could traverse the bilayer.

YouTube Lectures by Kevin HERE & HERE

Conversely, if C_2 was greater than C_1 (more glucose was in the cell than outside) the ΔG would be positive, so movement in the direction of C_2 would not be favored and instead the glucose would tend to move towards C_1, that is, out of the cell.

If $C_2 = C_1$, with the same concentration of glucose inside and outside, then the ΔG would be zero and there would be no net movement, as the system would be at equilibrium.

Using C_2 to indicate the concentration of materials inside the cell and C_1 for the concentration outside the cell (as before), then the free energy for movement of an ion from top to bottom is given by the following equation

$$\Delta G = RT\ln[C_2/C_1] + ZF\Delta\psi$$

Note here that this equation must take into consideration both the concentration differences and the charge differences. Z refers to the charge of the transported species, F is the Faraday constant (96,485 Coulombs/mol), and $\Delta\psi$ is the electrical potential difference (voltage difference) across the membrane.

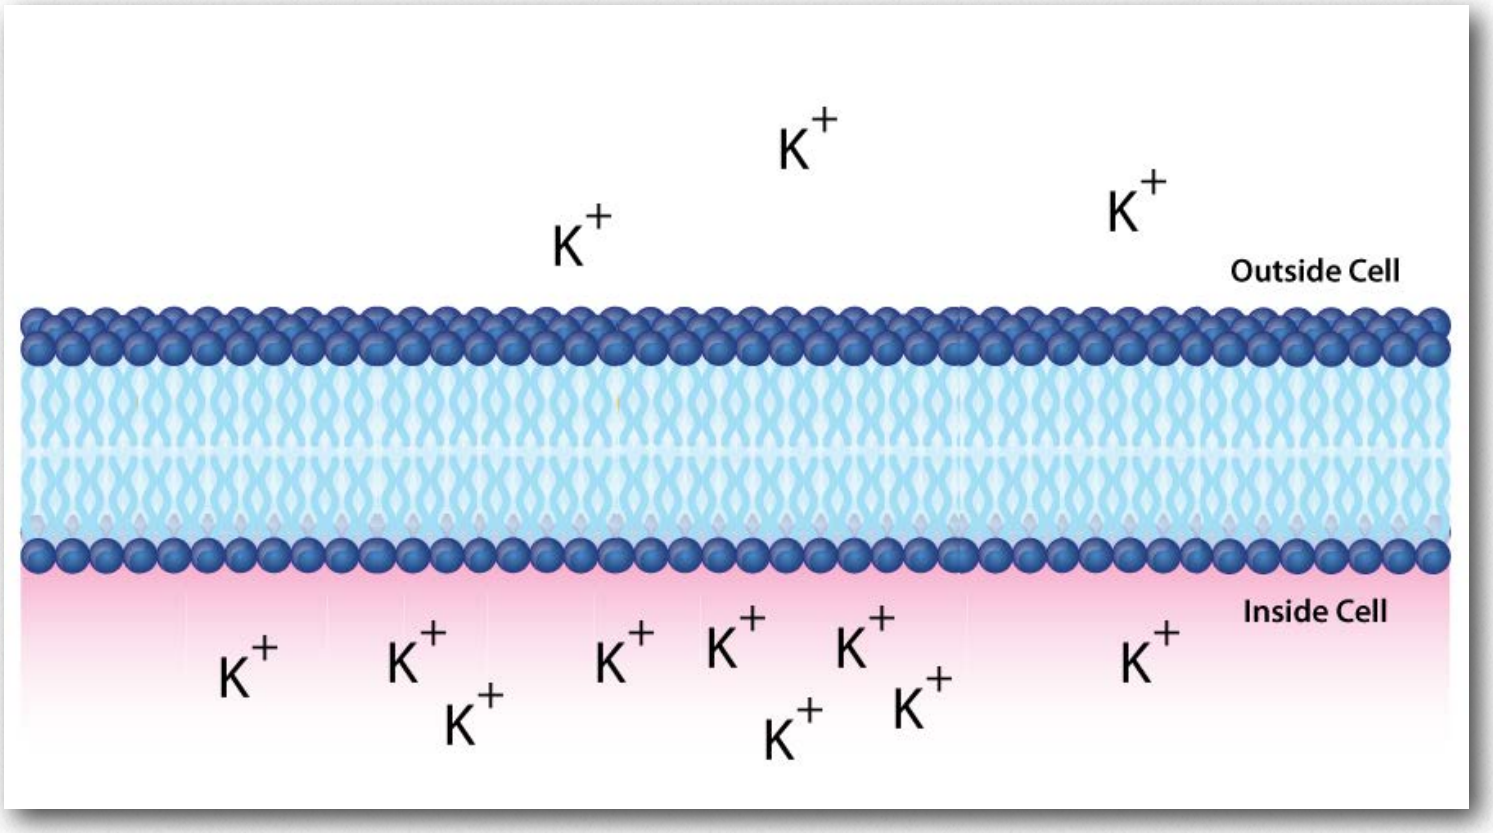

Figure 5.10 - An electrochemical gradient of potassium ions

Image by Aleia Kim

If we were to calculate the ΔG for movement of the potassium ion from top to bottom, it would be positive, since $[C_2/C_1]$ is greater than 1 (making for a positive ln term), and the $ZF\Delta\psi$ is positive because positively charged ions (Z) are moving against a positive charge gradient given by $\Delta\psi$ (greater concentration at the target (bottom) than the starting point (top)). If we were to calculate the concentration of ions moving from bottom to top, then the ln term would be negative (C2<C1) and the $ZF\Delta\psi$ would be negative as well (Z=positive, but $\Delta\psi$ negative).

Reduction potential

In discussing chemical potential, we must also consider reduction potential. Reduction potential measures the tendency of a chemical to be reduced by electrons. It is also designated by several other names/variables. These include redox potential, oxidation/reduction potential, ORP, pE, ε, E, and E_h.

Reduction potential is measured in volts, or millivolts. A substance with a higher reduction potential will have a greater tendency to accept electrons and be reduced. If two substances are mixed in an aqueous solution, the one with the greater (more positive) reduction potential will tend to take electrons away, thus being reduced, from the one with the lower reduction potential, which becomes oxidized.

Relative measures

Absolute reduction potentials are difficult to measure, so reduction potentials are typically defined relative to a reference electrode. In

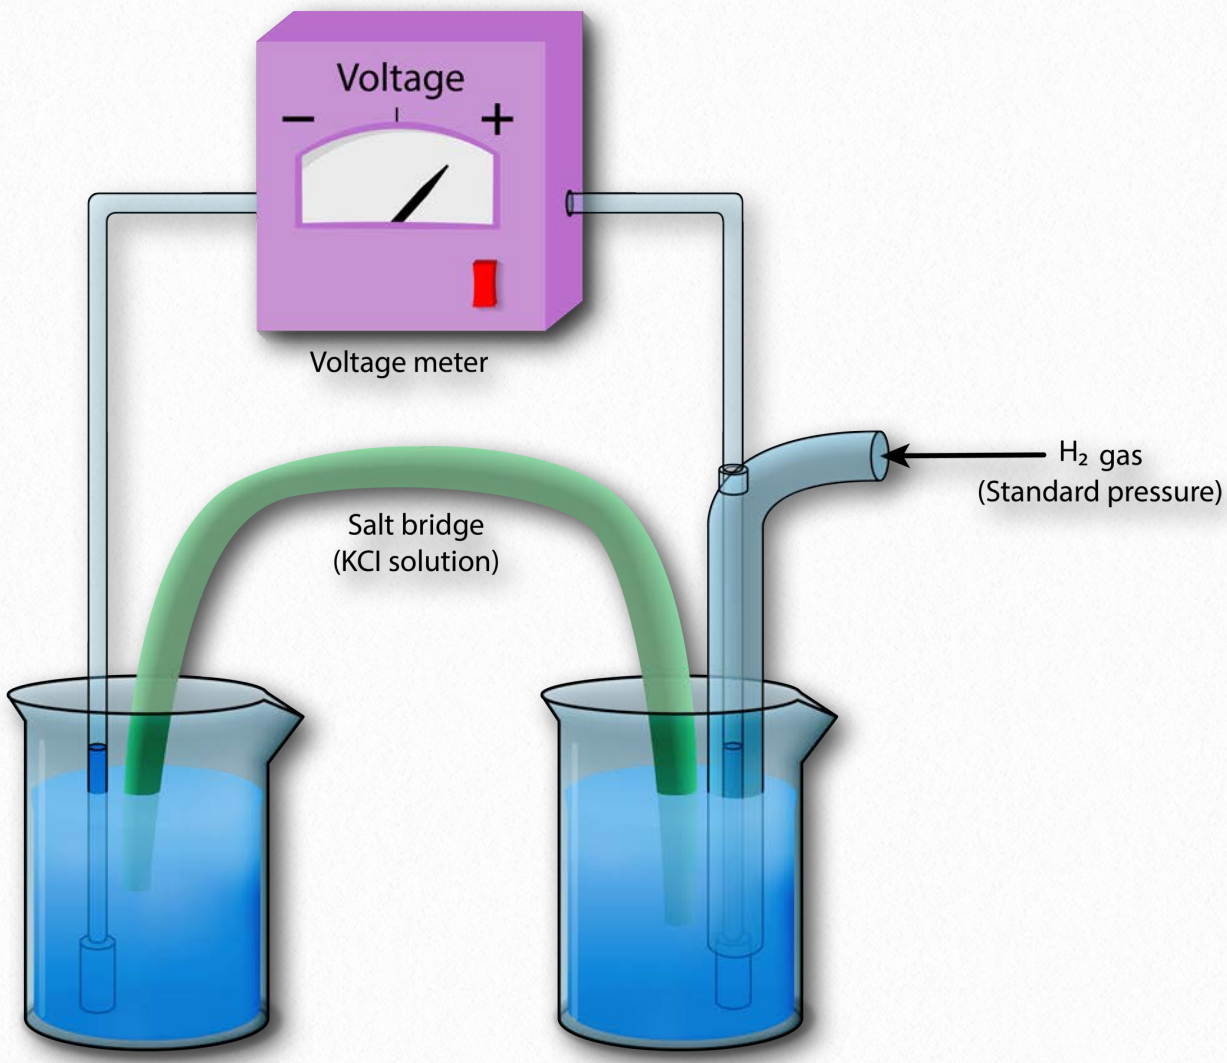

Figure 5.11 - Reference electrode for measuring reduction potentials.

Image by Pehr Jacobson

aqueous solutions, reduction potentials are measured as the potential difference between an inert sensing electrode (typically platinum) in contact with the test solution and a stable reference electrode (measured as a Standard Hydrogen Electrode - SHE) as shown in Figure 5.11. The standard of reference for measurement is the half-reaction

$$H^+ + e^- \rightarrow (1/2)H_2$$

The electrode where this reaction occurs (referred to as a half-cell) is given the value of E° (Standard Reduction Potential) of 0.00 volts. The hydrogen electrode is connected via an external circuit to another half cell containing a mixture of the reduced and oxidized species of another molecule (for example, Fe^{++} and Fe^{+++}) at 1M each and standard conditions of temperature (25°C) and pressure (1 atmosphere).

Direction and voltage measured

The direction and magnitude of electron movement is then measured. If the test mixture takes electrons from the hydrogen electrode, the sign of the voltage is positive and if the direction is reversed, the voltage is negative.

Thus, compounds which have greater affinity for electrons than hydrogen will register a positive voltage and negative voltages correspond to compounds with lesser affinity for electrons than hydrogen.

Movement of electrons

Under standard conditions, electrons will move from compounds generating lower voltages to ones generating higher (more positive) voltages. Just as the standard Gibbs free energy change is the Gibbs free energy change under standard conditions, so, too, is the standard reduction potential E° the reduction potential E under standard conditions.

The actual reduction potential of a half cell will vary with the concentration of each chemical species in the cell. The relationship between the reduction potential E and the standard reduction potential E° is given by the following equation (also called the Nernst equation)

$$E = E^\circ + (RT/nF)*\ln\left(\frac{[\text{reduced molecule}]}{[\text{oxidized molecule}]}\right)$$

where F is the Faraday constant (96,480 J/(Volts*moles), R is the gas constant (8.315 J/(moles*K), n is the number of moles of electrons being transferred, and T is the absolute temperature in Kelvin.

At 25°C, this equation becomes

$$E = E^\circ + (0.026V/n)*\ln\left(\frac{[\text{reduced molecule}]}{[\text{oxidized molecule}]}\right)$$

As for Gibbs free energy, it is useful to measure values at conditions found in cells. This means doing measurements at pH = 7, which differs from having all species at 1M.

Adjustment

Because of this adjustment, a slightly different standard reduction potential is defined and we designate it by E°', just as we defined a special standard Gibbs free energy change at pH 7 as ΔG°'.

There is a relationship between the change in Gibbs free energy ΔG and the change in reduction potential (ΔE). It is

$$\Delta G = -nF\Delta E$$

Similarly, the relation between the change in standard Gibbs free energy and the change in standard reduction potential is

$$\Delta G^{\circ\prime} = -nF\Delta E^{\circ\prime}$$

Energy storage in triphosphates

Formation of triphosphates, like ATP, is essential to meeting the cell's energy needs for synthesis, motion, and signaling. In a given day, an average human body makes and breaks down more than its weight in triphosphates. This is especially remarkable considering that there is only about 250 g of the molecule present in the body at any given time. Energy in ATP is released by hydrolysis of a phosphate from the molecule.

The three phosphates, starting with the one closest to the sugar are referred to as α, β, and γ (Figure 5.12). It is the γ phosphate that is cleaved in hydrolysis and the product is ADP. In a few reactions, the bond between the α and β is cleaved. When this happens, a pyrophosphate (β linked to γ) is released and AMP is produced. This latter reaction to produce AMP releases more energy (ΔG°' = -45.6

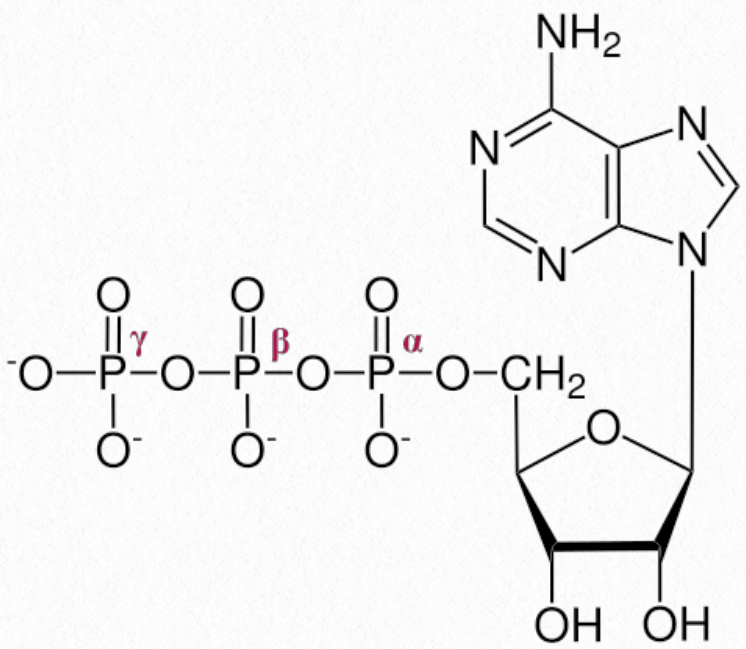

Figure 5.12 ATP showing α, β and γ phosphates

kJ/mol) than the first reaction which produces ADP (ΔG°' = -30.5 kJ/mol).

Since triphosphates are the "currency" that meet immediate needs of the cell, it is important to understand how triphosphates are made. There are three phosphorylation mechanisms – 1) substrate level; 2) oxidative; and 3) photophosphorylation. We consider them here individually.

Substrate level phosphorylation

The easiest type of phosphorylation to understand is that which occurs at the substrate level. This type of phosphorylation involves the direct synthesis of ATP from ADP and a high energy intermediate, typically a phosphate-containing molecule. Substrate level phosphorylation is a relatively minor contributor to the total synthesis of triphosphates by cells. An example substrate phosphorylation comes from glycolysis.

Phosphoenolpyruvate (PEP) + ADP ⇅ Pyruvate + ATP

This reaction has a very negative ΔG°' (-31.4 kJ/mol), indicating that the PEP contains more energy than ATP, thus tending to energetically favor ATP's synthesis. Other triphosphates can be made by substrate level phosphorylation, as well. For example, GTP can be synthesized by the following citric acid cycle reaction.

Succinyl-CoA + GDP + P_i ⇅ Succinate + GTP + CoA-SH

Triphosphates can be interchanged readily in substrate level phosphorylations catalyzed by the enzyme Nucleoside Diphosphate Kinase (NDPK). A generalized form of the reactions catalyzed by this enzyme is as follows:

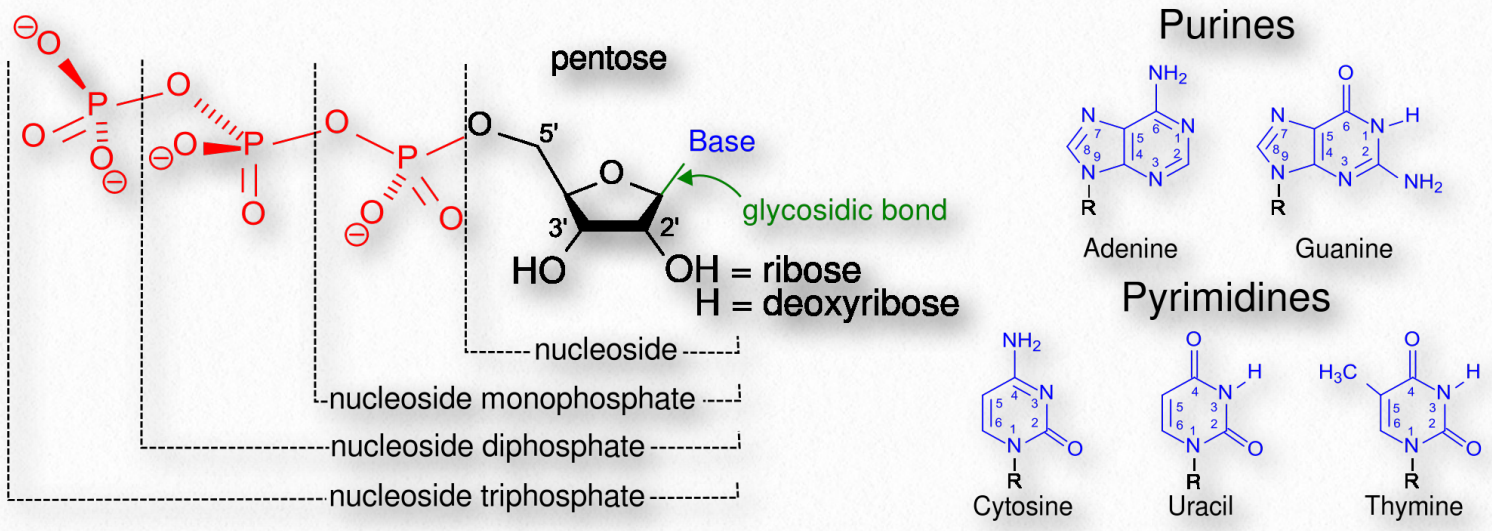

Figure 5.13 - Nucleotides, nucleosides, and bases

$$XTP + YDP \rightleftarrows XDP + YTP$$

where X = adenosine, cytidine, uridine, thymidine, or guanosine and Y can be any of these as well. Further, XTP and YDP can be any of the deoxynucleotides as well.

Last, an unusual way of synthesizing ATP by substrate level phosphorylation is via the reaction catalyzed by adenylate kinase

$$2\ ADP \rightleftarrows ATP + AMP$$

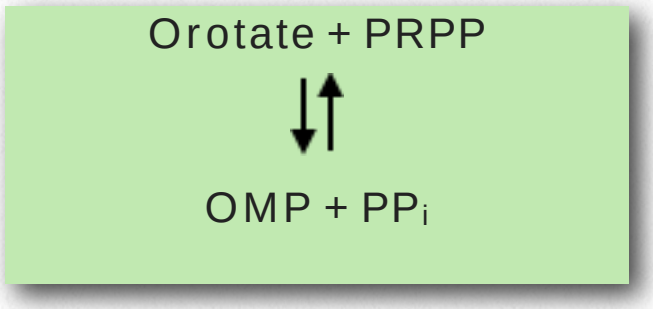
ATP source

This reaction is an important means of generating ATP when the cell doesn't have other sources of energy. Accumulation of AMP resulting from this reaction activates enzymes, such as phosphofructokinase, of glycolysis, which will catalyze reactions to give the cell additional, needed energy.

It is important to note that enzymes cannot make reactions happen that are energetically unfavorable. Enzymes speed reactions, but do not change their direction. Cells are thus bound by the rules of Gibbs free energy. So, how do energetically unfavorable reactions happen in a cell?

Reaction coupling

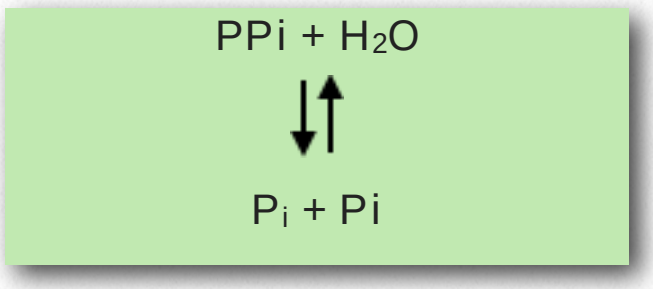
Reactions that are energetically unfavorable, can be made favorable by coupling them with the hydrolysis of ATP, a very energetically favorable reaction. There are numerous parallels in the "real world." Movement of automobiles is energetically unfavorable, but coupling movement of the automobile to oxidation of gasoline makes an unfavorable process favorable. Another approach to making an unfavorable reaction favorable is to manipulate the concentration of reactants and products. Consider the reaction below, which occurs in pyrimidine nucleotide metabolism (top of next page):



The ΔG°' for this reaction is -0.8 kJ/mol, meaning that if one starts with equal concentrations of reactants and products, at equilibrium, there will be a small excess of products. In the cell, however, this reaction moves strongly to the right (ΔG = very negative). Given that the ΔG°' is very close to zero, a very negative ΔG can only occur if the concentrations of reactants and products are altered, since

$$\Delta G = \Delta G^{\circ\prime} + RT\ln \frac{[OMP][PP_i]}{[Orotate][PRPP]}$$

Manipulation is exactly what happens here. The key item whose concentration is adjusted in this reaction is the pyrophosphate (PP_i). This is possible because cells contain an enzyme called pyrophosphorylase that catalyzes the following reaction



Hydrolysis of pyrophosphate is very energetically favored, causing the PPi produced in the reaction to be quickly hydrolyzed. As a result, the concentration of PP_i in the cell is kept very low. A low concentration of a product (PP_i) causes the natural log (ln) term of the orotate equation to become more negative, driving the ΔG term for the overall reaction to become much more negative.

Pushing and pulling

Reactions that yield pyrophosphate as a product are produced in the synthesis of DNA and RNA, as well as many other molecules. As shown in the previous example, this pyrophosphate is rapidly hydrolyzed, causing the overall reaction to move in the direction of pyrophosphate production. When reactants are removed/reduced in a metabolic reaction to decrease the concentration of a product, we say that the reaction is "pulled", to represent the increase in the forward reaction as a result of product depletion.

Pushing happens when reactants in a reaction are added/increased. This too has the effect of reducing the ΔG of a reaction and making it more favorable because the ratio of [Products]/[Reactants] is decreased with increasing [Reactants]. Pushing and pulling of reactions are additional tools for cells to overcome energy barriers, just like coupling energetically favorable processes to energetically unfavorable ones.

Oh Delta G

To the tune of "*Danny Boy*"

Metabolic Melodies Website HERE

Oh Delta G - the change in Gibbs free energy
Can tell us if a process will advance
'Cause if the value's less than naught it translates that
Reverse reactions haven't got a chance

But when the sign is plus it is the opposite
And then the backwards happens all the time
A factor is the standard Gibbs free energy
So don't forget about the Delta G naught prime

Recording by Tim Karplus

Energy: Electron Transport & Oxidative Phosphorylation

In eukaryotic cells, the vast majority of ATP synthesis occurs in the mitochondria in a process called oxidative phosphorylation. Even plants, which generate ATP by photophosphorylation in chloroplasts, contain mitochondria for the synthesis of ATP through oxidative phosphorylation.

Oxidative phosphorylation is linked to a process known as electron transport (Figure 5.14). The electron transport system, located in the inner mitochondrial membrane, transfers electrons donated by the reduced electron carriers NADH and $FADH_2$ (obtained from glycolysis, the citric acid cycle or fatty acid oxidation) through a series of electrons acceptors, to oxygen. As we shall see, movement of electrons through complexes of the electron transport system essentially "charges" a battery that is used to make ATP in oxidative phosphorylation. In this way, the oxidation of sugars and fatty acids is coupled to the synthesis

YouTube Lectures by Kevin HERE & HERE

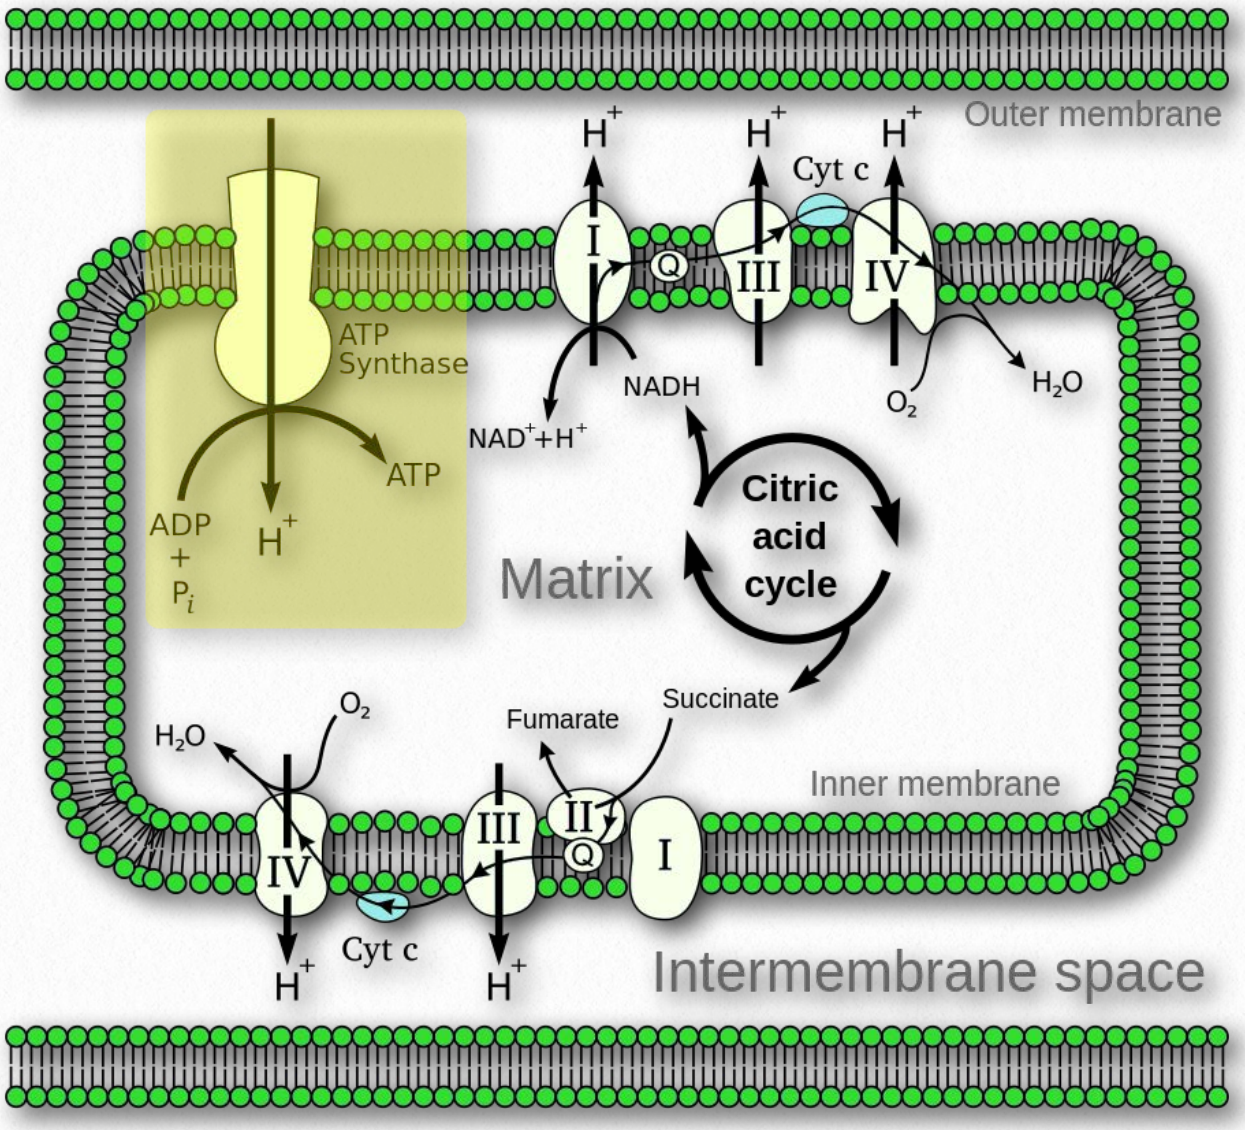

Figure 5.14 - Overview of electron transport (bottom left and top right) and oxidative phosphorylation (top left - yellow box) in the mitochondrion

of ATP, effectively extracting energy from food.

Chemiosmotic model

Dr. Peter Mitchell introduced a radical proposal in 1961 to explain the mechanism by which mitochondria make ATP. It is known as the chemiosmotic hypothesis and has been shown over the years to be correct. Mitchell proposed that synthesis of ATP in mitochondria depends on an electrochemical gradient, across the mitochondrial inner membrane, that arises ultimately from the energy of reduced electron carriers, $NADH$ and $FADH_2$.

Electron transport

Further, the proposal states that the gradient is created when $NADH$ and $FADH_2$ transfer their electrons to an electron transport system (ETS) located in the inner mitochondrial membrane. Movement of electrons through a series of of electron carriers is coupled to the pumping of protons out of the mitochondrial matrix across the inner mitochondrial membrane into the space between the inner and outer membranes. The result is creation of a gradient of protons whose potential energy can be used to make ATP. Electrons combine with oxygen and protons at the end of the ETS to make water.

ATP synthase

In oxidative phosphorylation, ATP synthesis is accomplished as a result of protons re-entering the mitochondrial matrix *via* the transmembrane ATP synthase complex, which combines ADP with inorganic phos-

phate to make ATP. Central to the proper functioning of mitochondria through this process is the presence of an intact mitochondrial inner membrane impermeable to protons.

Tight coupling

When this is the case, tight coupling is said to exist between electron transport and the synthesis of ATP (called oxidative phosphorylation). Chemicals which permeabilize the inner mitochondrial membrane to protons cause *uncoupling*, that is, they allow the protons to leak back into the mitochondrial matrix, rather than through the ATP synthase, so that the movement of electrons through the ETS is no longer linked to the synthesis of ATP.

Power plants

Mitochondria are called the power plants of the cell because most of a cell's ATP is produced there in the process of oxidative phosphorylation. The mechanism by which ATP is made in oxidative phosphorylation is one of the most interesting in all of biology.

Considerations

The process has three primary considerations. The first is electrical – electrons from reduced electron carriers, such as NADH and $FADH_2$, enter the electron transport system *via* Complex I and II, respectively. As seen in Figure 5.16 and Figure 5.17, electrons move from one complex to the next, not unlike the way they move through an electrical circuit. Such movement occurs a a result of a set of reduction-oxidation (redox) reactions with electrons moving from a more nega-

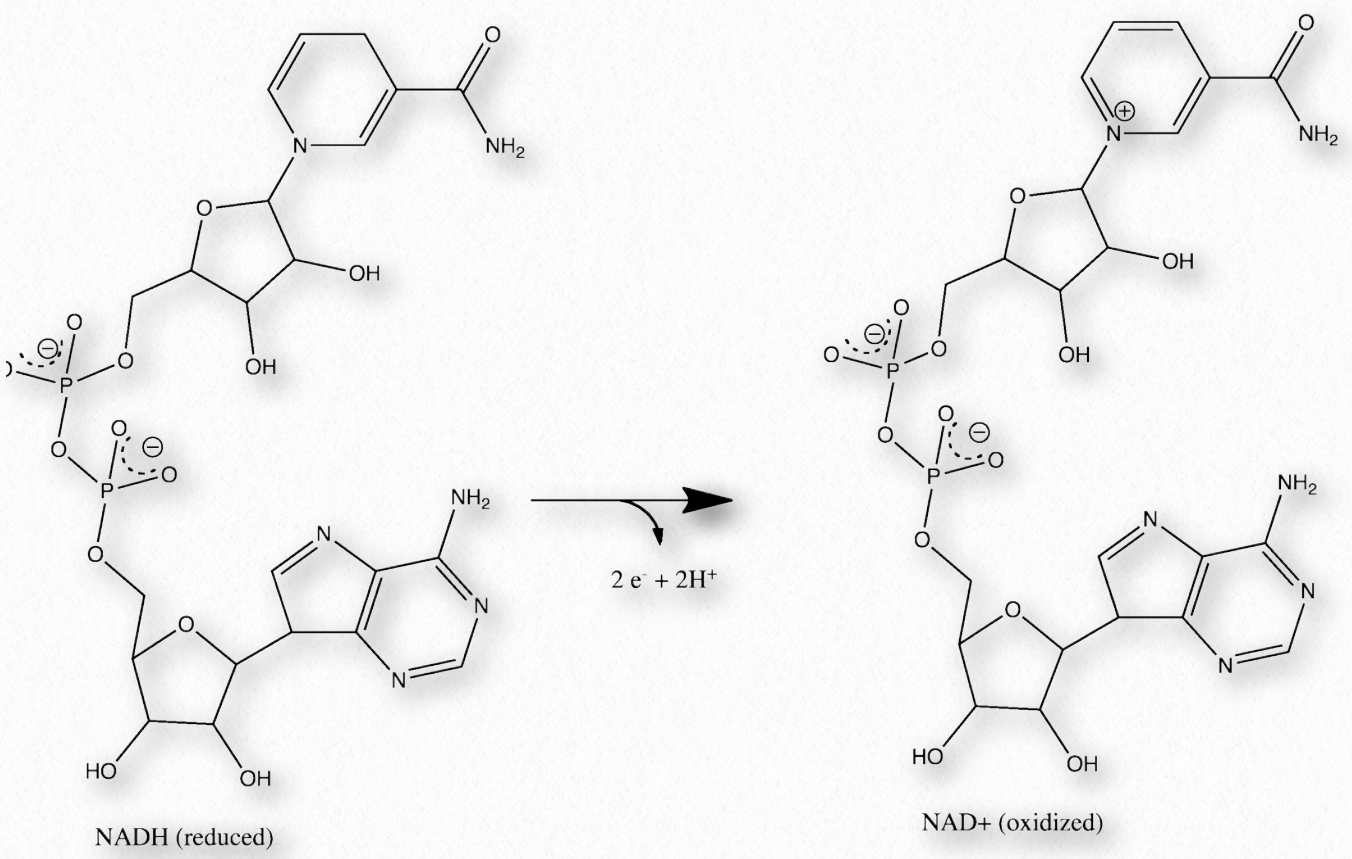

Figure 5.15 - Loss of electrons by NADH to form NAD^+. Relevant reactions occur in the top ring of the molecule.

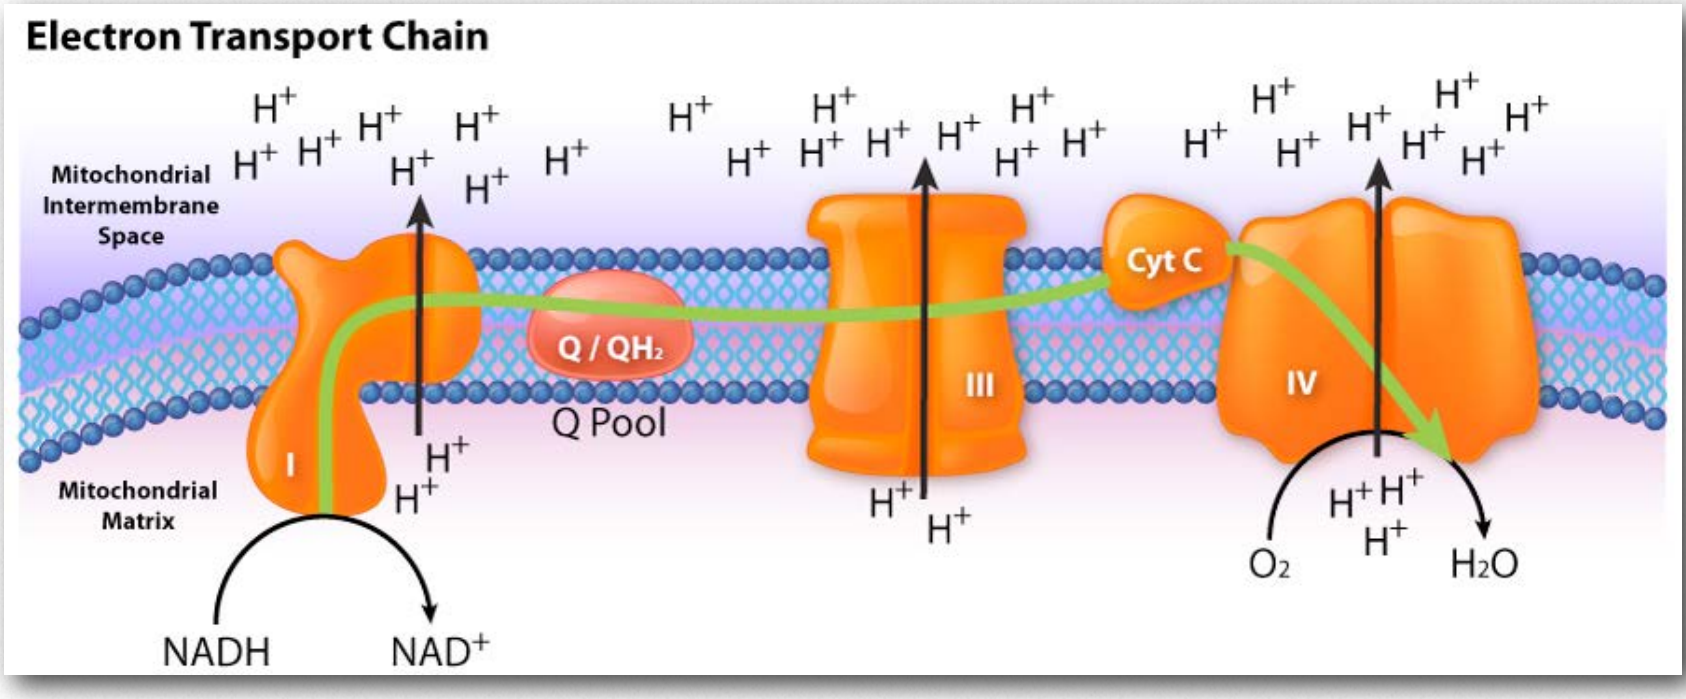

Figure 5.16 - Flow of electrons from NADH into the electron transport system. Entry is through complex I

Image by Aleia Kim

tive reduction potential to a more positive one.

One can think of this occurring as a process where carriers "take" electrons away from complexes with lower reduction potential, much the way a bully takes lunch money from a smaller child. In this scheme, the biggest "bully" is oxygen in Complex IV. Electrons gained by a

Image by Aleia Kim

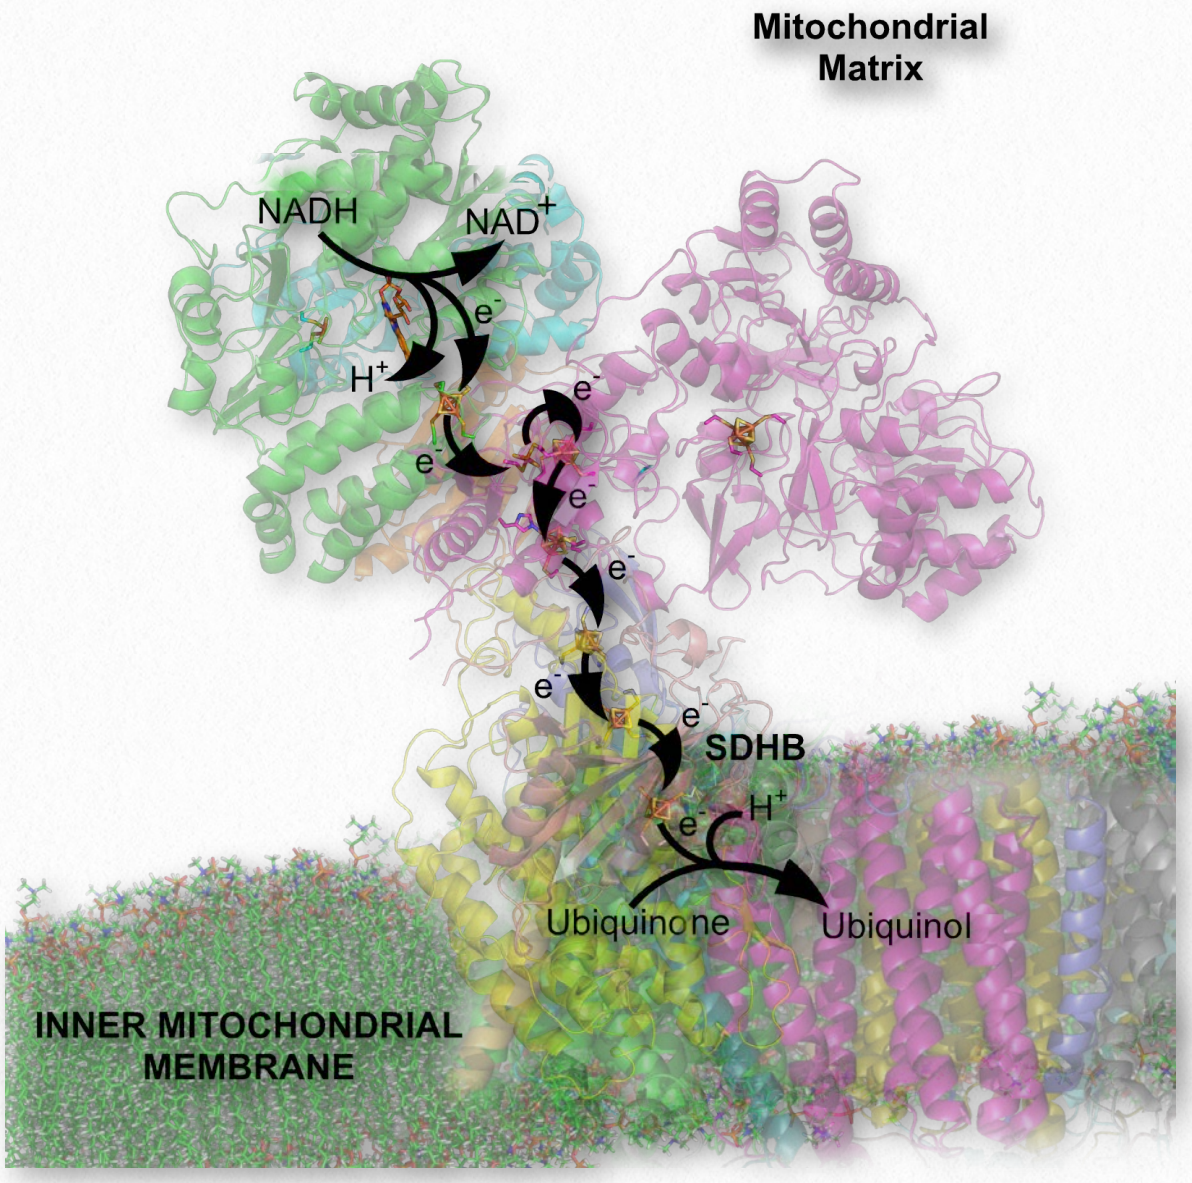

Figure 5.18 - Complex I embedded in the inner mitochondrial membrane. The mitochondrial matrix at at the top

Wikipedia

carrier cause it to be reduced, whereas the carrier giving up the electrons is oxidized.

Entry of electrons to system

Movement of electrons through the chain begins either by 1) transfer from NADH to Complex I (Figure 5.16) or 2) movement of electrons through a covalently bound $FADH_2$ (Figure 5.17) in the membrane-bound succinate dehydrogenase (Complex II). (An alternate entry point for electrons from $FADH_2$ is the Electron Transferring Flavoprotein *via* the electron-transferring-flavoprotein dehydrogenase, not shown).

Traffic cop

Both Complex I and II pass electrons to the inner membrane's coenzyme Q (CoQ - Figures 5.18 & 5.19). In each case, coenzyme Q accepts electrons in pairs and passes them off to Complex III ($CoQH_2$-cytochrome c reductase) singly. Coenzyme Q thus acts as a traffic cop, regulating the flow of electrons through the ETS.

Docking station

Complex III is a docking station or interchange for the incoming electron carrier (coenzyme Q) and the outgoing carrier (cytochrome c). Movement of electrons from Coenzyme Q to Complex III and then to cytochrome C occurs as a result of what is referred to as the Q-cycle (see below).

Complex III acts to ferry electrons from CoQ to cytochrome c. Cytochrome c takes one electron from Complex III and passes it to Complex IV (cytochrome oxidase). Complex IV is the final protein recipient of the electrons. It passes them to molecular oxygen (O_2) to make two molecules of water. Making two water

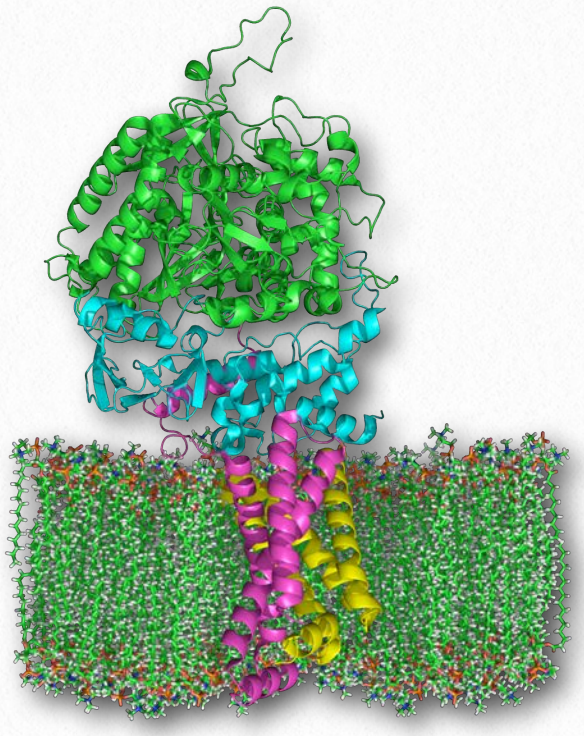

Figure 5.19 - Complex II embedded in inner mitochondrial membrane. Matrix is up.

Wikipedia

molecules requires four electrons, so Complex IV must accept, handle, and pass to molecular oxygen four separate electrons, causing the oxidation state of oxygen to be sequentially changed with addition of each electron.

Proton pumping

As electrons pass through complexes I, III, and IV, there is a release of a small amount of energy at each step, which is used to pump protons from the mitochondrial matrix (inside of mitochondrion) and deposit them in the intermembrane space (between the inner and outer membranes of the mitochondrion). The effect of this redistribution is to increase the electrical and chemical potential across the membrane.

YouTube Lectures by Kevin HERE & HERE

Potential energy

As discussed earlier, electrochemical gradients have potential energy. Students may think of the process as "charging the battery." Just like a charged battery, the potential arising from the proton differential across the membrane can be used to do things. In the mitochondrion, what the proton gradient does is facilitate the production of ATP from ADP and P_i. This process is known as oxidative phosphorylation, because the phosphorylation of ADP to ATP is dependent on the oxidative reactions occurring in the mitochondria.

Having understood the overall picture of the synthesis of ATP linked to the movement of electrons through the ETS, we will take a closer look at the individual components of the ETS.

Complex I

Complex I (also called NADH:ubiquinone oxidoreductase or NADH dehydrogenase (ubiquinone)) is the electron acceptor from NADH in the electron transport chain and the largest complex found in it.

Complex I contains 44 individual polypeptide chains, numerous iron-sulfur centers, a molecule of flavin mononucleotide (FMN) and has an L shape with

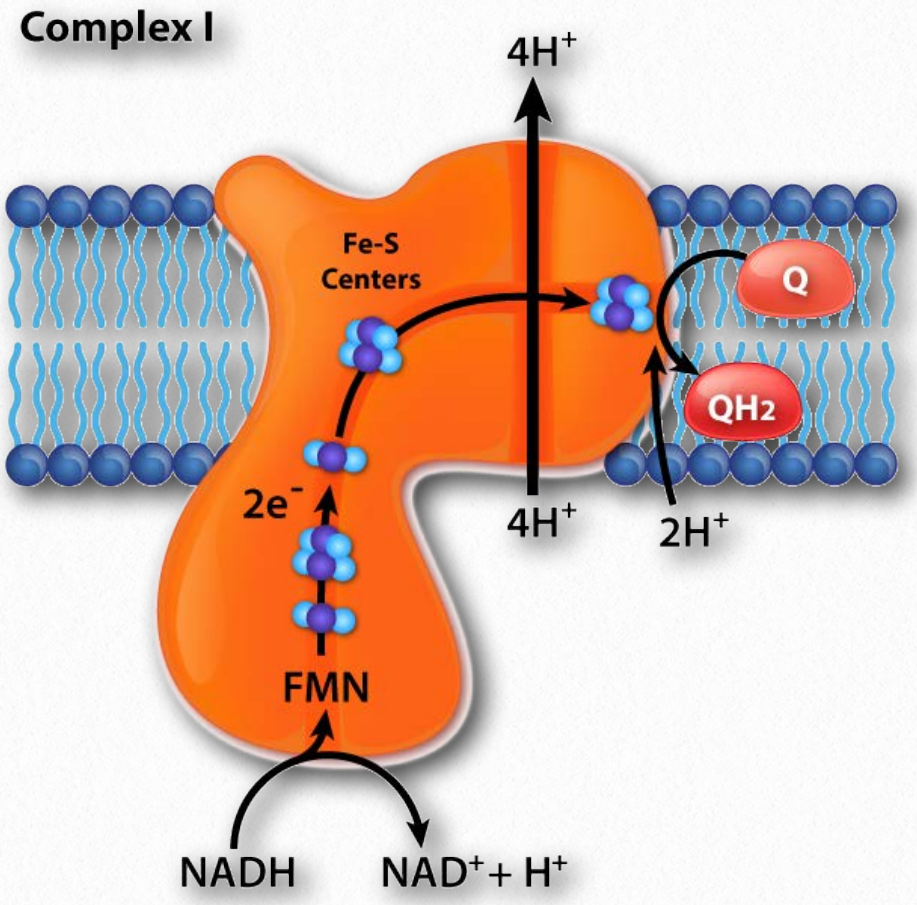

Figure 5.20 - Movement of electrons through complex I from NADH to coenzyme Q. The mitochondrial matrix is at the bottom

Image by Aleia Kim

about 60 transmembrane domains. In the process of electron transport through it, four protons are pumped across the inner membrane into the intermembrane space and electrons move from NADH to coenzyme Q, converting it from ubiquinone (no electrons) to ubiquinol (gain of two electrons). An intermediate form, ubisemiquinone (gain of one electron), is found in the Q-cycle.

Electrons travel through the complex *via* seven primary iron sulfur centers. The best known inhibitor of the complex, rotenone, works by binding to the CoQ binding site. Other inhibitors include ADP-ribose (binds to the NADH site) and piericidin A (rotenone analog). The process of electron transfer through complex I is reversible and when this occurs, superoxide (a reactive oxygen species) may be readily generated.

Complex II

Complex II (also called succinate dehydrogenase or succinate-coenzyme Q reductase) is a membrane bound enzyme of the citric acid cycle that plays a role in the electron transport process, transferring electrons from its covalently bound $FADH_2$ to coenzyme Q. The process occurs, as shown in Figure 5.20 and Figure 5.21, with transfer of electrons from succinate to FAD to

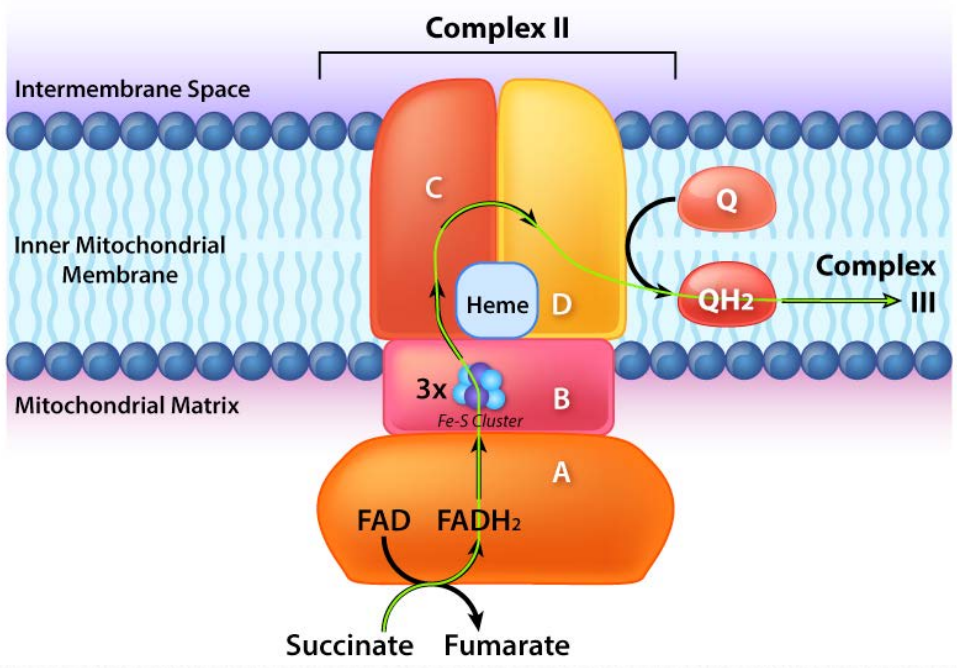

Figure 5.21 - Movement of electrons from succinate through complex II (A->B->C->D->Q). Mitochondrial matrix on bottom.

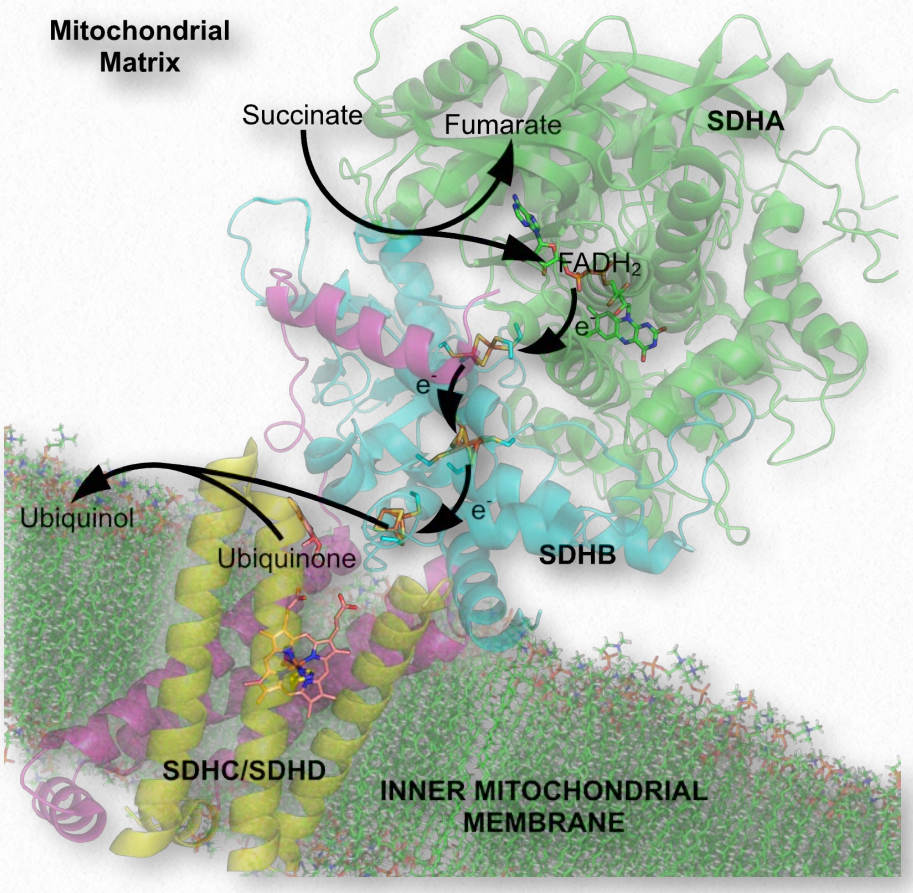

Figure 5.22 - Complex II in inner mitochondrial membrane showing electron flow. Matrix is up.

Wikipedia

form $FADH_2$ and fumarate. $FADH_2$, in turn, donates electrons to a relay system of iron-sulfur groups and they ultimately reduce ubiquinone (CoQ) along with two protons from the matrix to ubiquinol. The role of the heme group in the process is not clear. Inhibitors of the process include carboxin, malonate, malate, and oxaloacetate. The role of citric acid cycle intermediates as inhibitors is thought to be due to inhibition of the reversal of the transfer process which can produce superoxide.

Coenzyme Q

Coenzyme Q (Figure 5.23) is a 1,4 benzoquinone whose name is often given as Coenzyme Q_{10}, CoQ, or Q_{10}. The 10 in the name refers to the number of isoprenyl units it contains that anchor it to the mitochondrial inner membrane. CoQ is a vitamin-like lipid substance found in most eukaryotic cells as a component of the electron transport system. The requirement for CoQ increases with increasing energy needs of cells, so the highest concentrations of CoQ in the body are found in tissues that are the most metabolically active - heart, liver, and kidney.

Three forms

CoQ is useful because of its ability to carry and donate electrons and particularly because it can exist in forms with two extra electrons (fully reduced - ubiquinol), one extra electron (semi-reduced - ubisemiquinone),

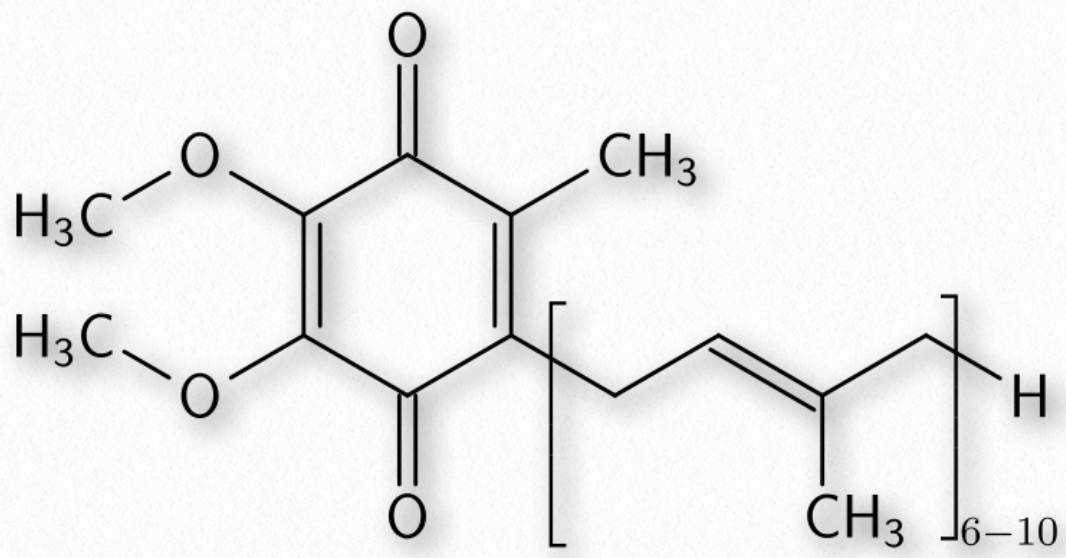

Figure 5.23 - Coenzyme Q

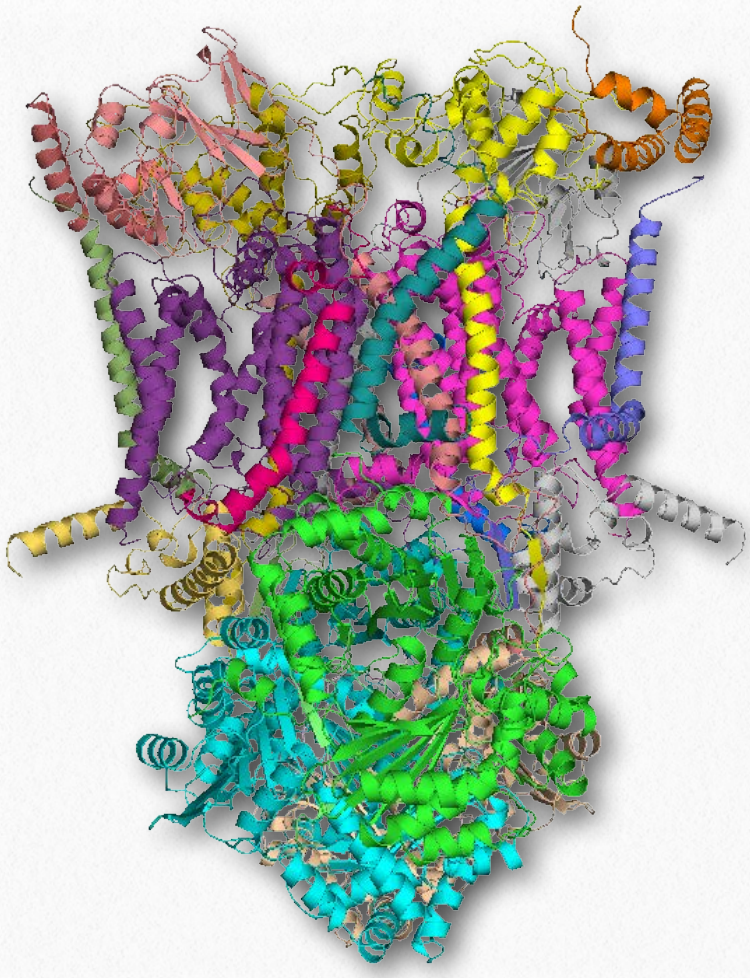

Figure 5.24 - Complex III

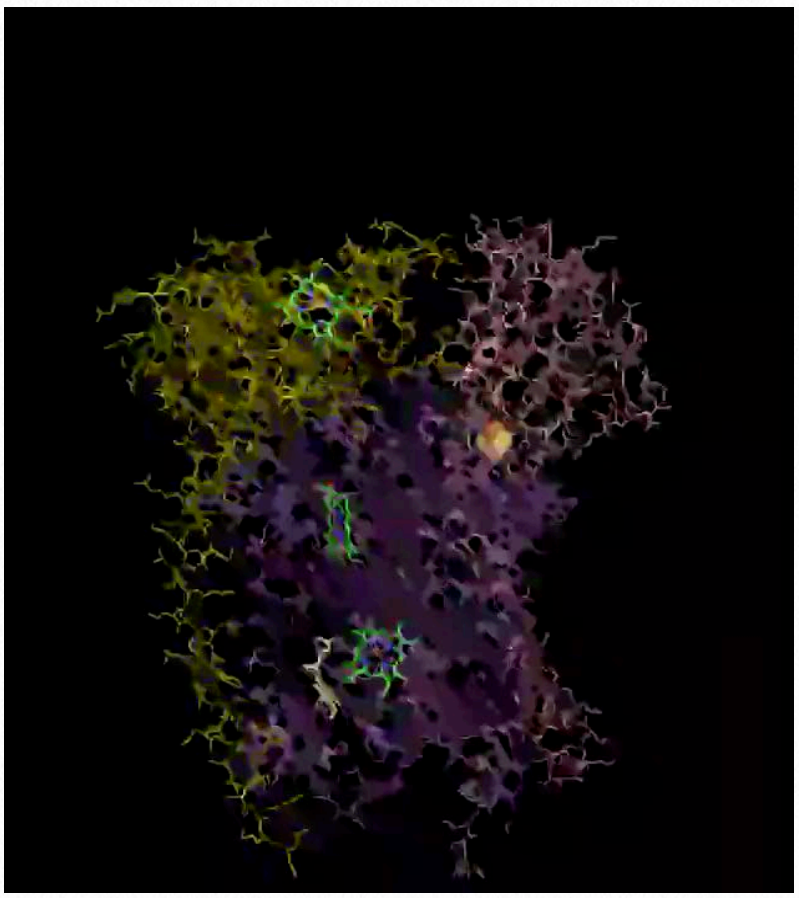
Wikipedia

or no extra electrons (fully oxidized - ubiquinone). This ability allows CoQ to provide transition between the first part of the electron transport system that moves electrons in pairs and the last part of the system that moves electrons one at a time.

Complex III

Complex III (also known as coenzyme Q : cytochrome c — oxidoreductase or the cytochrome bc_1 complex - Figure 5.24) is the third electron accepting complex of the electron transport system. It is a transmembrane protein with multiple subunits present in the mitochondria of all aerobic eukaryotic organisms and and the cell membrane of almost all bacteria. The complex contains 11 subunits, a 2-iron ferredoxin, cytochromes b and c_1 and belongs to the family of oxidoreductase enzymes.

It accepts electrons from coenzyme Q in electron transport and passes them off to cytochrome c. In this cycle, known as the Q cycle, electrons arrive from CoQ in pairs, but get passed to cytochrome c individually. In the overall process, two protons are consumed from the matrix and four protons are pumped into the intermembrane space. Movement of electrons through the complex can be inhibited by antimycin A, myxothiazol, and stigmatellin. Complex III is also implicated in creation of superoxide (a reactive oxygen species) when electrons from it leak



Movie 5.2 - The Q-cycle

Wikipedia

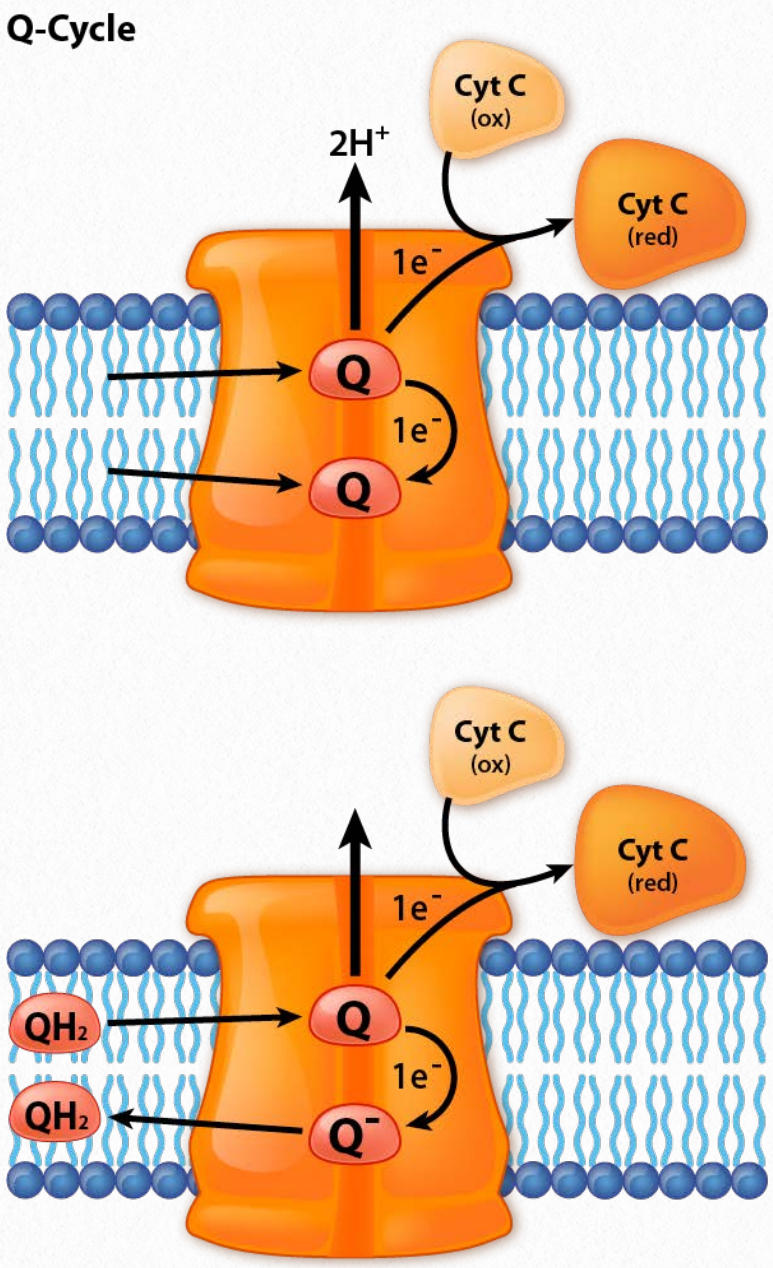


Figure 5.25 - The Q-cycle. Matrix is down.

Image by Aleia Kim

out of the chain of transfer. The phenomenon is more pronounced when antimycin A is present.

Q-cycle

In the Q-cycle, electrons are passed from ubiquinol (QH_2) to cytochrome c using Complex III as an intermediary docking station for the transfer. Two pair of electrons enter from QH_2 and one pair is returned to another CoQ to remake QH_2. The other pair is donated singly to two different cytochrome c molecules.

YouTube Lectures by Kevin HERE & HERE

Step one

The Q-cycle happens in a two step process. First, a ubiquinol ($CoQH_2$) and a ubiquinone (CoQ) dock at Complex III. Ubiquinol transfers two electrons to Complex III. One electron goes to a docked cytochrome c, reducing it and it exits (replaced by an oxidized cytochrome c). The other goes to the docked uniquinone to create the semi-reduced semiubiquinone ($CoQ.^-$) and leaving behind a ubiquinone, which exits. This is the end of step 1.

Step two

The gap left behind by the ubiquinone (Q) that departed is replaced by another ubiquinol (QH_2). It too donates two electrons to Complex III, which splits them. One goes to the newly docked oxidized cytochrome c, which is reduced and exits. The other goes to the ubisemiquinone. Two protons from the matrix combine with it to make another ubiquinol. It and the ubiquinone created by the electron donation exit Complex III and the process starts again. In the overall process, two protons are consumed from the matrix and four protons are pumped into the intermembrane space.

Cytochrome c

Cytochrome c (Figure 5.26) is a small (12,000 Daltons), highly conserved protein,

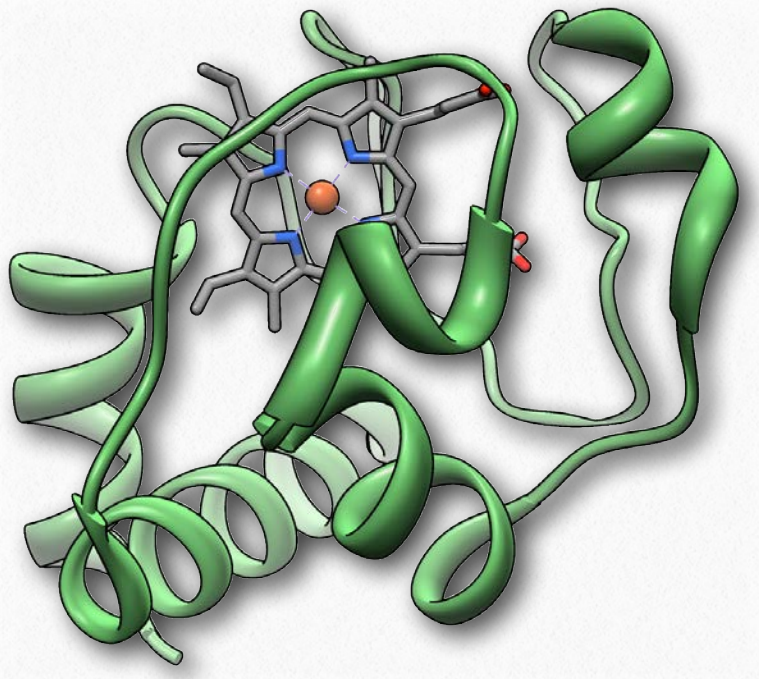

Figure 5.25 - Cytochrome c with bound heme Group

Wikipedia

from unicellular species to animals, that is loosely associated with the inner mitochondrial membrane where it functions in electron transport. It contains a heme group which is used to carry a single electron from Complex III to Complex IV. Cytochrome c also plays an important role in apoptosis in higher organisms. Damage to the mitochondrion that results in release of cytochrome c can stimulate assembly of the apoptosome and activation of the caspase cascade that leads to programmed cell death.

Complex IV

Complex IV, also known as cytochrome c oxidase is a 14 subunit integral membrane protein at the end of the electron transport chain (Figure 5.27). It is responsible for accepting one electron each from four cytochrome c proteins and adding them to molecular oxygen (O_2) along with four protons from the mitochondrial matrix to make two molecules of water. Four protons from the matrix are also pumped into the intermembrane space in the process. The complex has two molecules of heme, two cytochromes (a and a_3), and two copper centers (called CuA ad CuB). Cytochrome c docks near the CuA and donates an electron to it. The reduced CuA passes the electron to cytochrome a, which turns it over to the a_3-CuB center where the oxygen is reduced. The four electrons are thought to pass through the complex rapidly resulting in com-

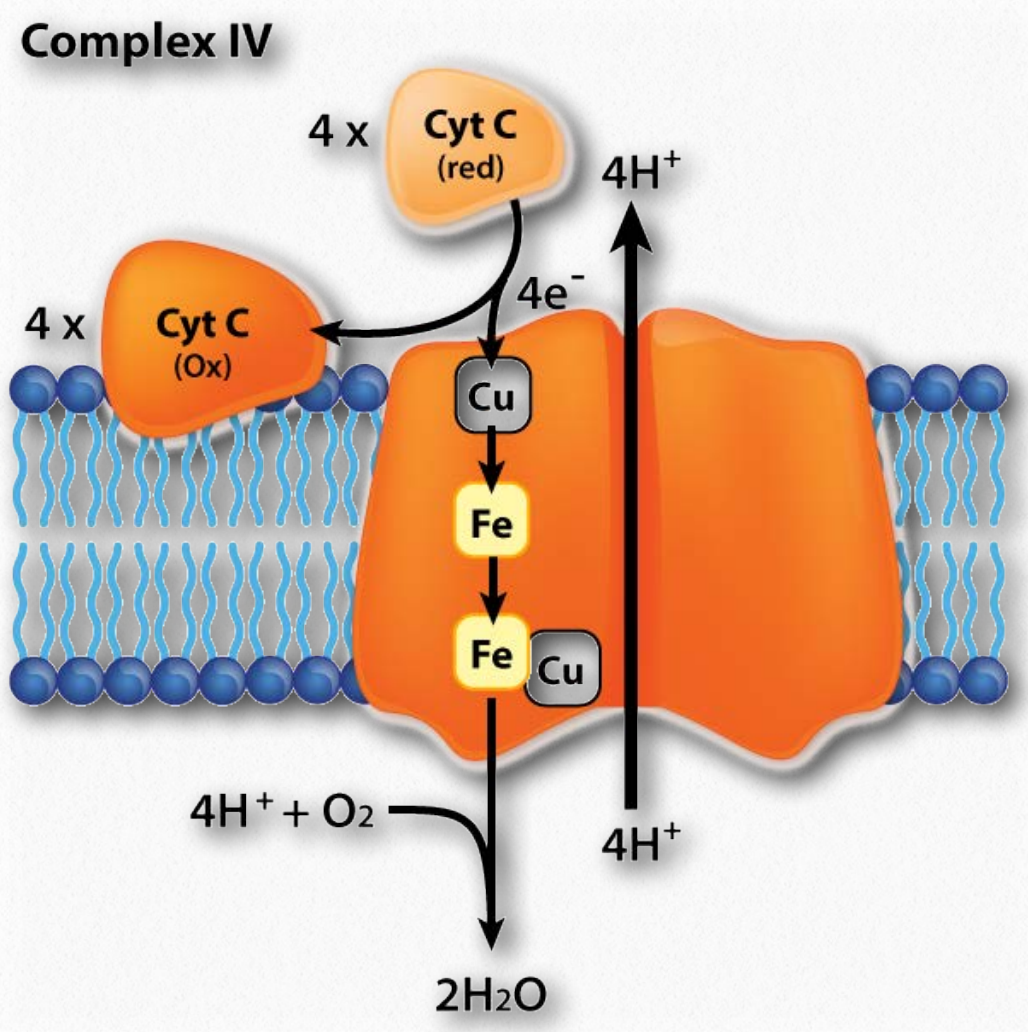

Figure 5.26 - Movement of electrons and protons through complex IV. Matrix is down

plete reduction of the oxygen-oxygen molecule without formation of a peroxide intermediate or superoxide, in contrast to previous predictions.

Respirasome

There has been speculation for many years that a supercomplex of electron carriers in the inner membrane of the mitochondrion may exist in cells with individual carriers making physical contact with each other. This would make for more efficient transfer reactions, minimize the production of reactive oxygen species and be similar to metabolons of metabolic pathway enzymes, for which there is some evidence. Now, evidence appears to be accumulating that complexes I, III, and IV form a supercomplex, which has been dubbed the respirasome[1].

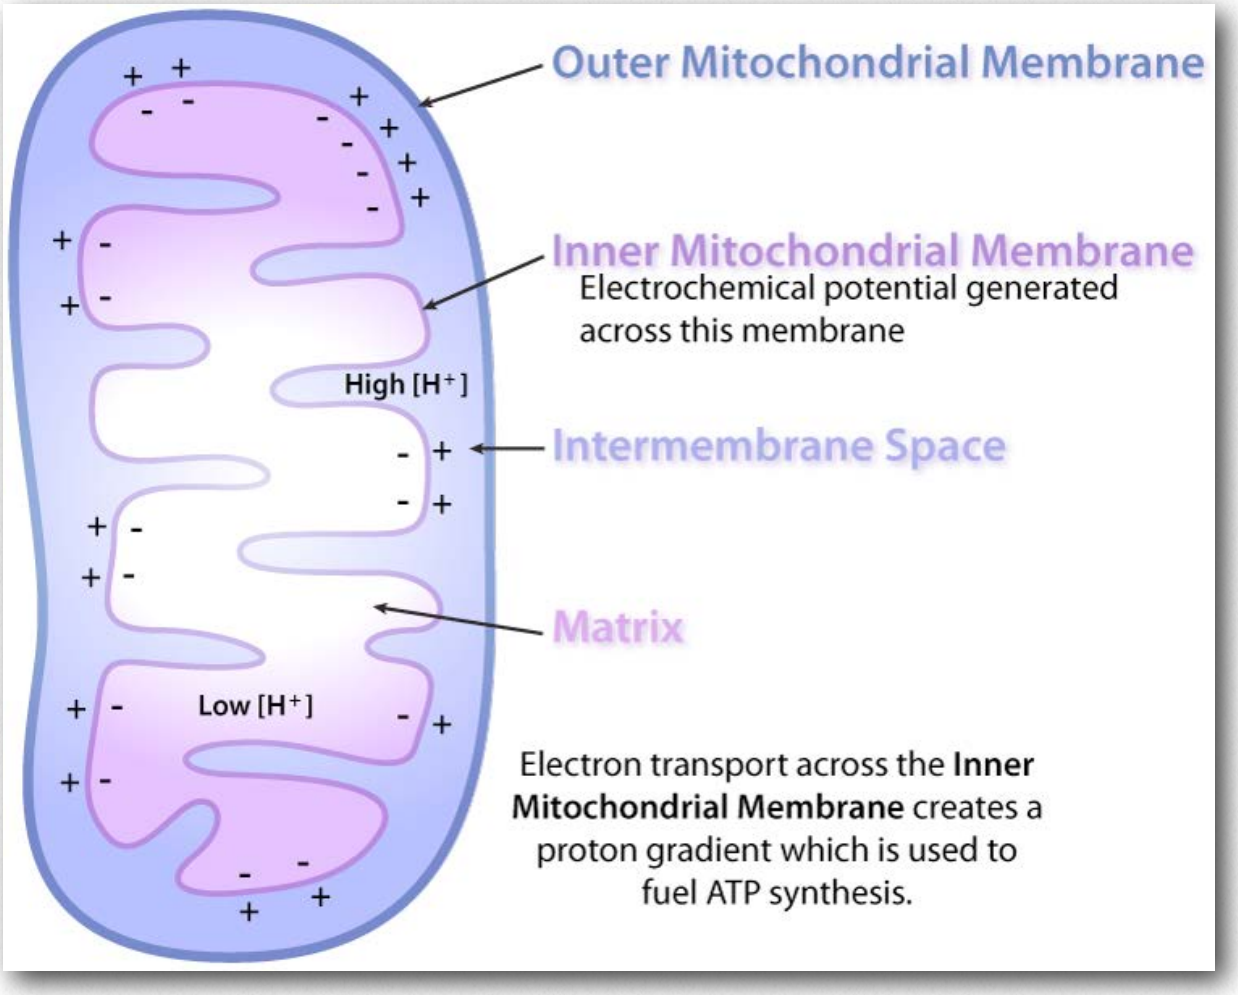

Figure 5.27 - Mitochondrial anatomy. Electron transport complexes and ATP synthase are embedded in the inner mitochondrial membrane

Image by Aleia Kim

Oxidative phosphorylation

The process of oxidative phosphorylation uses the energy of the proton gradient established by the electron transport system as a means of phosphorylating ADP to make ATP. The establishment of the proton gradient is dependent upon electron transport. If electron transport stops or if the inner mitochondrial membrane's impermeability to protons is compromised, oxidative phosphorylation will not occur because without the proton gradient to drive the ATP synthase, there will be no synthesis of ATP.

ATP synthase

The protein complex harvesting energy from the proton gradient and using it to make ATP from ADP is an enzyme that has several

names - Complex V, PTAS (Proton Translocating ATP Synthase), and ATP synthase (Figure 5.29). Central to its function is the movement of protons through it (from the intermembrane space back into the matrix). Protons will only provide energy to make ATP if their concentration is greater in the intermembrane space than in the matrix and if ADP is available.

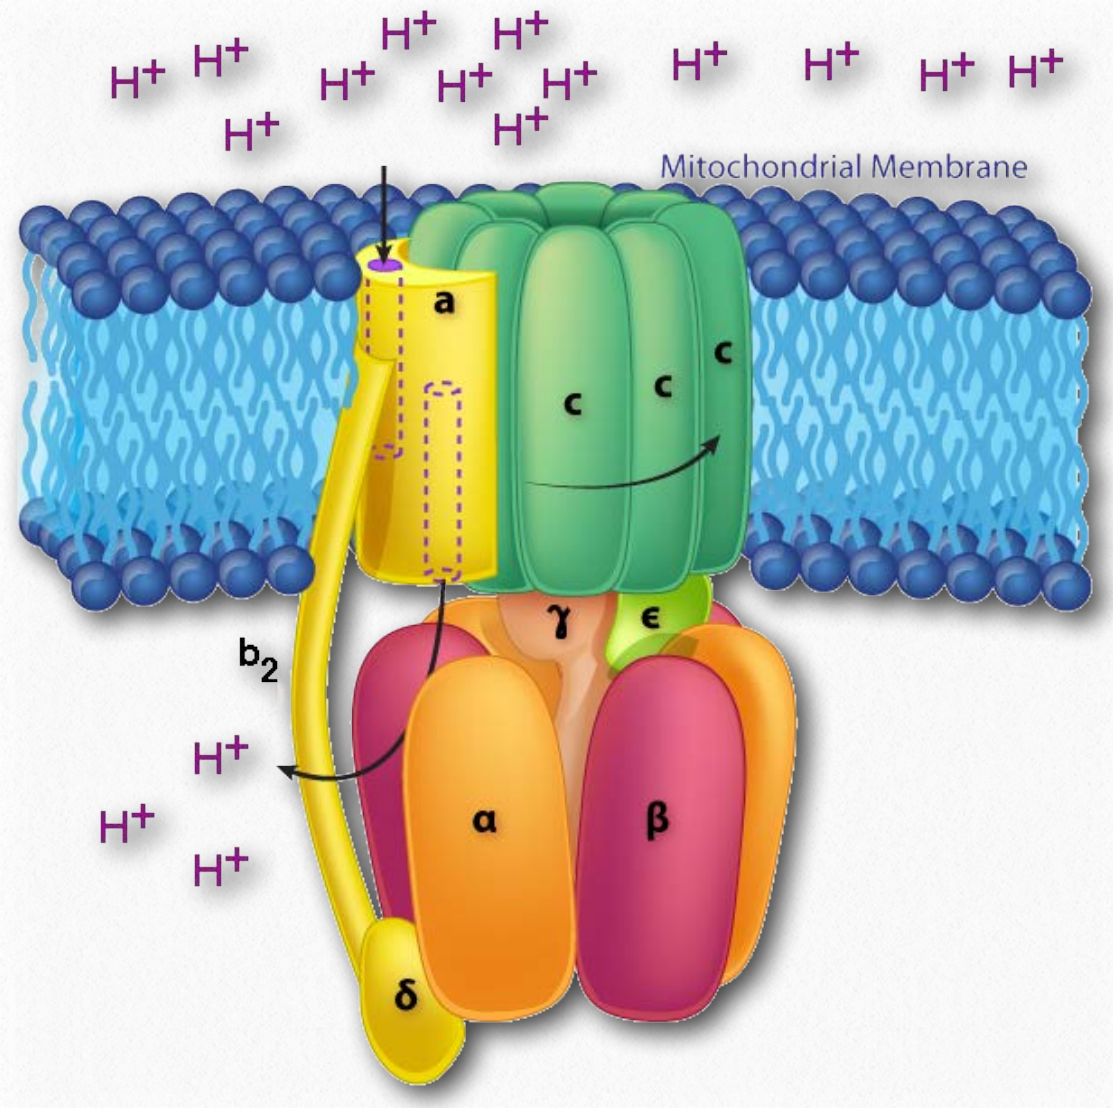

Figure 5.28 - ATP synthase. Protons pass from intermembrane space (top) through the complex and exit in the matrix (bottom).

Image by Aleia Kim

It is possible, in some cases, for the concentration of protons to be greater inside the matrix than outside of it. When this happens, the ATP synthase can run backwards, with protons moving from inside to out, accompanied by conversion of ATP to ADP + P_i. This is usually not a desirable circumstance and there are some controls to reduce its occurrence.

Normally, ATP concentration will be higher inside of the mitochondrion and ADP concentration be higher outside the mitochondrion. However, when the rate of ATP synthesis exceeds the rate of ATP usage, then ATP concentrations rise outside the mitochondrion and ADP concentrations fall everywhere.

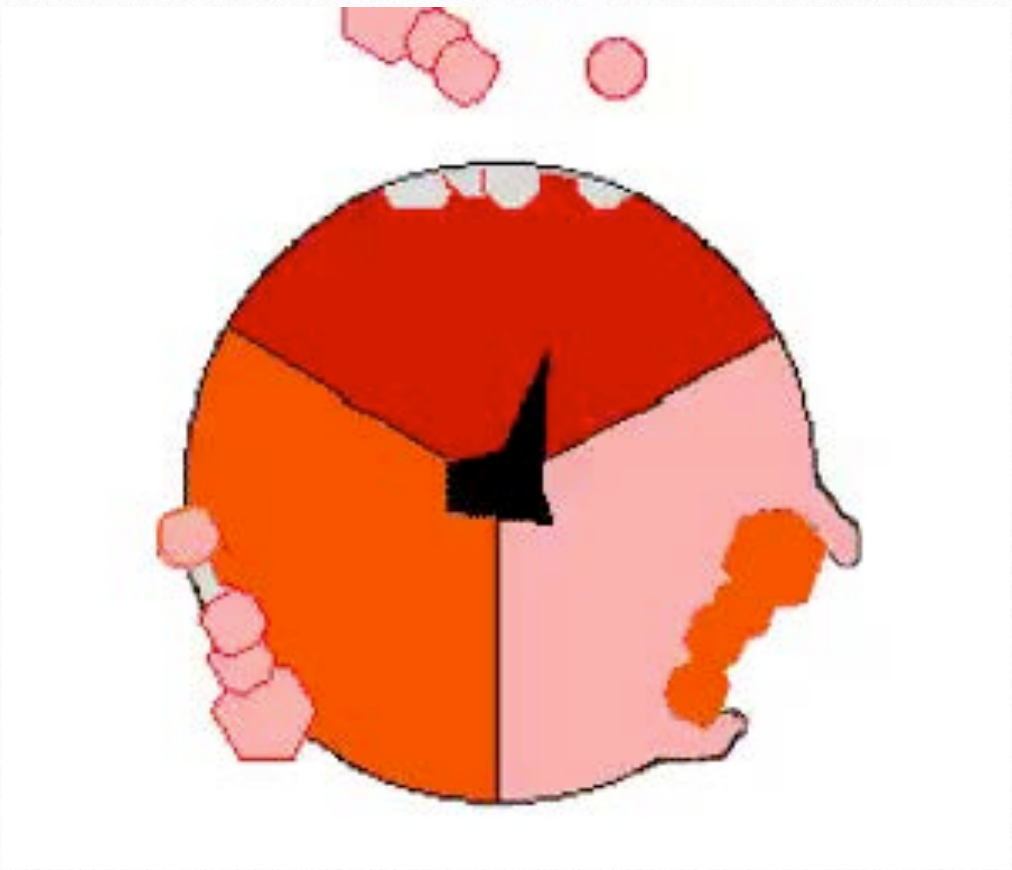
Interactive Learning Module HERE

This may happen, for example, during periods of rest. It has the overall effect of reducing transport and thus lowering the concentration of ADP inside the matrix. Reducing ADP concentration in the matrix reduces oxidative phosphorylation and has effects on respiratory control (see HERE).

Another important consideration is that when ATP is made in oxidative phosphorylation, it is released into the mitochondrial matrix, but must be trans-

ported into the cytosol to meet the energy needs of the rest of the cell. This is accomplished by action of the adenine nucleotide translocase, an antiport that moves ATP out of the matrix in exchange for ADP moving into the matrix. This transport system is driven by the concentrations of ADP and ATP and ensures that levels of ADP are maintained within the mitochondrion, permitting continued ATP synthesis.

One last requirement for synthesis of ATP from ADP is that phosphate must also be imported into the matrix. This is accomplished by action of the phosphate translocase, which is a symport that moves phosphate into the mitochondrial matrix along with a proton.



Movie 5.3 - ATP Synthase - ADP + Pi (pink) and ATP (red). The view is end-on from the cytoplasmic side viewing the β subunits

There is evidence that the two translocases and ATP synthase may exist in a complex, which has been dubbed the ATP synthasome.

In summary, the electron transport system charges the battery for oxidative phosphorylation by pumping protons out of the mitochondrion. The intact inner membrane of the mitochondrion keeps the protons out, except for those that re-enter through ATP Synthase. The ATP Synthase allows protons to re-enter the mitochondrial matrix and harvests their energy to make ATP.

ATP synthase mechanism

The ATP Synthase itself is an amazing nanomachine that makes ATP using a gradient of protons flowing through it from the intermembrane space back into the matrix. It is not easy to depict in a single image what the synthase does. Figure 5.31 and Figure 5.32 illustrate the multi-subunit nature of this membrane protein, which acts like a turbine at a hydroelectric dam. The movement of protons through the ATP Synthase c-ring causes it and the γ-ε

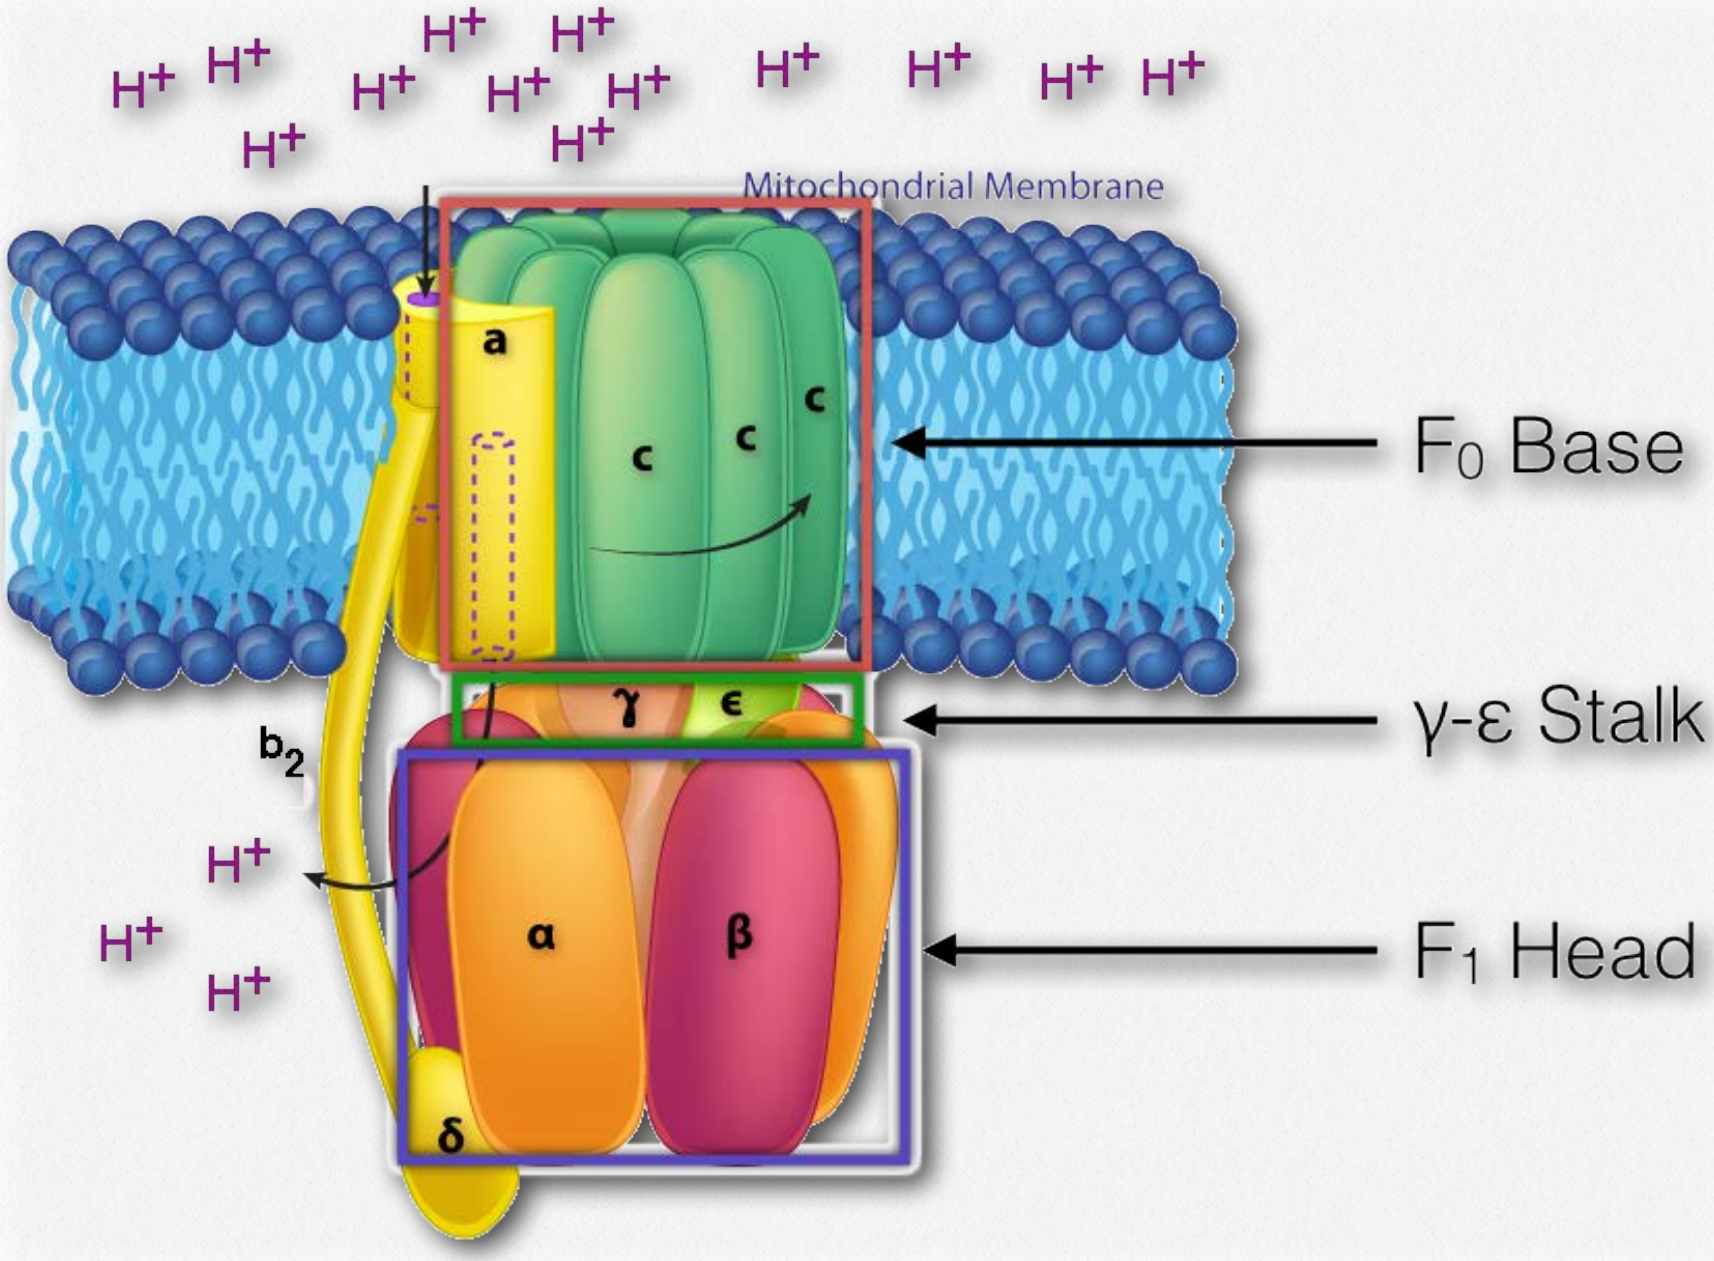


Figure 5.29 - Important structural features of the ATP synthase

Image by Aleia Kim

stalk attached to it to turn. It is this action that is necessary for making ATP.

In ATP Synthase, the spinning components, or rotor, are the membrane portion (c ring) of the F_0 base and the γ-ε stalk, which is connected to it. The γ-ε stalk projects into the F_1 head of the mushroom structure. The F_1 head contains the catalytic ability to make ATP. The F_1 head is hexameric in structure with paired α and β proteins arranged in a trimer of dimers. ATP synthesis occurs within the β subunits.

Rotation of γ unit

Turning of the γ shaft (caused by proton flow) inside the α-β trimer of the F_1 head causes each set of β proteins to change structure slightly into three different forms called Loose, Tight, and Open (L,T,O - Figure 5.31). Each of these forms has a function.

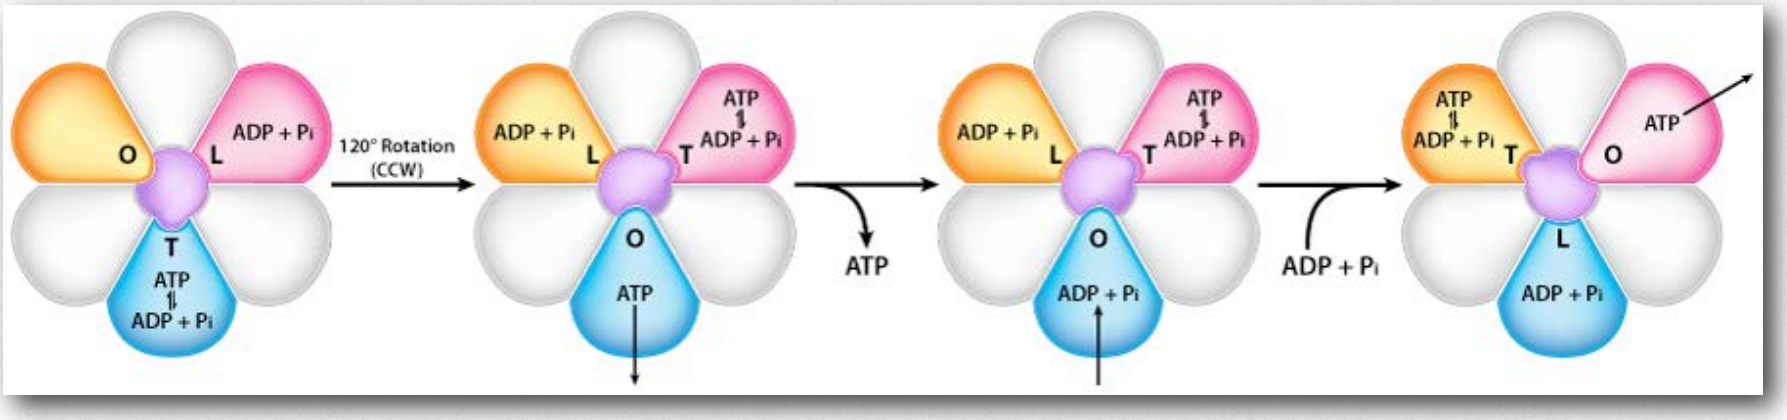

Figure 5.30 - Loose (L), Tight (T), and Open (O) structures of the F_1 head of ATP synthase. Change of structure occurs by rotation of γ-protein (purple) in center as a result of proton movement. Individual α and β units do not rotate

Image by Aleia Kim

The Loose form binds ADP + P_i. The Tight form "squeezes" them together to form the ATP. The Open form releases the ATP into the mitochondrial matrix. Thus, as a result of the proton flow through the ATP synthase, from the intermembrane space into the matrix, ATP is made from ADP and P_i.

Respiratory control

When a mitochondrion has an intact inner membrane and protons can only return to the matrix by passing through the ATP synthase, the processes of electron transport and oxidative phosphorylation are said to be tightly coupled.

Interdependence

In simple terms, tight coupling means that the processes of electron transport and oxidative phosphorylation are interdependent. Without electron transport going on in the cell, oxidative phosphorylation will soon stop. The reverse is also true, because if oxidative phosphorylation stops, the proton gradient will not be dissipated as it is being built by the electron transport system and will grow larger and larger. The greater the gradient, the greater the energy needed to pump protons out of the mitochondrion. Eventually, if nothing relieves the gradient, it becomes too large and the energy of electron transport is insufficient to perform the pumping. When pumping stops, so too does electron transport.

ADP dependence

Another relevant point is that ATP synthase is totally dependent upon a supply of ADP. In the absence of ADP, the ATP synthase stops functioning and when it stops, so too does movement of protons back into the mitochondrion. With this information, it is possible to understand the link between energy usage and metabolism. The root of this, as noted, is respiratory control.

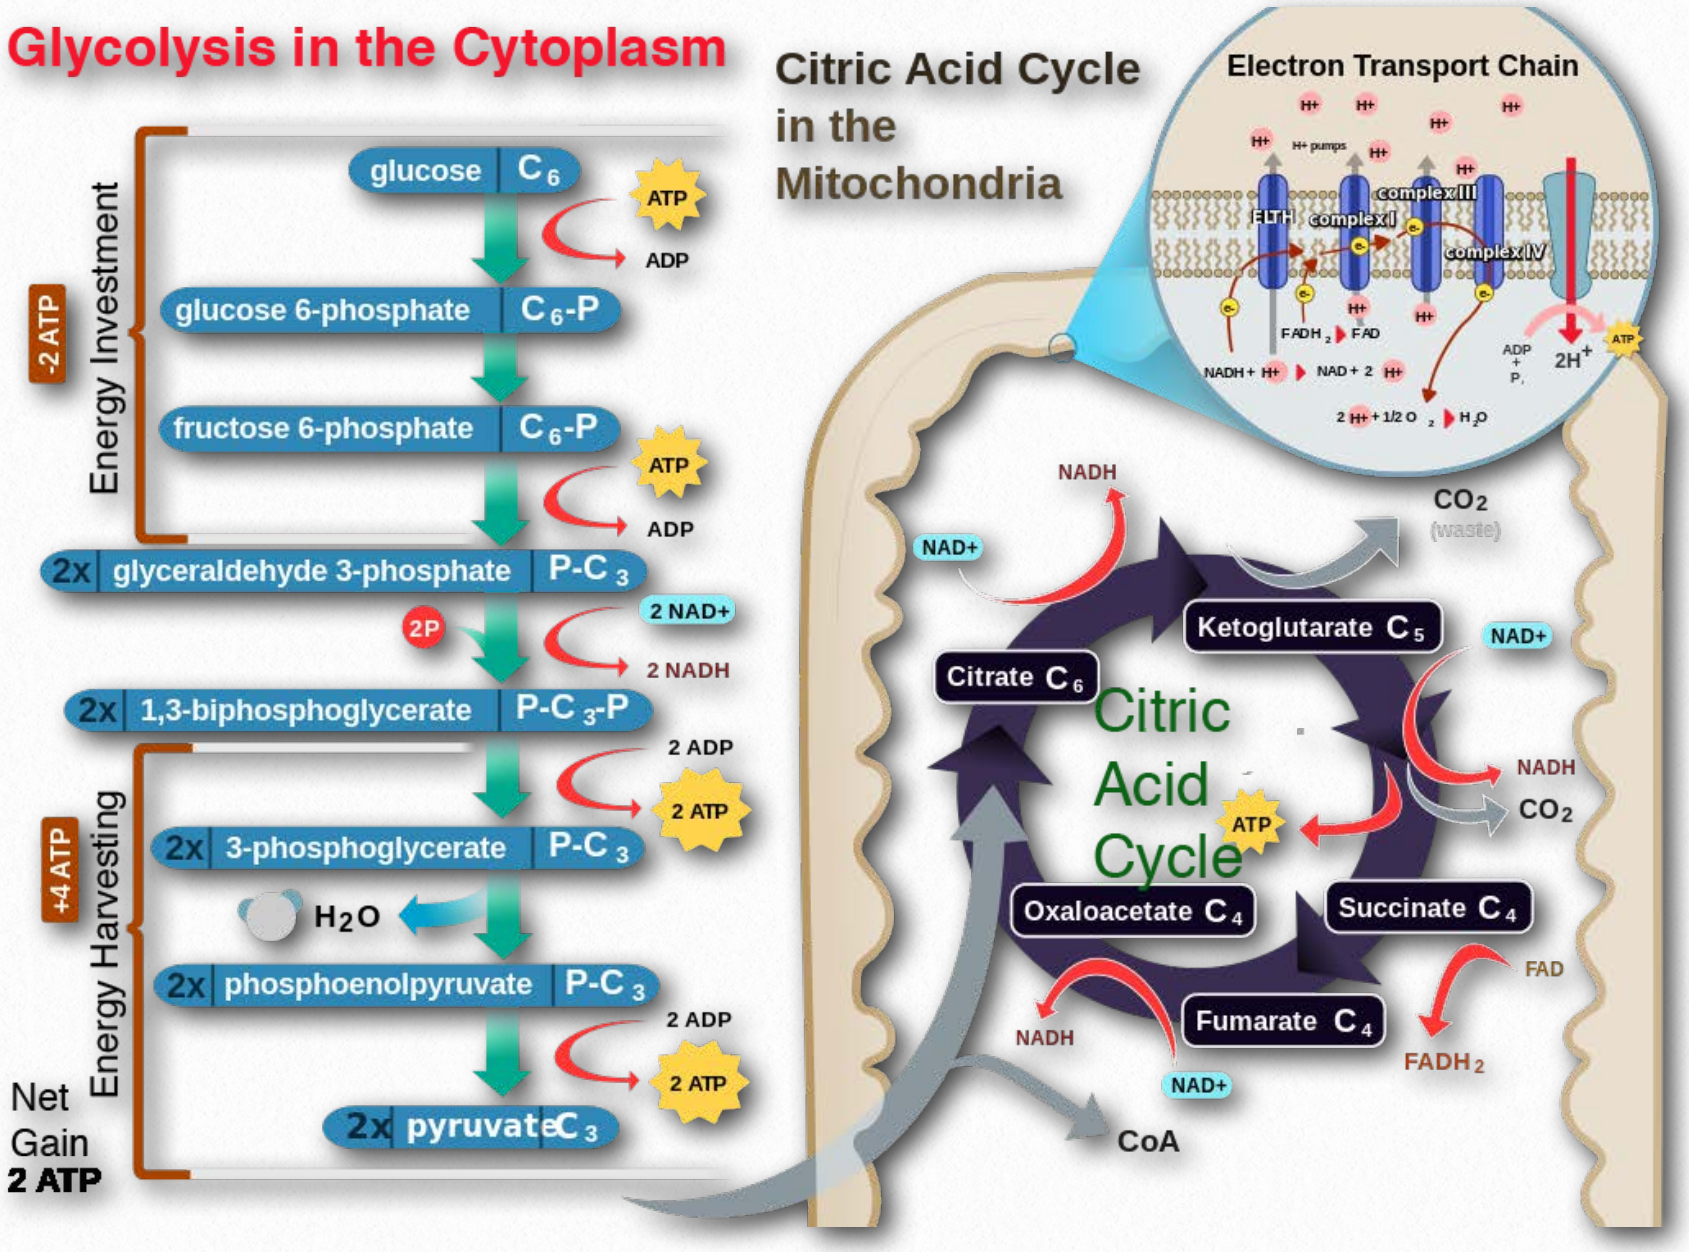

Figure 5.31 - Respiration overview in eukaryotic cells

Wikipedia

At rest

To illustrate these links, let us first consider a person, initially at rest, who then suddenly jumps up and runs away. At first, the person's ATP levels are high and ADP levels are low (no exercise to burn ATP), so little oxidative phosphorylation is occurring and thus the proton gradient is high. Electron transport is moving slowly, if at all, so it is not using oxygen and the person's breathing is slow, as a result.

YouTube Lectures by Kevin HERE & HERE

Exercise

When running starts, muscular contraction, which uses energy, causes ATP to be converted to ADP. Increasing ADP in muscle cells favors oxidative phosphorylation to attempt to make up for the ATP being burned. ATP synthase begins working and protons begin to come back into the mitochondrial matrix. The proton gradient decreases, so electron transport re-starts.

Electron transport needs an electron acceptor, so oxygen use increases and when oxygen use increases, the person starts breathing more heavily to supply it. When the person stops running, ATP concentrations get rebuilt by ATP synthase. Eventually, when ATP levels are completely restored, ADP levels fall and ATP synthase stops or slows considerably. With little or no proton movement, electron transport stops because the proton gradient is too large. When electron transport stops, oxygen use decreases and the rate of breathing slows down.

Interactive Learning Module HERE

Electron transport critical

The really interesting links to metabolism occur relative to whether or not electron transport is occurring. From the examples, we can see that electron transport will be relatively slowed when not exercising and more rapid when exercise (or other ATP usage) is occurring. Remember that electron transport is the way in which reduced electron carriers, NADH and $FADH_2$, donate their electrons to the ETS , becoming oxidized to NAD^+ and FAD, respectively.

Oxidized carriers, such as NAD^+ and FAD are needed by catabolic pathways, like glycolysis, the citric acid cycle, and fatty acid oxidation. Anabolic pathways, such as fatty acid/fat synthesis and gluconeogenesis rely on reduced electron carriers, such as $FADH_2$, NADH, and the related carrier, NADPH.

Links to exercise

High levels of NADH and $FADH_2$ prevent catabolic pathways from operating, since NAD^+ and FAD levels will be low and these are needed to accept the electrons released during catabolism by the oxidative processes.

Thanks to respiratory control, when one is exercising, NAD^+ and FAD levels increase (because electron transport is running), so catabolic pathways that need NAD^+ and FAD can function. The electrons lost in the oxidation reactions of catabolism are captured by

Rest

- ATP High / ADP Low
- Oxidative Phosphorylation Low
- Electron Transport Low
- Oxygen Use Low
- NADH High / NAD^+ Low
- Citric Acid Cycle Slow

Exercise

- ATP Low / ADP High
- Oxidative Phosphorylation High
- Electron Transport High
- Oxygen Use High
- NADH Low / NAD^+ High
- Citric Acid Cycle Fast

NAD^+ and FAD to yield NADH and $FADH_2$, which then supply electrons to the electron transport system and oxidative phosphorylation to make more needed ATP.

Thus, during exercise, cells move to a mode of quickly cycling between reduced electron carriers (NADH/$FADH_2$) and oxidized electron carriers (NAD^+/FAD). This allows rapidly metabolizing tissues to transfer electrons to NAD^+/FAD and it allows the reduced electron carriers to rapidly become oxidized, allowing the cell to produce ATP.

Rest

When exercise stops, NADH and $FADH_2$ levels rise (because electron transport is slowing) causing catabolic pathways to slow/stop. If one does not have the proper amount of exercise, reduced carriers remain high in concentration for long periods of time. This means we have an excess of energy and then anabolic pathways, particularly fatty acid synthesis, are favored, so we get fatter.

Altering respiratory control

One might suspect that altering respiratory control could have some very dire consequences and that would be correct. Alterations can take the form of either inhibiting electron transport/oxidative phosphorylation or uncoupling the two . These alterations can be achieved using compounds with specific effects on particular components of the system.

All of the chemicals described here are laboratory tools and should never be used by people. The first group for discussion are the inhibitors. In tightly coupled mitochondria, inhibiting either electron transport or oxidative phosphorylation has the effect of inhibiting the other one as well.

Electron transport inhibitors

Common inhibitors of electron transport include rotenone and amytal, which stop movement of electrons past Complex I, malonate, malate, and oxaloacetate, which

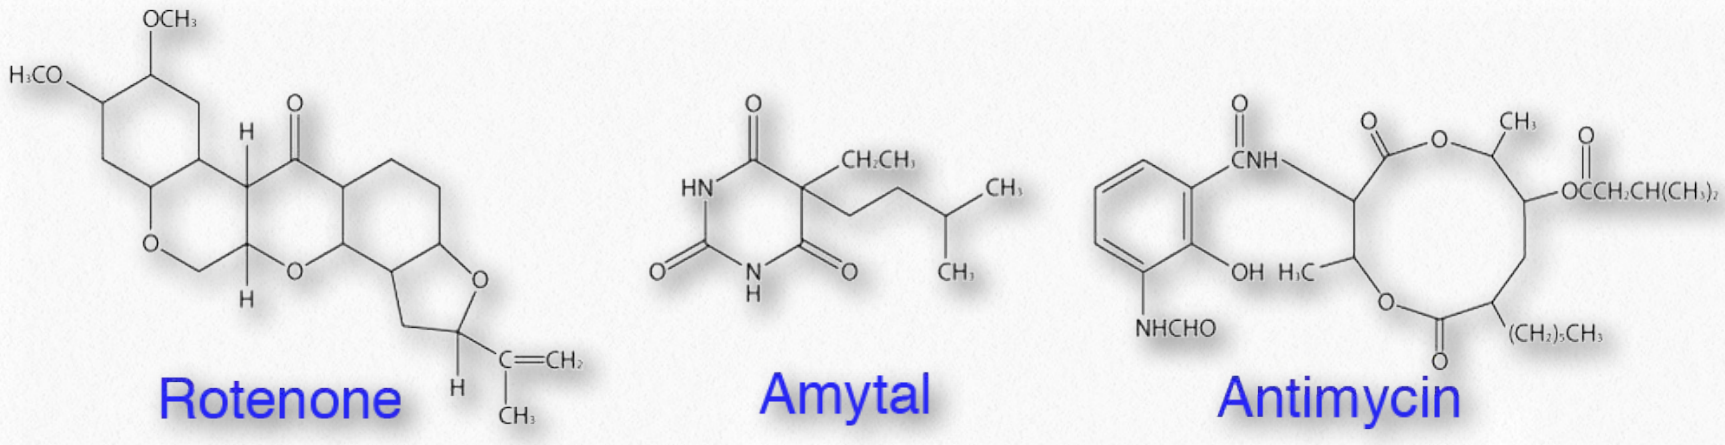

Figure 5.32 - Three inhibitors of electron transport

Image by Aleia Kim

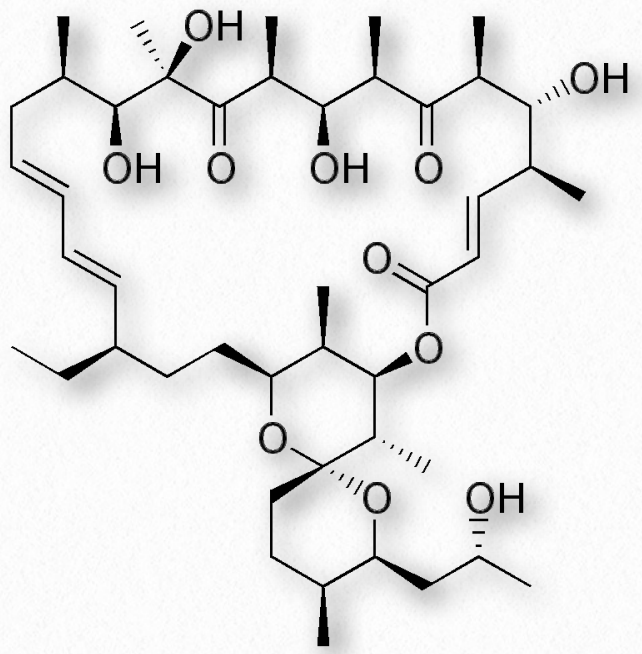

Figure 5.33 - Oligomycin A - An inhibitor of ATP synthase

hibit movement of electrons through Complex II, antimycin A which stops movement of electrons past Complex III, and cyanide, carbon monoxide, azide, and hydrogen sulfide, which inhibit electron movement through Complex IV (Figure 5.33). All of these compounds can stop electron transport directly (no movement of electrons) and oxidative phosphorylation indirectly (proton gradient will dissipate). While some of these compounds are not commonly known, almost everyone is aware of the hazards of carbon monoxide and cyanide, both of which can be lethal.

ATP synthase inhibitor

It is also possible to use an inhibitor of ATP synthase to stop oxidative phosphorylation directly (no ATP production) and electron transport indirectly (proton gradient not relieved so it becomes increasingly difficult to pump protons out of matrix). Oligomycin A (Figure 5.34) is an inhibitor of ATP synthase.

Rotenone

Rotenone, which is a plant product, is used as a natural insecticide that is permitted for organic farming. When mitochondria are treated with this, electron transport will stop at Complex I and so, too, will the pumping of protons out of the matrix. When this occurs, the proton gradient rapidly dissipates, stopping oxidative phosphorylation as a consequence. There are other entry points for electrons than Complex I, so this type of inhibition is not as serious as using inhibitors of Complex IV, since no alternative route for electrons is available. It is for this reason that cyanide, for example, is so poisonous.

2,4-DNP

Respiratory control can be completely destroyed by using a reagent that permeabilizes the inner mitochondrial membrane to protons. There are several such reagents, but the best known one is 2,4

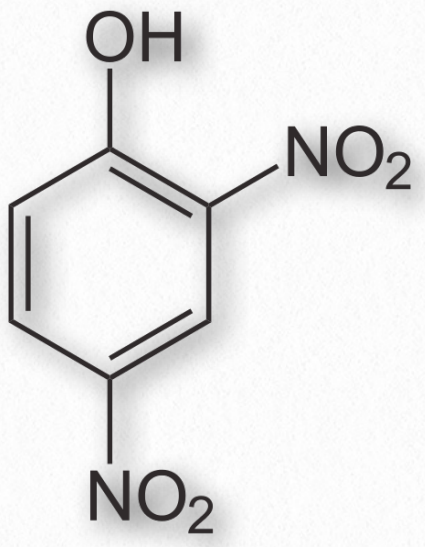

Figure 5.34 - 2,4 DNP - an uncoupler of respiratory control

dinitrophenol (2,4 DNP - Figure 5.35). Treatment of mitochondria with 2,4 DNP makes the mitochondrial inner membrane "leaky" to protons. This has the effect of providing an alternate route for protons to reenter the matrix besides going through ATP synthase, and uncouples oxidative phosphorylation from electron transport.

Imagine a dam holding back water with a turbine generating electricity through which water must flow. When all water flows through the turbine, the maximum amount of electricity can be generated. If one pokes a hole in the dam, though, water will flow through the hole and less electricity will be created. The generation of electricity will thus be uncoupled from the flow of water. If the hole is big enough, the water will all drain out through the hole and no electricity will be made.

YouTube Lectures by Kevin HERE & HERE

Bypassing ATP synthase

Imagine, now, that the proton gradient is the equivalent of the water, the inner membrane is the equivalent of the dam and the ATP synthase is the turbine. When protons have an alternate route, little or no ATP will be made because protons will pass through the membrane's holes instead of spinning the turbine of ATP synthase.

It is important to recognize, though, that uncoupling by 2,4 DNP works differently from the electron transport inhibitors or the ATP synthase inhibitor. In those situations, stopping oxidative phosphorylation resulted in indirectly stopping electron transport, since the two processes were coupled and the inhibitors did not uncouple them. Similarly, stopping electron transport indirectly stopped oxidative phosphorylation for the same reason.

Such is not the case with 2,4 DNP. Stopping oxidative phosphorylation by destroying the proton gradient allows electron transport to continue unabated (it actually stimulates it), since the proton gradient cannot build no matter how much electron transport runs. Consequently, electron trans-

In Cells With Tight Coupling	In Cells That Are Uncoupled
1. O_2 use depends on metabolism	1. O_2 use high
2. NAD^+ levels vary with exercise	2. NAD^+ Levels high
3. Proton gradient high with no exercise	3. Little or no proton gradient
4. Catabolism depends on energy needs	4. Catabolism high
5. ETS runs when OxPhos runs and vice versa	5. OxPhos does not run, but ETS runs rapidly

port runs like crazy but oxidative phosphorylation stops. When that happens, NAD^+ and FAD levels rise, and catabolic pathways run unabated with abundant supplies of these electron acceptors. The reason such a scenario is dangerous is because the body is using all of its nutrient resources, but no ATP is being made. Lack of ATP leads to cellular (and organismal) death. In addition, the large amounts of heat generated can raise the temperature of the body to unsafe levels.

Thermogenin

One of the byproducts of uncoupling electron transport is the production of heat. The faster metabolic pathways run, the more heat is generated as a byproduct. Since 2,4 DNP causes metabolism to speed up, a considerable amount of heat can be produced. Controlled uncoupling is actually used by the body in special tissues called brown fat. In this case, brown fat cells use the heat created to help thermoregulate the temperature of newborn children.

Permeabilization of the inner membrane is accomplished in brown fat by the synthesis of a protein called thermogenin (also known as uncoupling protein). Thermogenin binds to the inner membrane and allows protons to pass through it, thus bypassing the ATP synthase. As noted for 2,4 DNP, this results in activation of catabolic pathways and the more catabolism occurs, the more heat is generated.

Dangerous drug

In uncoupling, whether through the action of an endogenous uncoupling protein or DNP, the energy that would have normally been captured in ATP is lost as heat. In the case of uncoupling by thermogenin, this serves the important purpose of keeping newborn infants warm. But in adults, uncoupling merely wastes the energy that would have been harvested as ATP. In other words, it mimics starvation, even though there is plenty of food, because the energy is dissipated as heat.

This fact, and the associated increase in metabolic rate, led to DNP being used as a weight loss drug in the 1930s. Touted as an effortless way to lose weight without having to eat less or exercise more, it was hailed as a magic weight loss pill. It quickly became apparent, however, that this was very dangerous. Many people died from using this drug before laws were passed to ban the use of DNP as a weight loss aid.

Alternative oxidase

Another approach to generating heat that doesn't involve breaking respiratory control is taken by some fungi, plants, and protozoa. They use an alternative electron transport.

In these organisms, there is an enzyme called alternative oxidase (Figure 5.36). Alternative oxidase is able to accept electrons from CoQ and pass them directly to oxygen.

The process occurs in coupled mitochondria. Its mechanism of action is to reduce the yield of ATP, since fewer protons are being pumped per reduced electron carrier. Thus NAD^+ concentrations increase, oxygen consumption increases, and the efficiency of ATP production decreases.

Organisms using this method must activate catabolic pathways by the increase in NAD^+ concentration. This, in turn produces quantities of NADH and $FADH_2$ necessary to make sufficient amounts of ATP. The byproduct of this increased catabolism is more heat. Not surprisingly, the alternative oxidase pathway can be activated by cold temperatures.

Energy efficiency

Cells are not 100% efficient in energy use. Nothing we know is. Consequently, cells do not get as much energy out of catabolic processes as they put into anabolic processes. A good example is the synthesis and breakdown of glucose, something liver cells are frequently doing. The complete conversion of glucose to pyruvate in glycolysis (catabolism) yields two pyruvates plus 2 NADH plus 2 ATPs. Conversely, the complete conversion of two pyruvates into glucose by gluconeogenesis (anabolism) requires 4 ATPs, 2 NADH, and 2 GTPs. Since the energy of GTP is essentially equal to that of ATP, gluconeogenesis requires a net of 4 ATPs more than glycolysis yields. This difference must be made up in order for the organism to meet its energy needs. It is for this reason that we eat. In addition, the inefficiency of our capture of energy in reactions results in the production of heat and helps to keep us warm, as noted.

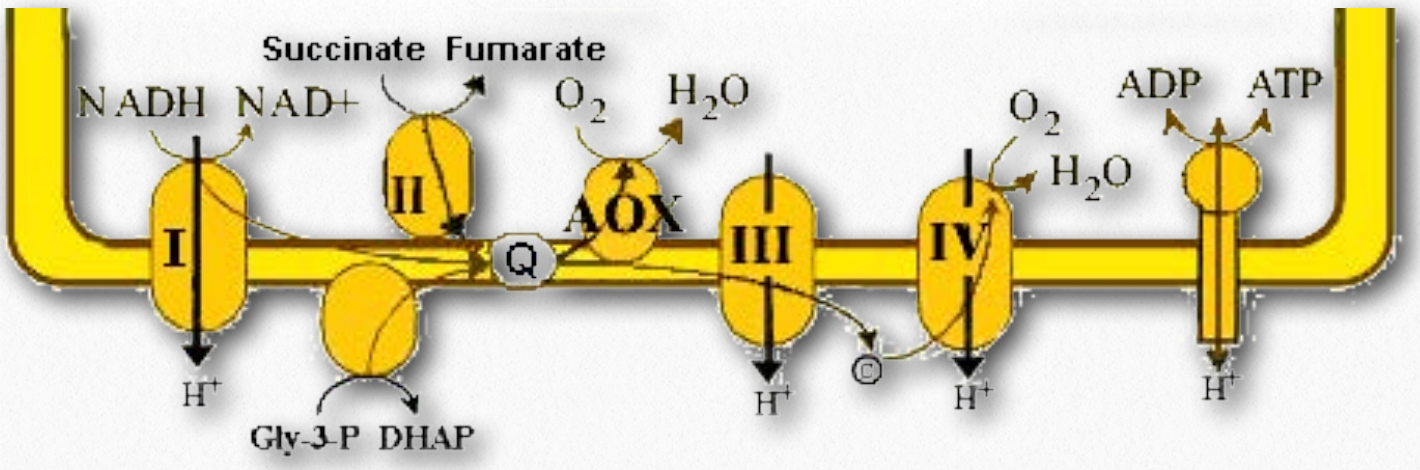

Figure 5.35 - Alternative oxidase (AOX) of fungi, plants, and protozoa bypasses part of electron transport by taking electrons from CoQ and passing them to oxygen.

You can read more about glycolysis (HERE) and gluconeogenesis (HERE).

Metabolic controls of energy

It is also noteworthy that cells do not usually have both catabolic and anabolic processes for the same molecules occurring simultaneously inside of them (for example, breakdown of glucose and synthesis of glucose) because the cell would see no net production of anything but heat and a loss of ATPs with each turn of the cycle. Such cycles are called futile cycles and cells have controls in place to limit the extent to which they occur. Since futile cycles can, in fact, yield heat, they are used as sources of heat in some types of tissue. Brown adipose tissue of mammals uses this strategy, as described earlier. See also HERE for more on heat generation with a futile cycle.

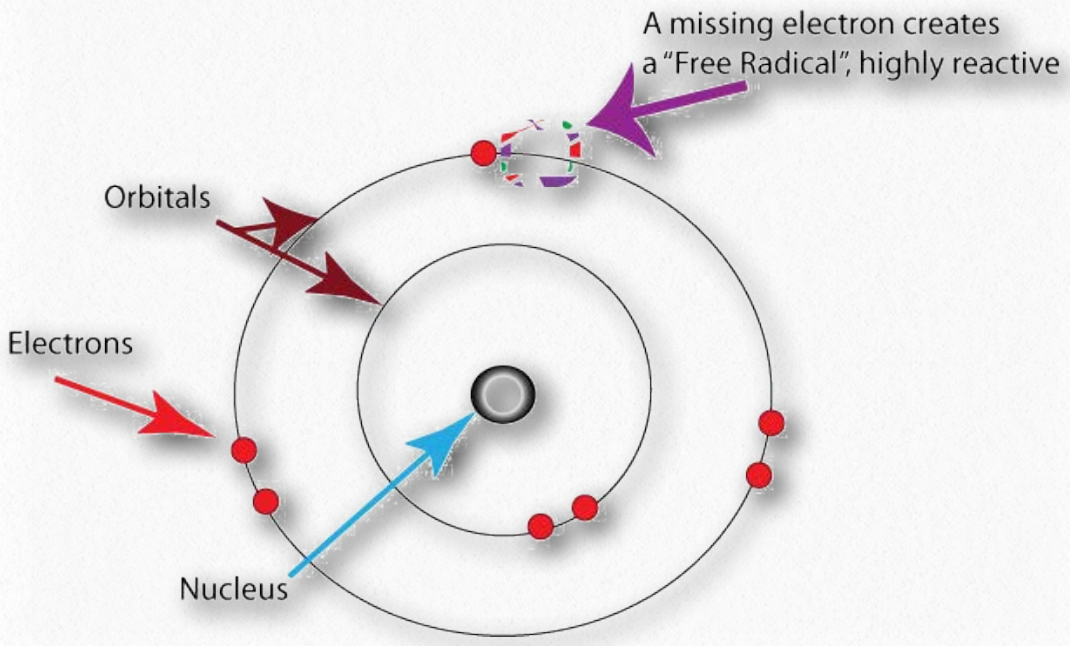

Figure 5.36 - Structure of an oxygen free radical
Wikipedia

Reactive oxygen species

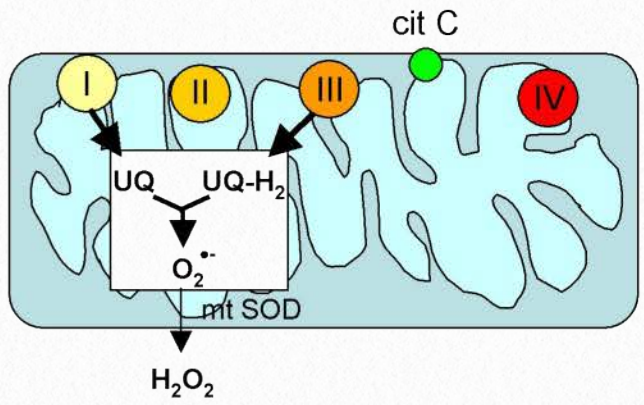
Reactive oxygen species (ROS - Figure 5.37) are oxygen containing molecules, such as peroxides, hydroxyl radical, superoxide, peroxynitrite, and others that are very chemically reactive. Though some ROS, such as peroxide and nitric oxide have important biological functions in signaling, increases in reactive oxygen species in times of stress can cause significant damage in the cell. Exogenous sources of ROS, such as pollution, tobacco, smoke, radiation or drugs can also cause significant problems.

Endogenous production of ROS is directed towards intracellular signaling (H_2O_2 and nitric oxide, for example) and defense. Many cells, for example, have NADPH oxidase (Figure 5.38) embedded in the exterior portion of the plasma membranes, in peroxisomes, and endoplasmic reticulum. It produces superoxides in the reaction below to kill bacteria.

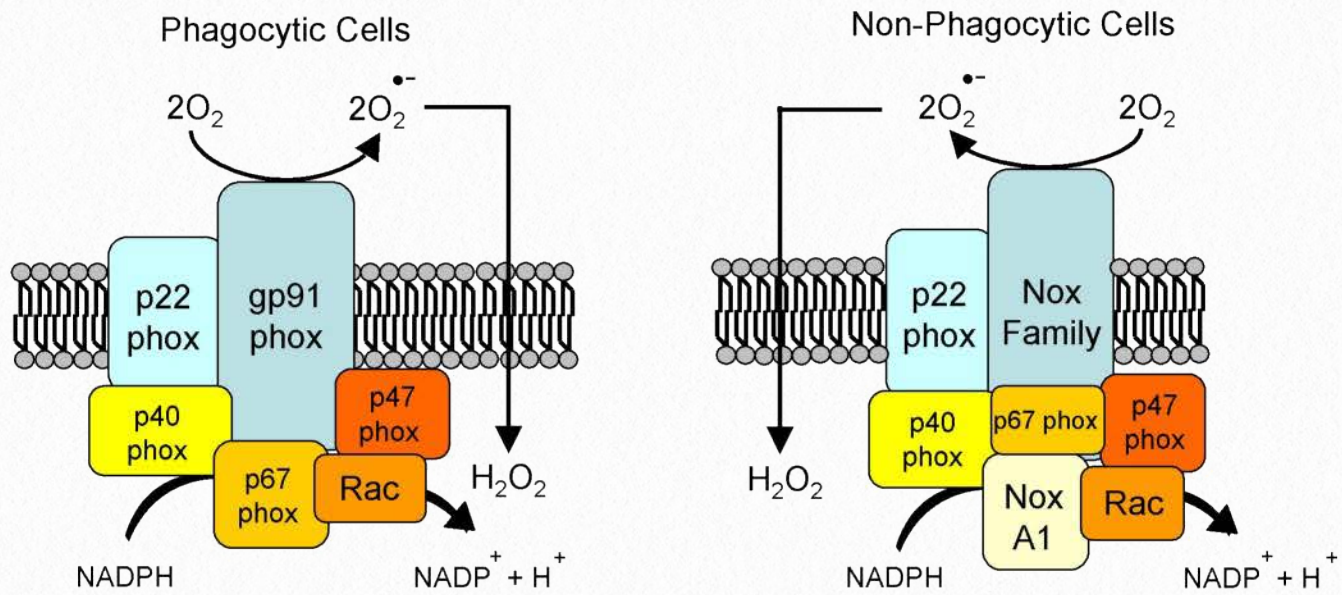
$$\mathbf{NADPH} + 2O_2 \rightleftharpoons \mathbf{NADP^+} + 2\mathbf{O_2^-} + H^+$$

a) Mitochondria

Stimuli inducing increased mitochondrial generation of ROS:	
- serum deprivation	- hypoxia
- integrin signalling	- ceramide
- apoptosis	- p53
- TNFα	- oncogenic Ras



b) NADPH oxidase



Stimuli for activation of NADPH oxidase and 5-lipooxygenase	
- integrin signalling	- immunological stimuli
- growth factors	- hypoxia
- cytokines/hormones	- oncogenic Ras

c) 5-lipoxygenase

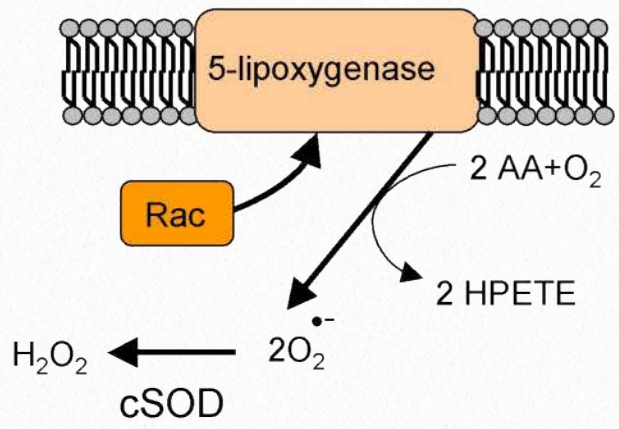


Figure 5.37 - Three sources of reactive oxygen species (ROS) in cells

Wikipedia

In the immune system, cells called phagocytes engulf foreign cells and then use ROS to kill them. ROS can serve as signals for action. In zebrafish, damaged tissues have increased levels of H_2O_2 and this is thought to be a signal for white blood cells to converge on the site. In fish lacking the genes to produce hydrogen peroxide, white blood cells do not converge at the damage site. Sources of hydrogen peroxide include peroxisomes, which generate it as a byproduct of oxidation of long chain fatty acids.

Wikipedia

Aging

Reactive oxygen species are at the heart of the free radical theory of aging, which states that organisms age due to the accumulation of damage from free radicals in their cells. In yeast and *Drosophila*, there is evidence that reducing oxidative damage can increase lifespan. In mice, increasing oxidative damage decreases life span, though in *Caenorhabditis*, blocking production of superoxide dismutase actually increases lifespan, so the role of ROS in aging is not completely clear.

It is clear, though, that accumulation of mitochondrial damage is problematic for individual cells. Bcl-2 proteins on the surface of mitochondria monitor damage and if they detect it, will activate proteins called Bax to stimulate the release of cytochrome c from the mitochondrial membrane, stimulating apoptosis (programmed cell death). Eventually the dead cell will be phagocytosed.

A common endogenous source of superoxide is the electron transport chain. Superoxide can be produced when movement of electrons into and out of the chain don't match well. Under these circumstances, semi-reduced CoQ can donate an electron to O_2 to form superoxide (O_2^-). Superoxide can react with many molecules, including DNA where it can cause damage leading to mutation. If it reacts with the aconitase enzyme, ferrous iron (Fe^{++}) can be released which, in turn, can react in the Fenton reaction to produce another reactive oxygen species, the hydroxyl radical (Figure 5.39).

Countering the effects of ROS are enzymes, such as catalase, superoxide dismutase, and anti-oxidants, such as glutathione and vitamins C and E.

Glutathione protects against oxidative damage by being a substrate for the enzyme glutathione peroxidase. Glutathione peroxidase catalyzes the conversion of hydrogen peroxide to water (next page).

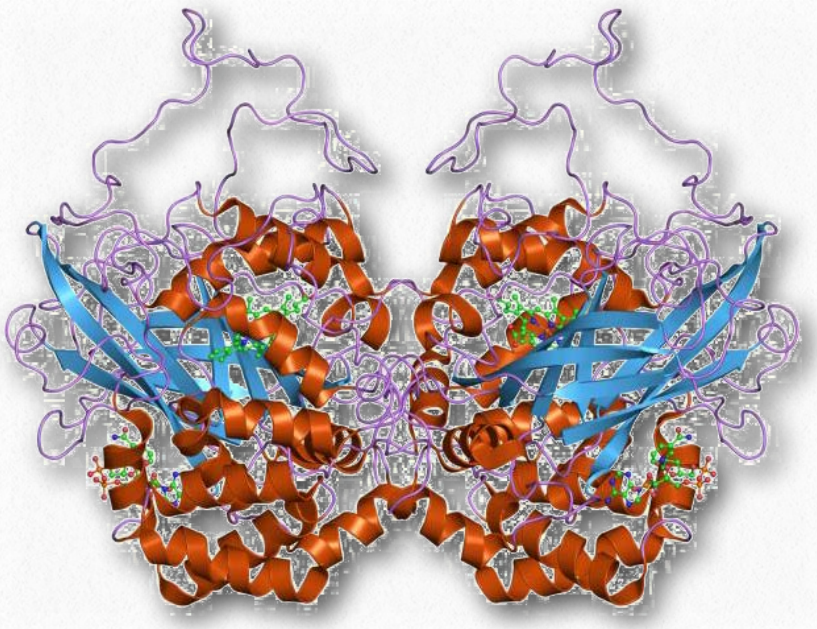

Figure 5.39 - Catalase

Reduced **Glutathione** (GSH) + H_2O_2

Oxidized **Glutathione** (GSSG) + H_2O

Catalase

Catalase (Figure 5.40) is an important enzyme for cells of all types that live in an oxygen environment. A first line of defense against reactive oxygen species, catalase catalyzes the breakdown of hydrogen peroxide into water and oxygen.

$$2\ H_2O_2 <=> 2\ H_2O + O_2$$

The enzyme, which employs four heme groups in its catalysis, works extremely rapidly, converting up to 40,000,000 molecules of hydrogen peroxide to water and oxygen per enzyme per second. It is abundantly found in peroxisomes.

In addition to catalase's ability to break down hydrogen peroxide, the enzyme can also use hydrogen peroxide to oxidize a wide variety organic compounds, including phenols, formic acid, formaldehyde, acetaldehyde, and alcohols, but with much lower efficiency.

Health

The importance of catalase for health is uncertain. Mice deficient in the enzyme appear healthy and humans with low levels of the enzyme display few problems. On the other hand, mice engineered to produce higher levels of catalase, in at least one study, lived longer. The ability of organisms to live with lower levels or no catalase may arise from another group of enzymes, the peroxiredoxins, which also act on hydrogen peroxide and may make up for lower quantities of catalase. Last, there is evidence that reduced levels of catalase with aging may be responsible for the graying of hair. Higher levels of H_2O_2 with

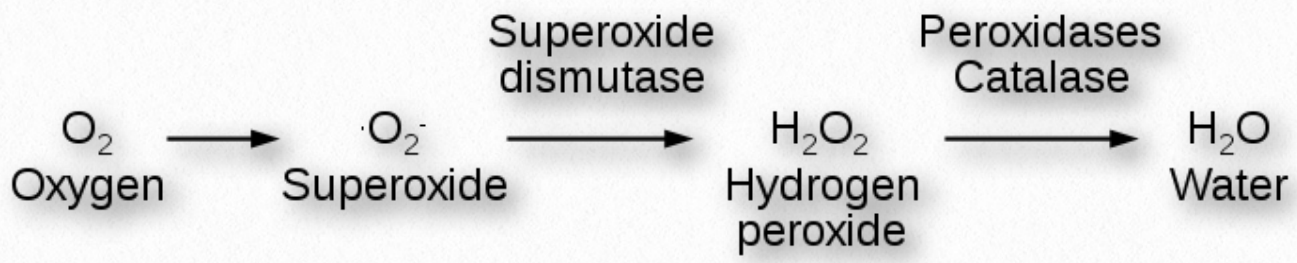

Figure 5.40 - Detoxifying reactive oxygen species

reduced catalase results in a bleaching of hair follicles.

Superoxide dismutase

Another important enzyme for protection against reactive oxygen species is superoxide dismutase (SOD), which is found, like catalase, in virtually all organisms living in an oxygen environment. Superoxide dismutase, also like catalase, has a very high K_{cat} value and, in fact, has the highest K_{cat}/K_m known for any known enzyme. It catalyzes the reactions at the top of the next column (superoxides shown in red):

The enzyme thus works by a ping-pong (double displacement) mechanism (see HERE), being converted between two different forms.

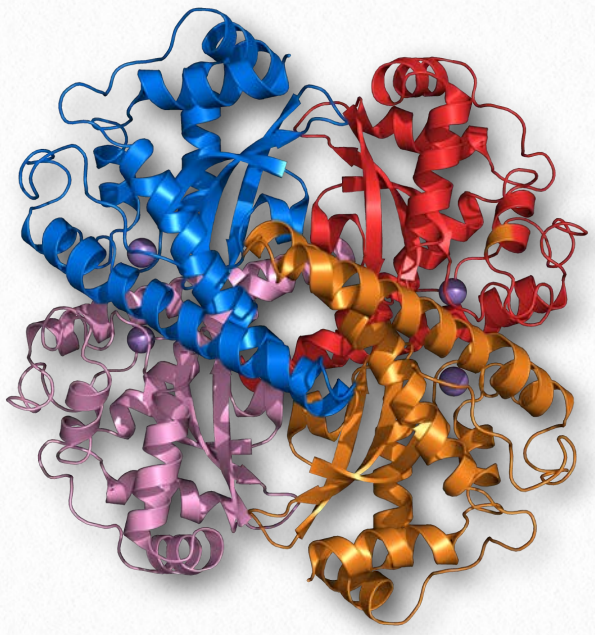

Figure 5.41 - SOD2 of humans

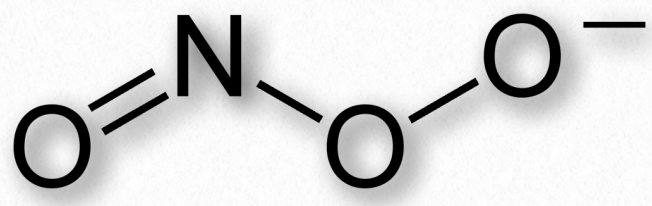

Figure 5.42 3 - Peroxynitrite Ion

1. O_2^- + Enzyme-Cu^{++}

$\rightleftharpoons$

O_2 + Enzyme-Cu^{+}

2. O_2^- + Enzyme-Cu^{+} + $2H^+$

$\rightleftharpoons$

H_2O_2 + Enzyme-Cu^{++}

The hydrogen peroxide produced in the second reaction is easily handled by catalase and is also less harmful than superoxide, which can react with nitric oxide (NO) to form very toxic peroxynitrite ions (Figure 5.43). Peroxynitrite has negative effects on cells, as shown in Figure 5.45.

In addition to copper, an ion of Zn^{++} is also bound by the enzyme and likely plays a role in the catalysis. Forms of superoxide dismutase that use manganese, nickel, or iron are also known and are mostly found in prokaryotes and protists, though a manganese SOD is found in most mitochondria. Copper/zinc enzymes are common in eukaryotes.

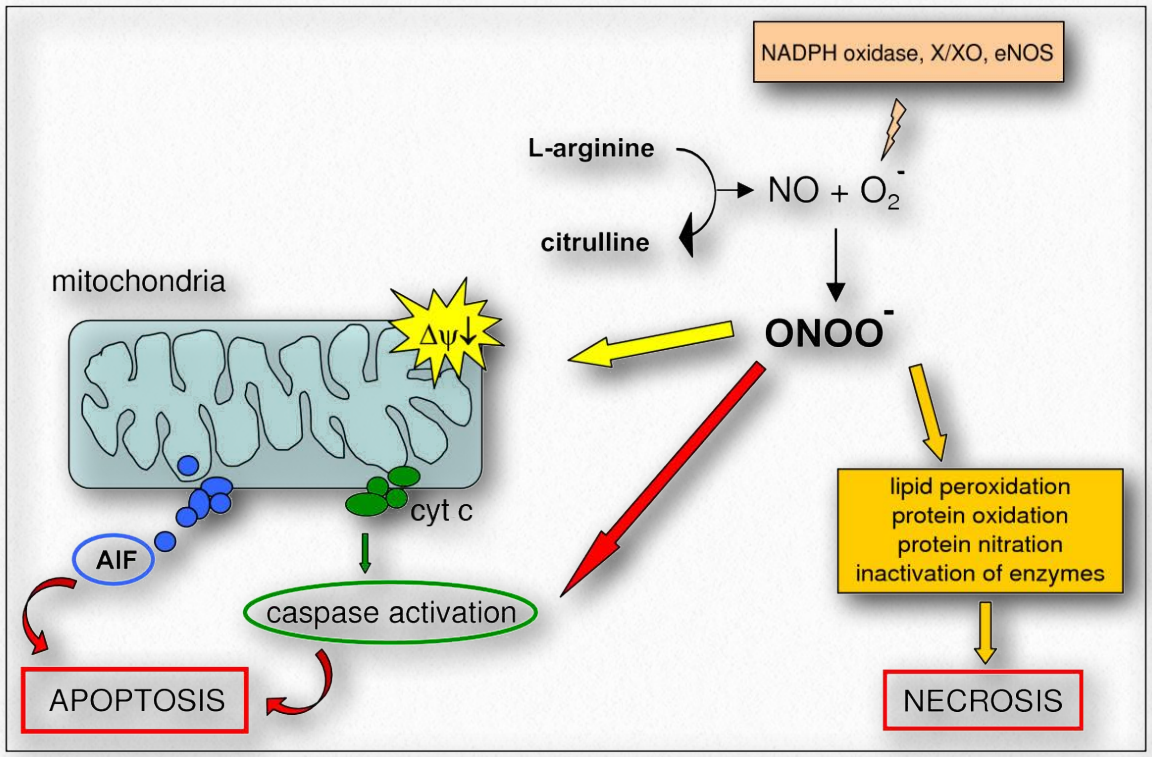

Figure 5.43 - Peroxynitrite's effects on cells lead to necrosis or apoptosis

Mixed function oxidases

Other enzymes catalyzing reactions involving oxygen include the mixed function oxidases. These enzymes use molecular oxygen for two different purposes in one reaction. The mixed function part of the name is used to indicate reactions in which two different substrates are being oxidized simultaneously.

Three forms of superoxide dismutase are found in humans and localized to the cytoplasm (SOD1 - Figure 5.45), mitochondria (SOD2 - Figure 5.46), and extracellular areas (SOD3 - Figure 5.47). Mice lacking any of the three forms of the enzyme are more sensitive to drugs, such as paraquat. Deficiency of SOD1 in mice leads to hepatocellular carcinoma and early loss of muscle tissue related to aging. *Drosophila* lacking SOD2 die before birth and those lacking SOD1 prematurely age.

In humans, superoxide dismutase mutations are associated with the genetically-linked form of Amyotrophic Lateral Sclerosis (ALS) and over-expression of the gene is linked to neural disorders associated with Down syndrome.

Wikipedia

Figure 5.44 - SOD1 of humans

Wikipedia

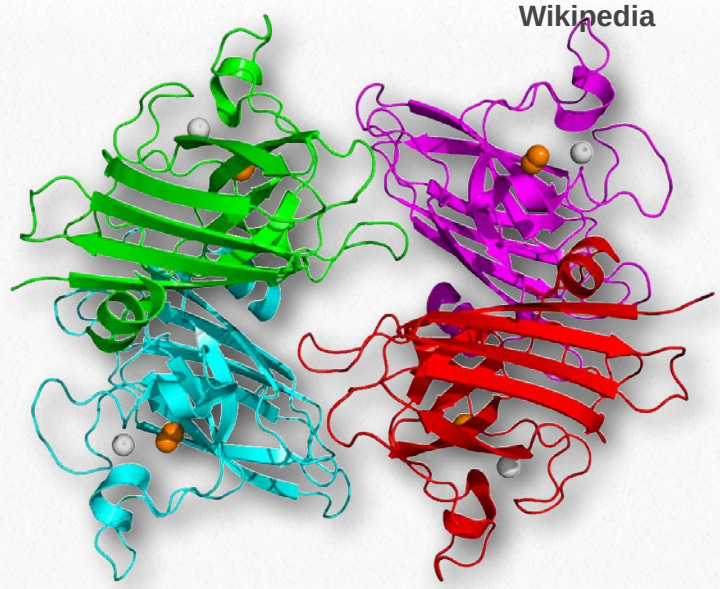

Figure 5.45 - SOD3 of humans

$$RH + O_2 + \mathbf{NADPH} + H^+ \rightleftharpoons ROH + H_2O + NADP^+$$

Monooxygenases are examples of mixed function oxidases. An example of a mixed function oxidase reaction is shown below.

$$AH + BH2 + O_2 <=> AOH + B + H_2O$$

In this case, the oxygen molecule has one atom serve as an electron acceptor and the other atom is added to the AH, creating an alcohol.

Cytochrome P_{450} enzymes

Cytochrome P_{450} enzymes (called CYPs) are family of heme-containing mixed function oxidase enzymes found in all domains of life. Over 21,000 CYP enzymes are known. The most characteristic reaction catalyzed by these enzymes follows

Monooxygenase reactions such as this are relatively rare in the cell due to their use of molecular oxygen. CYPs require an electron donor for reactions like the one shown here and frequently require a protein to assist in transferring electrons to reduce the heme iron. There are six different classes of P_{450} enzymes based on how they get electrons

1. Bacterial P_{450} - electrons from ferredoxin reductase and ferredoxin

2. Mitochondrial P_{450} - electrons from adrenodoxin reductase and adrenodoxin

3. CYB5R/cyb5 - electrons come from cytochrome b5

4. FMN/Fd - use a fused FMN reductase

5. Microsomal P_{450} - NADPH electrons come via cytochrome P_{450} reductase or from cytochrome b_5 and cytochrome b_5 reductase

6. P_{450} only systems - do not require external reducing power

The CYP genes are abundant in humans and catalyze thousand of reactions on both cellular and extracellular chemicals. There are 57 human genes categorized into 18 different families of enzymes. Some CYPs are specific for one or a few substrates, but others can act on many different substrates.

CYP enzymes are found in most body tissues and perform important functions in synthesis of steroids (cholesterol, estrogen, testosterone, Vitamin D, e.g.), breakdown of endogenous compounds (bilirubin), and in detoxification of toxic compounds including drugs. Because they act on many drugs, changes in CYP activity can produce unexpected results and cause problems with drug interactions.

Bioactive compounds, for example, in grapefruit juice, can inhibit CYP3A4 activity, lead-

ing to increased circulating concentrations of drugs that would normally have been acted upon by CYP3A4. This is the reason that patients prescribed drugs that are known to be CYP3A4 substrates are advised to avoid drinking grapefruit juice while under treatment. St. Johns Wort, an herbal treatment, on the other hand, induces CYP3A4 activity, but inhibits CYP1A1, CYP1B1, and CYP2D6. Tobacco smoke induces CYP1A2 and watercress inhibits CYP2E1.

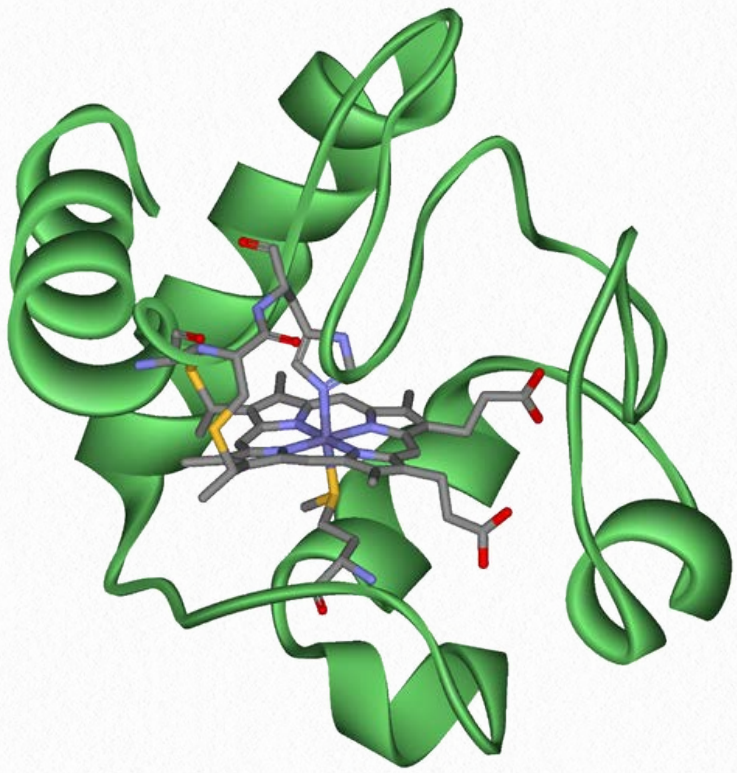

Figure 5.46 - Cytochrome c with its heme group

Cytochromes

Cytochromes are heme-containing proteins that play major roles in the process of electron transport in the mitochondrion and in photosynthesis in the chloroplast. They exist either as monomers (cytochrome c) or as subunits within large redox complexes (Complex III and Complex IV of electron transport. An atom of iron at the center of the heme group plays a central role in the process, flipping between the ferrous (Fe^{++}) and ferric (Fe^{+++}) states as a result of the movement of electrons through it.

There are several different cytochromes. Cytochrome c (Figure 5.47) is a soluble protein loosely associated with the mitochondrion. Cytochromes a and a_3 are found in Complex IV. Complex III has cytochromes b and c_1 and the plastoquinol-plastocyanin reductase of the chloroplast contains cytochromes b_6 and f. Another important class of enzymes containing cytochromes is the cytochrome P_{450} oxidase group (see above). They get their name from the fact that they absorb light at 450 nm when their heme iron is reduced.

Iron-Sulfur Proteins

Iron-sulfur proteins contain iron-sulfur clusters in a variety of formats, including sulfide-linked di-, tri-, and tetrairon centers existing in different oxidation states (Figures 5.48 & 5.49). The clusters play a variety of roles, but the best known ones are in electron transport where they function in the redox reactions involved in the movement of electrons.

Complexes I and Complex II contain multiple Fe-S centers. Iron-sulfur proteins, though, have many other roles in cells. Aconitase uses an iron-sulfur center in its catalytic ac-

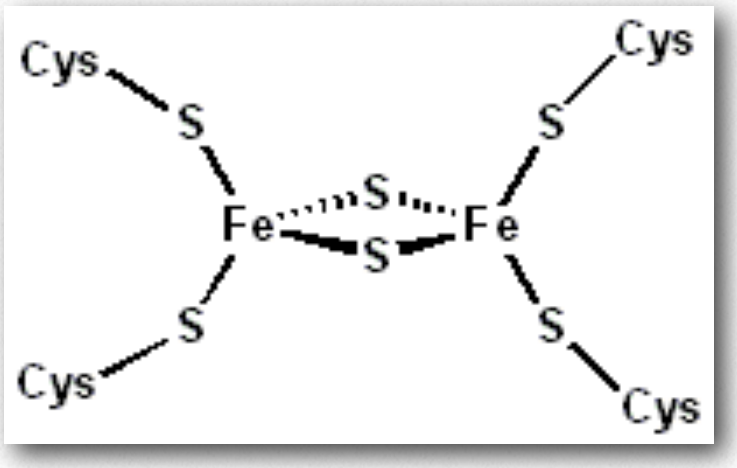

Figure 5.47 - Fe_2S_2 Cluster

tion and the ability of the enzyme to bind iron allows it to function as a barometer of iron concentration in cells. Iron-sulfur centers help to generate radicals in enzymes using S-Adenosyl Methionine (SAM) and can serve as a source of sulfur in the synthesis of biotin and lipoic acid. Some iron-sulfur proteins even help to regulate gene expression.

YouTube Lectures by Kevin HERE & HERE

Ferredoxin

Ferredoxins are iron-sulfur containing proteins performing electron transfer in a wide variety of biological systems and processes. They include roles in photosynthesis in chloroplasts. Ferredoxins are classified structurally by the iron-sulfur clustered centers they contain. Fe_2S_2 clusters (Figure 5.50) are found in chloroplast membranes and can donate electrons to glutamate synthase, nitrate reductase, and sulfite reductase and serve as electron carriers between reductase flavoproteins and bacterial dioxygenase systems. Adrenodoxin is a soluble human Fe_2S_2 ferredoxin (also called ferredoxin 1) serving as an electron carrier (to cytochrome P_{450}) in mitochondrial monooxygenase systems. Fe_4S_4 ferredoxins are subdivided as low and high potential ferredoxins, with the latter ones functioning in anaerobic electron transport chains.

Ferritin

Ferritin is an intracellular iron-storage protein found in almost all living organisms, from bacteria to higher plants and animals. It is a globular protein complex with 24 subunits

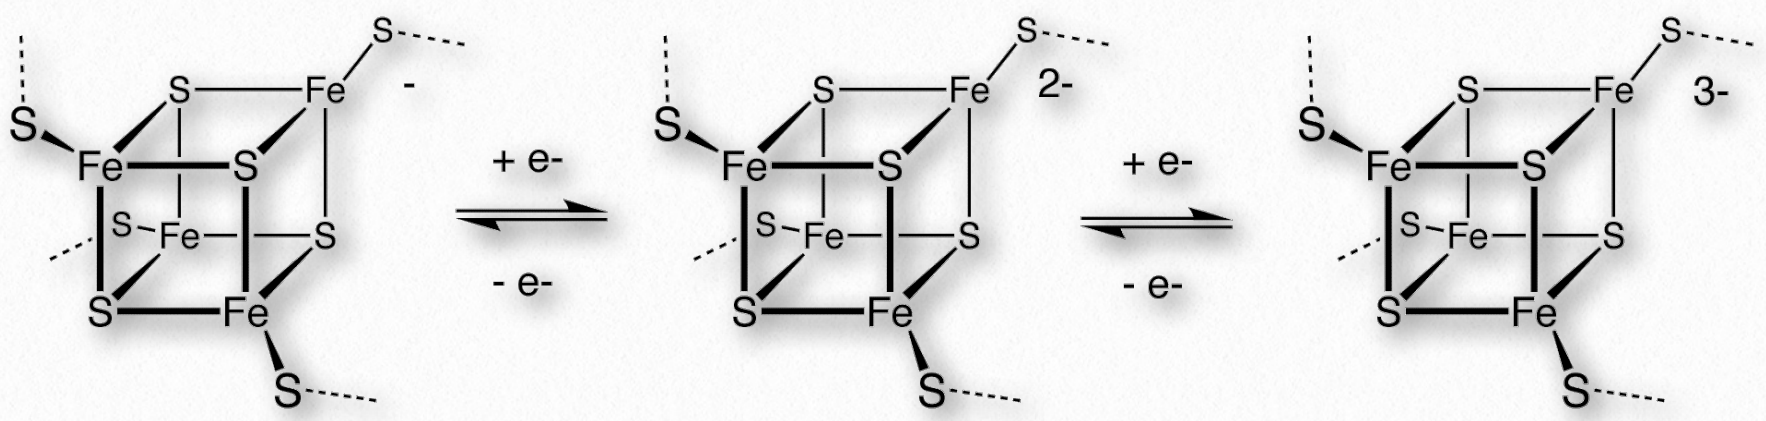

Figure 5.48 - Redox reactions for Fe_4S_4 clusters

and is the primary intracellular iron-storage protein in eukaryotes and prokaryotes. Ferritin functions to keep iron in a soluble and non-toxic form. Its ability to safely store iron and release it in a controlled fashion allow it to act like the prime iron buffer and solubilizer in cells - keeping the concentration of free iron from going to high or falling too low. Ferritin is located in the cytoplasm in most tissues, but it is also found in the serum acting as an iron carrier. Ferritin that doesn't contain any iron is known as apoferritin.

Monoamine oxidases

Monoamine oxidases are enzymes that catalyze the oxidative deamination of monoamines, such as serotonin, epinephrine, and dopamine. Removal of the amine with oxygen results in the production of an aldehyde and ammonia. The enzymes are found inside and outside of the central nervous system.

There are two types of monoamine oxidase enzymes - MAO-A and MAO-B. MAO-A is particularly important for oxidizing monoamines consumed in the diet. Both MAO-A and MAO-B play important roles in inactivating monoaminergic neurotransmitters. Both enzymes act on dopamine, tyramine (Figure 5.50), and tryptamine. MAO-A is the primary enzyme for metabolizing melatonin, serotonin, norepinephrine, and epinephrine, while MAO-B is the primary enzyme for phenethylamine (Figure 5.51) and benzylamine. MAO-B levels have been reported to be considerably reduced with tobacco usage.

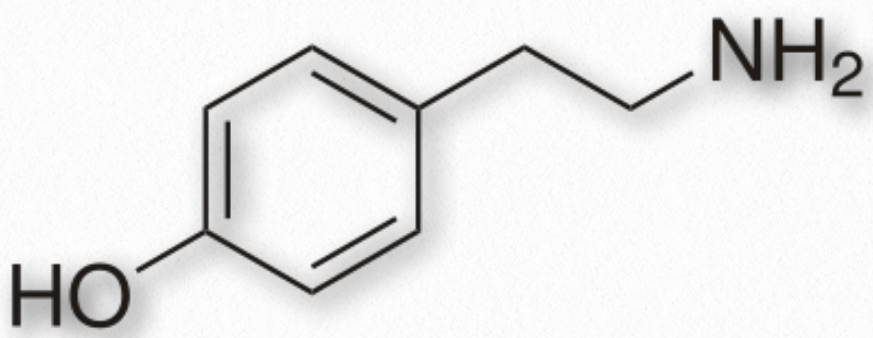

Figure 5.49 - Tyramine

Actions of monoamine oxidases thus affects levels of neurotransmitters and consequently are thought to play roles in neurological and/or psychiatric disorders. Aberrant levels of MAOs have been linked to numerous psychological problems, including depression, attention deficit disorder (ADD), migraines, schizophrenia, and substance abuse. Medications targeting MAOs are sometimes used to treat depression as a last resort - due to potential side effects. Excess levels of catecholamines, such as epinephrine, norepineph-

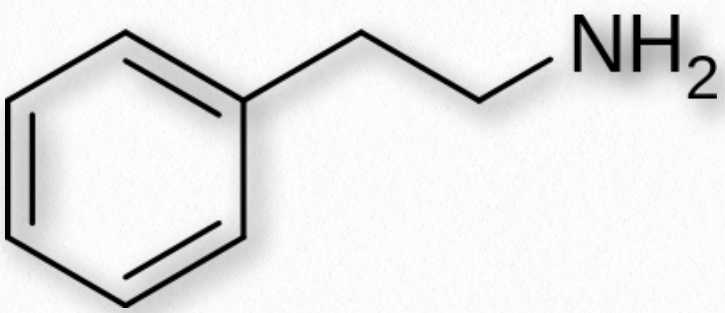

Figure 5.50 - Phenethylamine

rine, and dopamine, can result in dangerous hypertension events.

DNA damage theory of aging

The DNA Damage Theory of Aging is based on the observation that, over time, cells are subject to extensive oxidative events. As already noted, these afford opportunities for the formation of ROS that can damage cellular molecules, and it follows that accumulation of such damage, especially to the DNA would be deleterious to the cell. The build-up of DNA damage could, thus, be responsible for the changes in gene expression that we associate with aging.

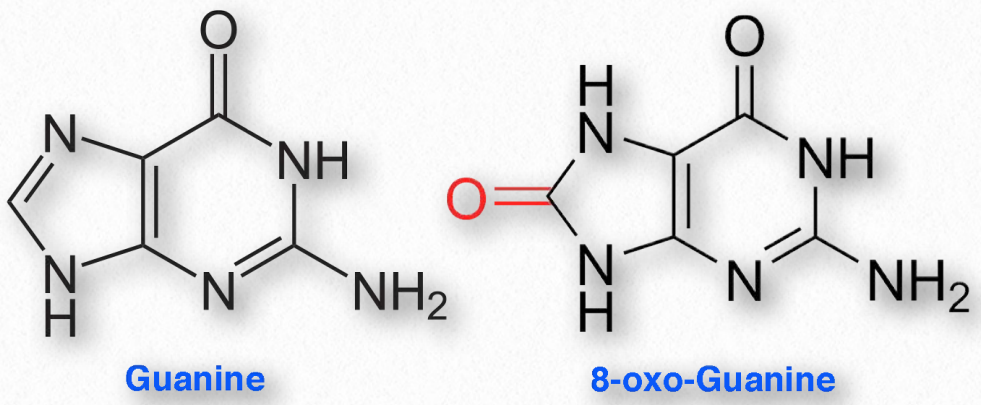

Figure 5.51 - Guanine and 8-oxo-guanine

Numerous damage events

The amount of DNA damage that can occur is considerable. In mice, for example, it is estimated that each cell experiences 40,000 to 150,000 damage events per day. The damage, which happens to nuclear as well as to mitochondrial DNA, can result in apoptosis and/or cellular senescence. DNA repair systems, of course, protect against damage to DNA, but over time, unrepairable damage may accumulate.

Oxidative damage

DNA damage can occur in several ways. Oxidation can damage nucleotides and alter their base-pairing tendencies. Oxidation of guanine by reactive oxygen species, for example, can produce 8-oxoguanine (Figures 5.52 and 5.53). This oxidized nucleobase commonly produced lesion in DNA arising from action of reactive oxygen species like superoxides. 8-oxoguanine is capable of forming a stable base pairing interaction within a DNA duplex with adenine, potentially giving rise to a mutation when DNA rep-

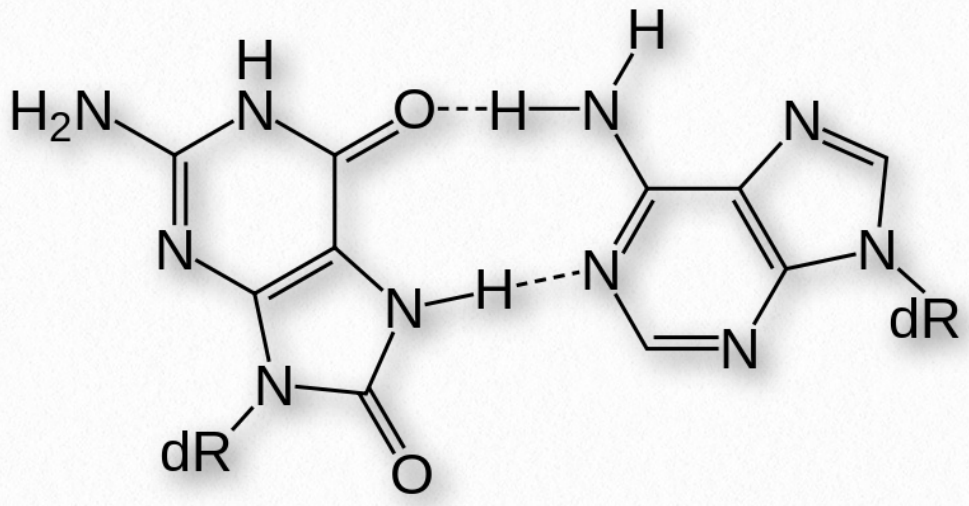

Figure 5.52 - Adenine-8-oxo-guanine base pair. dR = deoxyribose

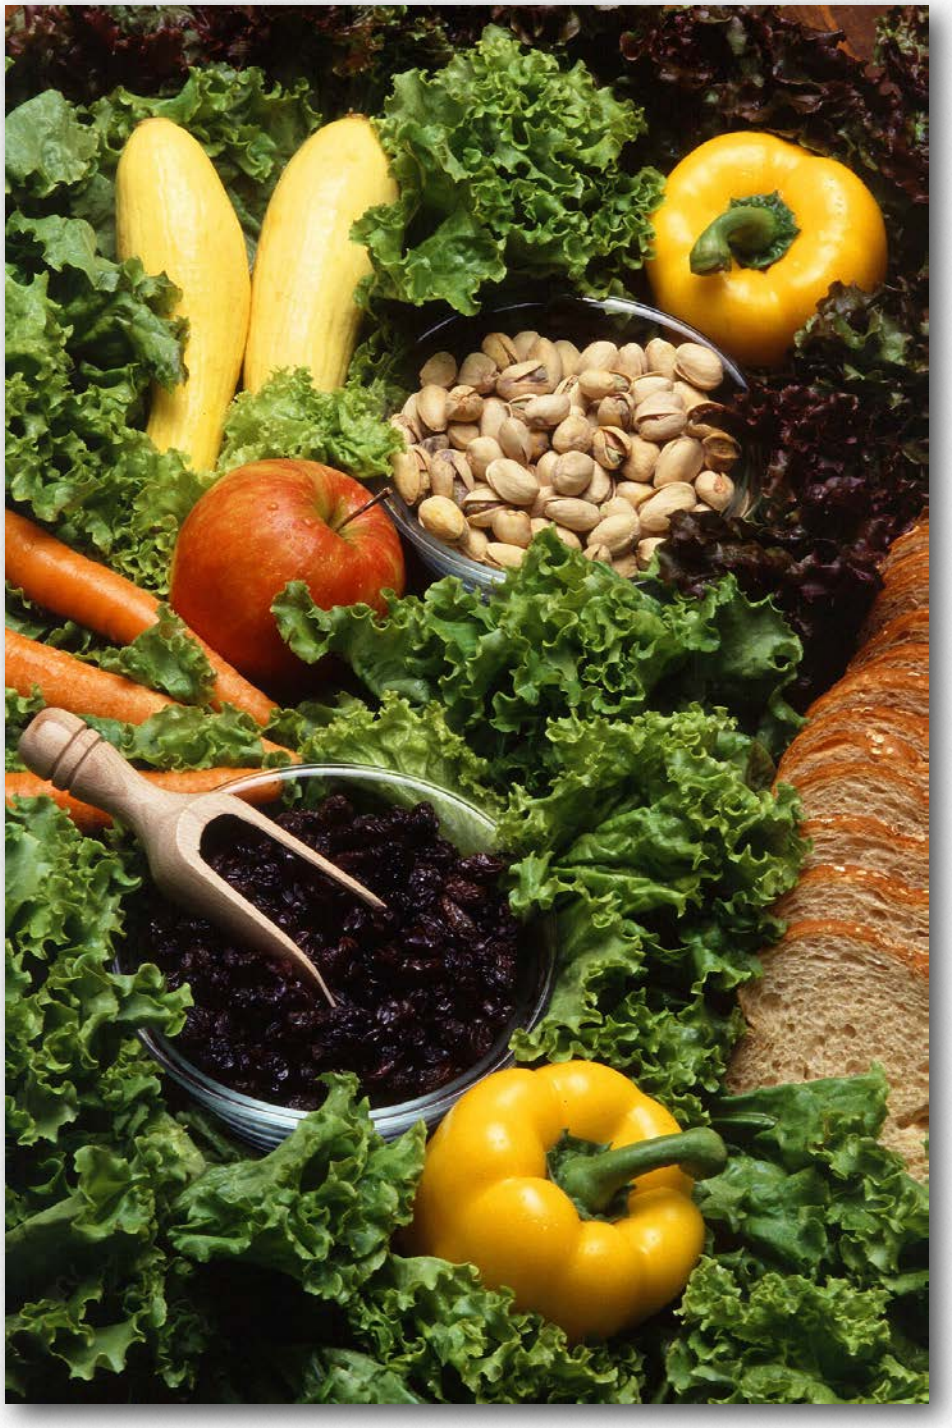

Figure 5.53 - Good antioxidant sources

lication proceeds. 8-oxoguanine can be repaired if recognized in time by a DNA glycosylase, which acts to clip out the damaged base and it can then be replaced by the proper one. Polycyclic aromatic hydrocarbons from cigarette smoke, diesel exhaust, or overcooked meat can covalently bind to DNA and, if unrepaired, lead to mutation. Chemical damage to DNA can result in broken or cross-linked DNAs.

Diseases of DNA repair

The importance of DNA repair in the aging process is made clear by diseases affecting DNA repair that lead to premature aging. These include Werner syndrome, for whom the life expectancy is 47 years. It arises as a result of loss of two enzymes in base excision repair. People suffering from Cockayne syndrome have a life expectancy of 13 years due to mutations that alter transcription-coupled nucleotide excision repair, which is an important system for fixing oxidative damage.

Further, the life expectancies of 13 species of mammalian organisms correlates with the level of expression of the PARP DNA repair-inducing protein. Interestingly, people who lived past the age of 100 had a higher level of PARP than younger people in the population.

Antioxidants

There is a growing interest in the subject of antioxidants because of health concerns raised by our knowledge of problems created as a result of spontaneous oxidation of biomolecules by Reactive Oxygen Species (ROS), such as superoxide. Antioxidants have the chemical property of protecting against oxidative damage by being readily oxidized themselves, preferentially to other biomolecules.

Biologically, cells have several lines of antioxidant defense. They include molecules, such

as vitamins C, A, and E, glutathione, and enzymes that destroy ROS such as superoxide dismutase, catalase, and peroxidases.

Health effects

Oxidation by ROS is mutagenic and has been linked to atherosclerosis. Nonetheless, randomized studies of oral supplementation of various vitamin combinations have shown no protective effect against cancer and supplementation of Vitamin E and selenium has revealed no decrease in the risk of cardiovascular disease. Further, no reduction in mortality rates as a result of supplementation with these materials has been found, so the protective effects, if any, of antioxidants on ROS in human health remain poorly understood.

Glutathione

The major endogenous antioxidant found in cells spanning most living systems, glutathione is a tripeptide protecting cells against damage caused by reactive oxygen species and heavy metals (Figures 5.55 & 5.56). The three amino acids in glutathione (glutamate, cysteine, and glycine) are joined in an unusual fashion.

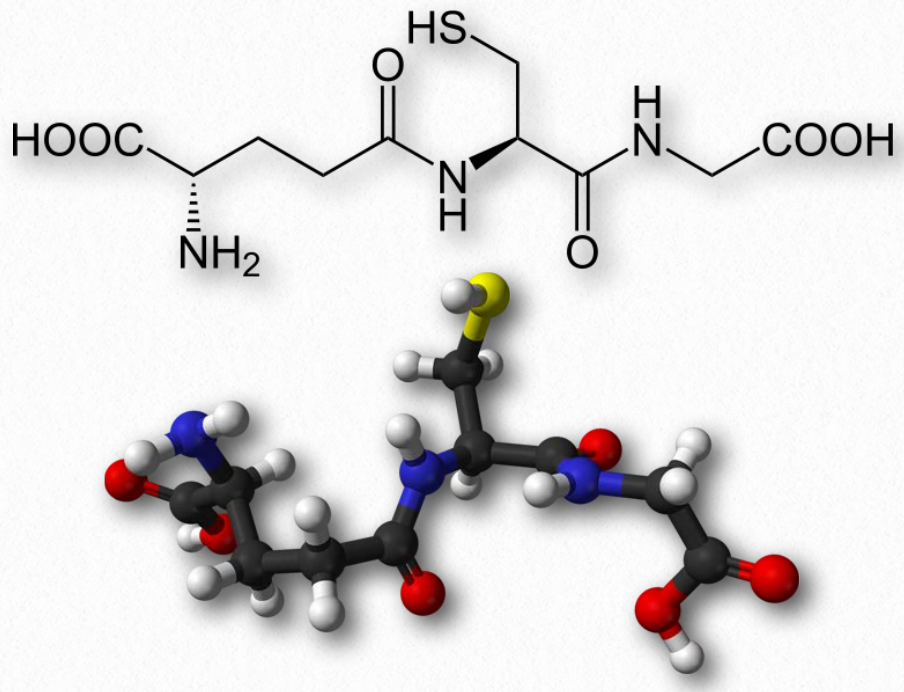

Figure 5.54 - Structure of reduced glutathione (GSH)

The glutamate is joined to the center cysteine by a peptide bond between the R-group carboxyl of glutamate and the α-amine of cysteine. The bond between cysteine and glycine is a normal peptide bond between the α-carboxyl of cysteine and the α-amine of glycine.

The thiol group of cysteine is a reducing agent that reduces disulfide bonds to sulfhydryls in cytoplasmic proteins. This, in turn, is the bridge when two glutathiones get oxidized and form a disulfide bond with each other (Figure 5.56). Glutathione's two oxidative states are abbreviated as follows: GSH (reduced) and GSSG (oxidized).

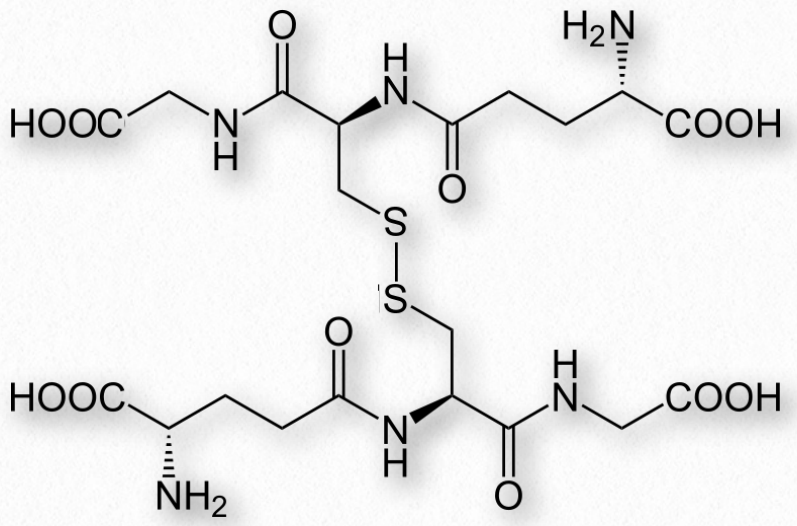

Figure 5.55 - Oxidized glutathiones (GSSG) joined by a disulfide bond

Wikipedia

Disulfide-joined glutathiones can be separated by reduction of their bonds with glutathione reductase, using electrons from NADPH for the reduction.

Non-ribosomal synthesis

Glutathione is not made by ribosomes. Rather, two enzymes catalyze its synthesis. The enzyme γ-glutamylcysteine synthetase catalyzes the joining of the glutamate to the cysteine and then glutathione synthetase catalyzes the peptide bond formation between the cysteine and the glycine. Each step requires energy from ATP.

YouTube Lectures by Kevin HERE & HERE

Essential for life

Glutathione is important for life. Mice lacking the first enzyme involved in its synthesis in the liver die in the first month after birth. In healthy cells, 90% of glutathione is in the GSH state. Higher levels of GSSG correspond to cells that are oxidatively stressed.

Besides reducing disulfide bonds in cells, glutathione is also important for the following:

• Neutralization of free radicals and reactive oxygen species.

• Maintenance of exogenous antioxidants such as vitamins C and E in their reduced forms.

• Regulation of the nitric oxide cycle

Resveratrol

Categorized as a stilbenoid, resveratrol (Figure 5.57) is a phenolic compound produced in the skin of plants such as grapes, raspberries, and blueberries, in response to injury or when they are being attacked by pathogens.

Numerous health benefits are claimed for the compound, though evidence of such benefits is in short supply. Resveratrol is metabolized rapidly in the body, so it is difficult to maintain levels of it.

Some data indicates resveratrol may improve the functioning of mitochondria. It also acts as an antioxidant and causes concentration of another anti-oxidant, glutathione, to increase. The compound appears to induce expression of manganese superoxide dis-

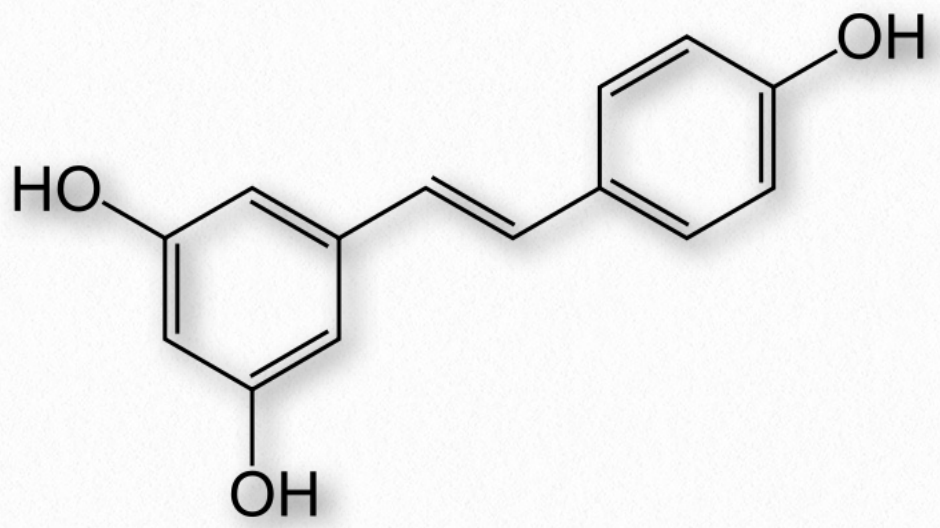

Figure 5.56 - Resveratrol

mutase (protects against reactive oxygen species) and inhibits several phosphodiesterases. This causes an increase in cAMP which results in increases in oxidation of fatty acids, mitochondria formation, gluconeogenesis, and glycogen breakdown. It has been claimed to be the cause of the French Paradox in which drinking of red wine is supposed to give protection for the cardiovascular system. Research data is lacking in support of the claim, however. Resveratrol is known to activate Sirtuin proteins, which play roles in gene inactivation.

Summary

In summary, energy is needed for cells to perform the functions that they must carry out in order to stay alive. At its most basic level, this means fighting a continual battle with entropy, but it is not the only need for energy that cells have.

Lyrics by Kevin Ahern

N-A-D

To the tune of "*Penny Lane*"

Metabolic Melodies Website HERE

In the catabolic pathways that our cells employ
Oxidations help create the ATP
While they lower Gibbs free energy
Thanks to enthalpy

If a substrate is converted from an alcohol
To an aldehyde or ketone it is clear
Those electrons do not disappear
They just rearrange – very strange

N-A-D is in my ears and in my eyes
Help-ing mol-e-cules get oxidized
Making N-A-D-H then

And the latter is a problem anaerobically
'Cuz accumulations of it muscles hate
They respond by using pyruvate
To produce lactate

Catalyzing is essential for the cells to live
So the enzymes grab their substrates eagerly
If they bind with high affinity
Low K_m you see, just as me

N-A-D is in my ears and in my eyes
Help-ing mol-e-cules get oxidized
Making N-A-D-H then

Superoxide Dismutase

To the tune of "*Supercalifragilistiexpialidocious*"
Metabolic Melodies Website HERE

When oxygen's electrons all are in the balanced state
There's twelve of them for oh-two. The molecule is great
But problems sometimes happen on the route to complex IV
Making reactive species that the cell cannot ignore

Oh superoxide dismutase is super catalytic
Keeping cells from getting very peroxynitritic
Faster than a radical, its actions are terrific
Superoxide dismutase is super catalytic

Enzyme, enzyme deep inside
Blocking all the bad oxides

The enzyme's main advantage is it doesn't have to wait
By binding superoxide in a near-transition state
It turns it to an oxygen in mechanism one
Producing "h two oh two" when the cycle is all done

Oh superoxide dismutase you're faster than all them
You've got the highest ratio of kcat over KM
This means that superoxide cannot cause too much mayhem
Superoxide dismutase is faster than all them

Superoxide dismutase
Stopping superoxide's ways

The enzyme's like a ping-pong ball that mechanistic-ly
Bounces between two copper states, plus one and two you see
So S-O-D behaves just like an anti-oxidant
Giving as much protection as a cell could ever want

Oh superoxide dismutase, the cell's in love with you
Because you let electron transport do what it must do
Without accumulation of a radical oh two
Superoxide dismutase - that's why a cell loves you

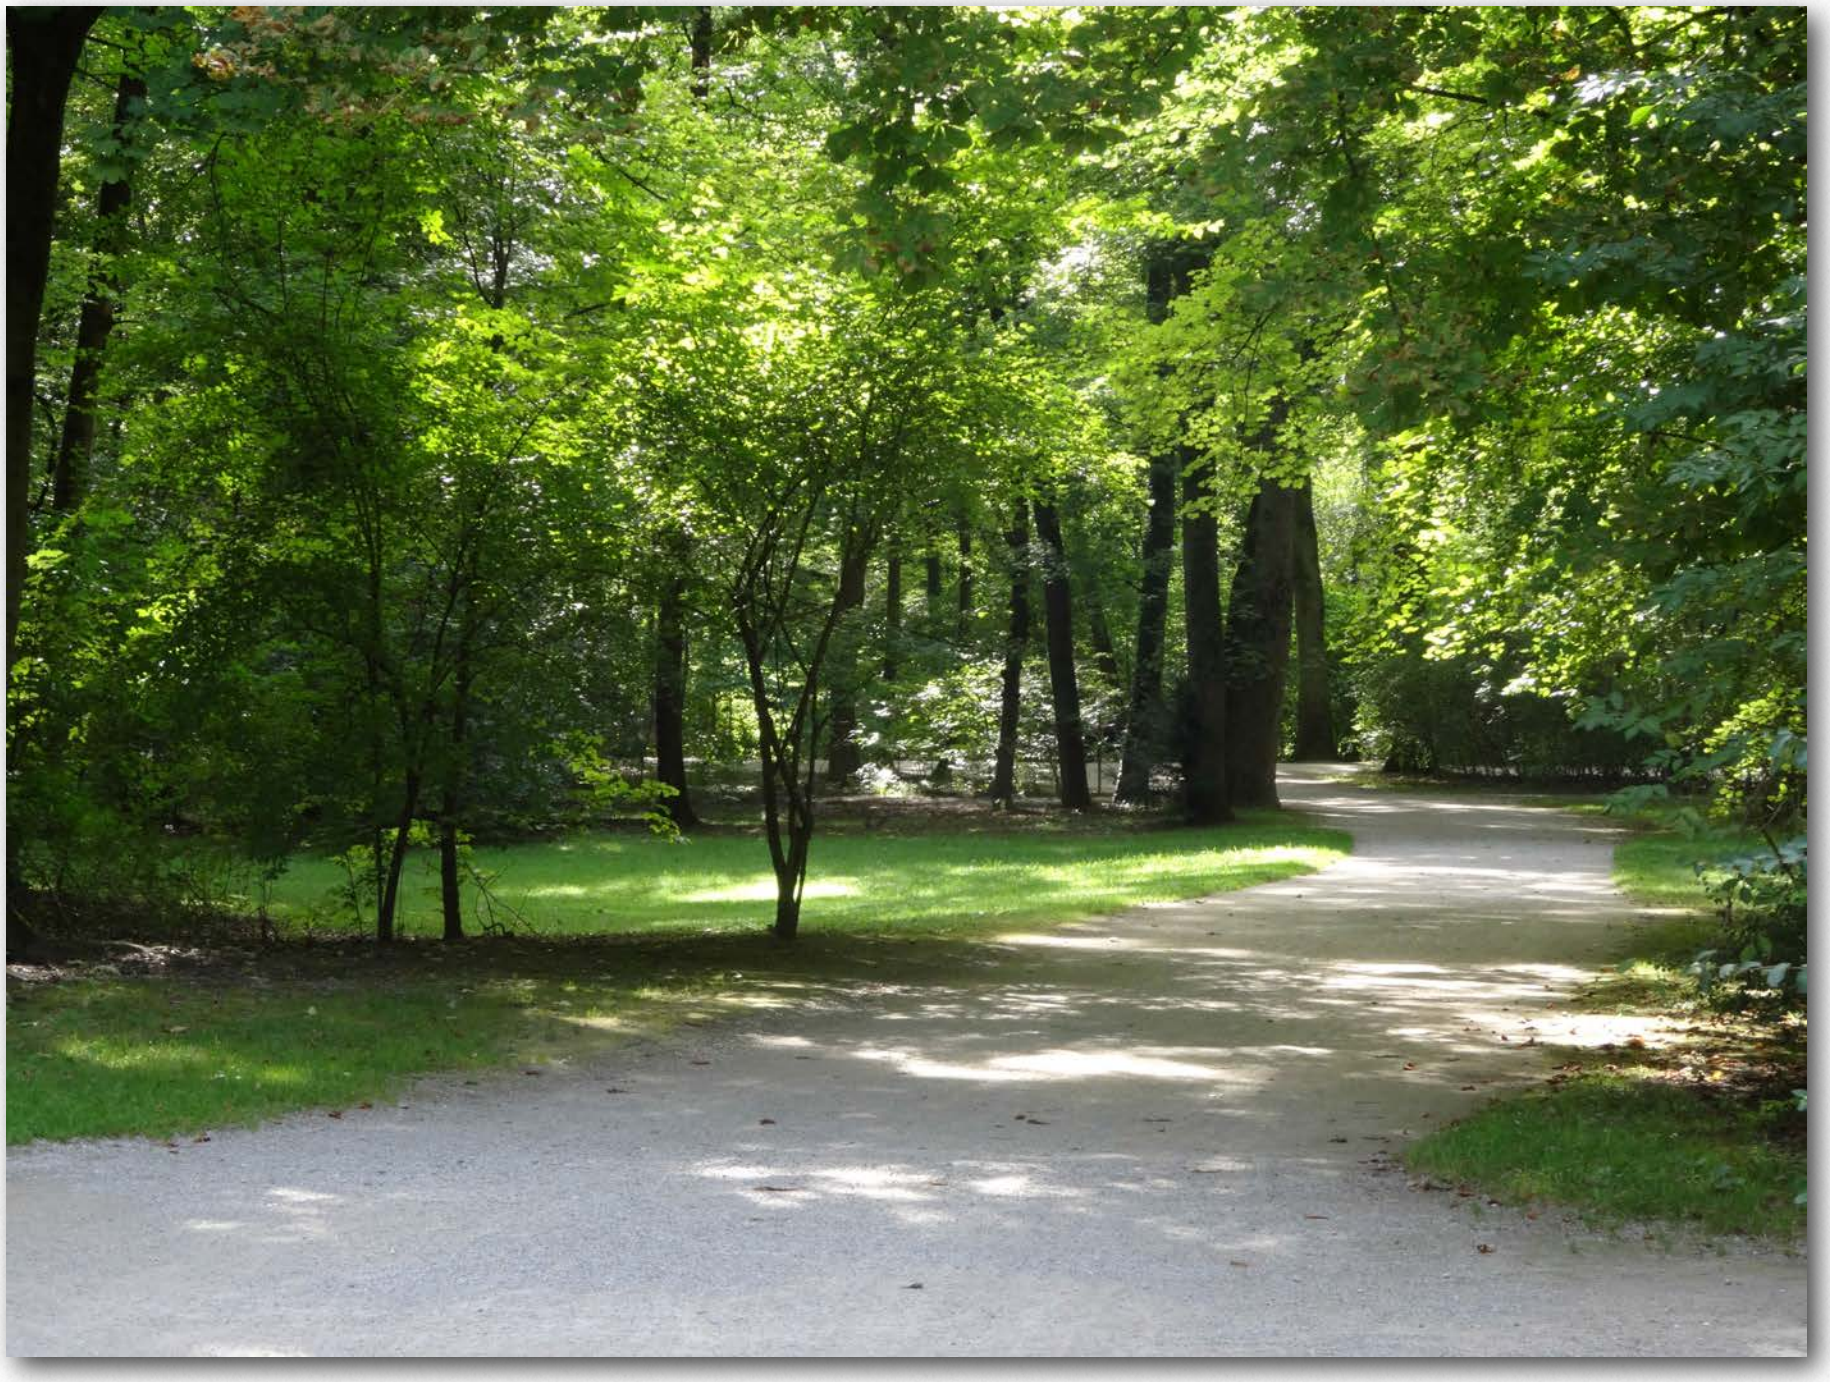
Energy: Photophosphorylation



Photophosphorylation

The third type of phosphorylation to make ATP is found only in cells that carry out photosynthesis. This process is similar to oxidative phosphorylation in several ways. A primary difference is the ultimate source of the energy for ATP synthesis. In oxidative phosphorylation, the energy comes from electrons produced by oxidation of biological molecules. In photosynthesis, the energy comes from the light of the sun.

YouTube Lectures by Kevin HERE & HERE

Photons from the sun interact with chlorophyll molecules in reaction centers in the chloroplasts (Figures 5.58 & 5.59)of plants or membranes of photosynthetic bacteria.

The similarities of photophosphorylation to oxidative phosphorylation include:

• a membrane associated electron transport chain

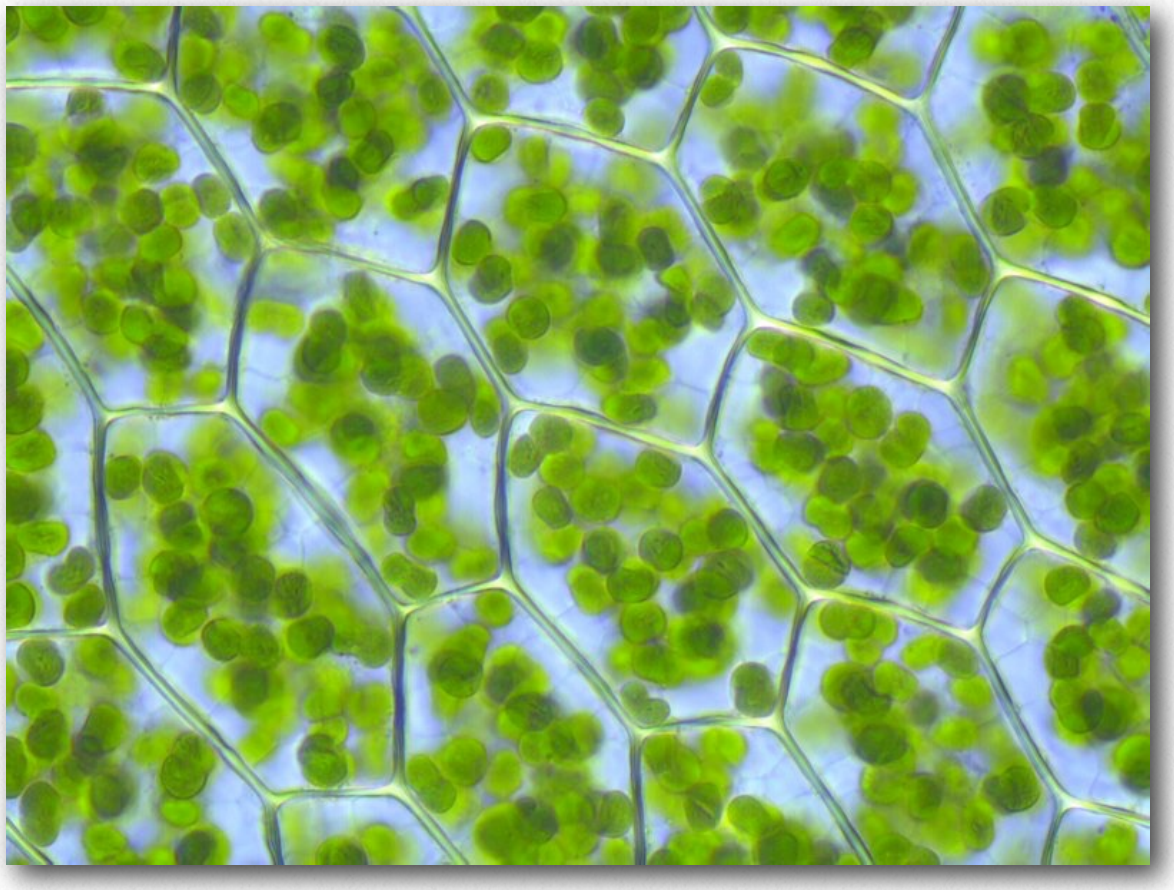


Figure 5.57 - Chloroplasts in moss cells

Wikipedia

- creation of a proton gradient
- harvesting energy of the proton gradient by making ATP with the help of an ATP synthase.

Differences

Some of the differences include :

- the source of the electrons – H_2O for photosynthesis versus NADH/$FADH_2$ for oxidative phosphorylation

- direction of proton pumping – into the thylakoid space of the chloroplasts versus outside the matrix of the mitochondrion

- movement of protons during ATP synthesis – out of the thylakoid space in photosynthesis versus into the mitochondrial matrix in oxidative phosphorylation

- nature of the terminal electron acceptor – $NADP^+$ in photosynthesis versus O_2 in oxidative phosphorylation.

Electron transport: chloroplasts *vs* mitochondria

In some ways, the movement of electrons in chloroplasts during photosynthesis is opposite that of electron transport in mitochondria. In photosynthesis, water is the source of

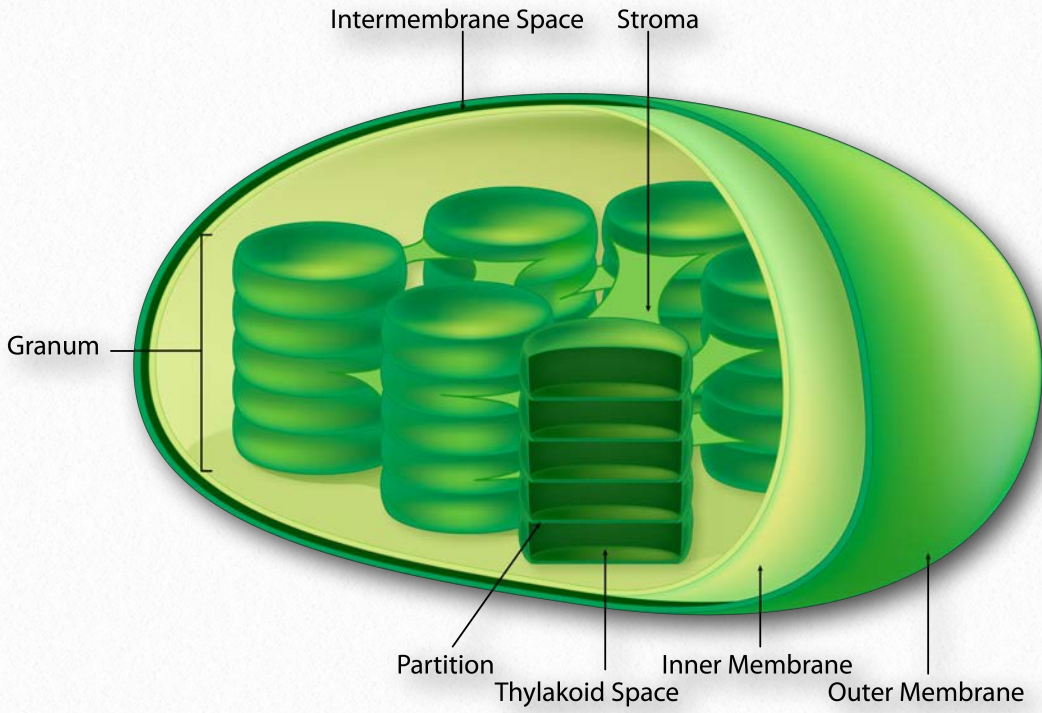

Figure 5.58 - The chloroplast

Image by Aleia Kim

electrons and their final destination is $NADP^+$ to make NADPH. In mitochondria, $NADH/FADH_2$ are electron sources and H_2O is their final destination. How do biological systems get electrons to go both ways? It would seem to be the equivalent of going to and from a particular place while always going downhill, since electrons will move according to potential.

Solar power

The answer is the captured energy of the photons from the sun (Figure 5.60), which elevates electrons to an energy where they move "downhill" to their NADPH destination in a Z-shaped scheme. The movement of electrons through this scheme in plants requires energy from photons in two places to "lift" the energy of the electrons sufficiently.

Last, it should be noted that photosynthesis actually has two phases, referred to as the light cycle (described above) and the dark cycle, which is a set of chemical reactions that captures CO_2 from the atmosphere and "fixes" it, ultimately into glucose. The dark cycle is also referred to as the Calvin Cycle and is discussed HERE.

Photosynthesis

Photosynthesis is an energy capture process found in plants and other organisms to harvest light energy and convert it into chemical energy. This photochemical energy is stored ultimately in carbohydrates which are made using ATP (from the energy harvesting), carbon dioxide and water. In most cases, a byproduct of the process is oxygen, which is released from water in the capture process. Photosynthesis is responsible for most of the oxygen in the atmosphere and it supplies the organic materials and most of the energy used by life on Earth.

Steps

The steps in the photosynthesis process varies slightly between organisms. In a broad overview, it always starts with energy capture from light by protein complexes, containing chlorophyll pigments, called reaction centers. Plants sequester these proteins in chlo-

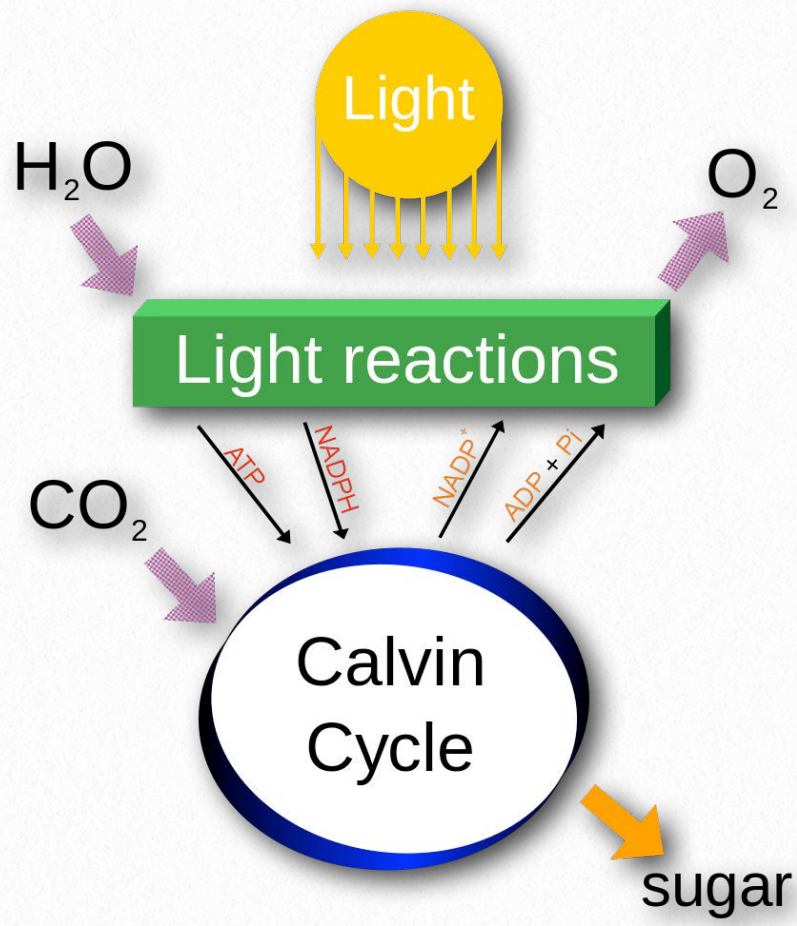

Figure 5.59 - Overview of photosynthesis
Wikipedia

roplasts, but bacteria, which don't have organelles, embed them in their plasma membranes.

Energy from the light is used to strip electrons away from electron donors (usually water) and leave a byproduct (oxygen, if water was used). Electrons are donated to a carrier and ultimately are accepted by $NADP^+$, to become NADPH. As electrons travel towards $NADP^+$, they generate a proton gradient across the thylakoid membrane, which is used to drive synthesis of ATP. Thus NADPH, ATP, and oxygen are the products of the first phase of photosynthesis called the light reactions. Energy from ATP and electrons from NADPH are used to reduce CO_2 and build sugars, which are the ultimate energy storage directly arising from photosynthesis.

Chloroplasts

Chloroplasts are found in almost all aboveground plant cells, but are primarily concentrated in leaves. The interior of a leaf, below the epidermis is made up of photosynthesis tissue called mesophyll, which can contain up to 800,000 chloroplasts per square millimeter.

The chloroplast's membrane has a phospholipid inner membrane, a phospholipid outer membrane, and a region between them called the intermembrane space (Figure 5.61). Within the inner chloroplast membrane is the stroma, in which the chloroplast DNA and the enzymes of the Calvin cycle are located. Also within the stroma are stacked, flattened disks known as thylakoids which are defined by their thylakoid membranes. The space within the thylakoid membranes are termed the thylakoid spaces or thylakoid lumen. The protein complexes containing the light-absorbing pigments, known as photosystems, are located on the thylakoid membrane. Besides chlorophylls, carotenes and xanthophylls are also present, allowing for absorption of light energy over a wider range. The same pigments are used by green algae and land plants.

ments are held in a very organized fashion complexes called antenna proteins that help funnel energy, through resonance energy transfer, to the reaction center chlorophylls. A system so organized is called a light harvesting complex. The electron transport complexes of photosynthesis are also located on the thylakoid membranes.

YouTube Lectures by Kevin HERE & HERE

Light reactions of photosynthesis

In chloroplasts, the light reactions of photosynthesis involving electron transfer occur in the thylakoid membranes (Figure 5.62). Separate biochemical reactions involving the assimilation of carbon dioxide to make glucose are referred to as the Calvin cycle, also sometimes referred to as the "dark reactions". This will be discussed elsewhere in the section on metabolism (HERE).

The chloroplasts are where the energy of light is captured, electrons are stripped from water, oxygen is liberated, electron transport occurs, NADPH is formed, and ATP is generated. The thylakoid membrane corresponds to the inner membrane of the mitochondrion for transport of electrons and proton pumping (Figure 5.63).

The thylakoid membrane does its magic using four major protein complexes. These include Photosystem II (PS II), Cytochrome b6f complex (Cb6f), Photosystem I (PS I), and ATP synthase. The roles of these complexes, respectively, are to capture light energy, create a proton gradient from electron movement, capture light energy

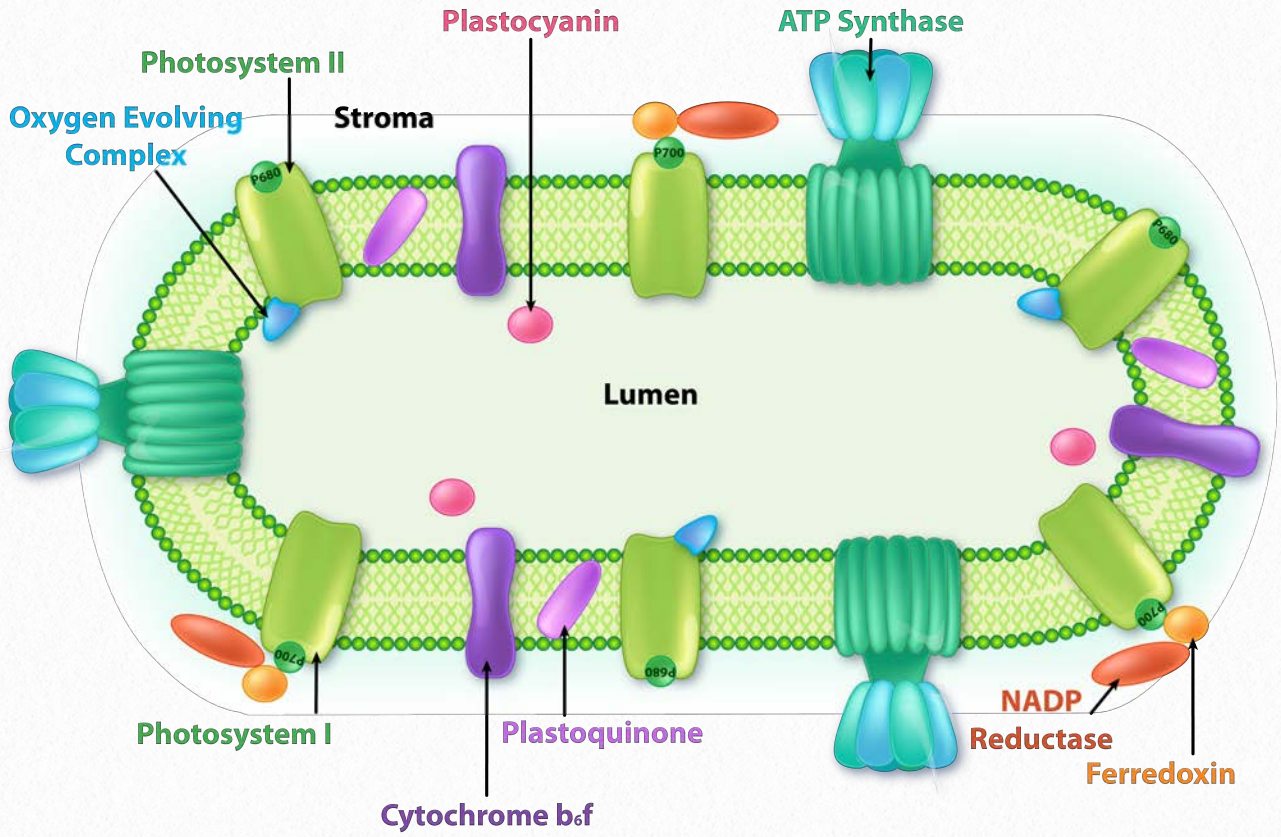

Figure 5.62 - Complexes in the thylakoid membrane

Image by Aleia Kim

(again), and use proton gradient energy from the overall process to synthesize ATP.

Light harvesting

Harvesting the energy of light begins in PS II with the absorption of a photon of light at a reaction center. PS II performs this duty best with light at a wavelength of 680 nm and it readily loses an electron to excitation when this occurs, leaving PS II with a positive charge. This electron must be replaced. The ultimate replacement source of electrons is water, but water must lose four electrons and PS II can only accept one at a time.

Photosynthesis left me aghast
As electrons all went whizzing past
Leaving water at start
They trace the Z chart
In the membranes of each chloroplast

Manganese centers

An intermediate Oxygen Evolving Complex (OEC) contains four manganese centers that provide the immediate replacement electron that PSII requires. After four electrons have been donated by the OEC to PS II, the OEC extracts four electrons from two water molecules, liberating oxygen and dumping four protons into the thylakoid space, thus contributing to the proton gradient. The excited electron from PS II must be passed to another carrier very quickly, lest it decay back to its original state. It does this, giving its electron within picoseconds to pheophytin (Figure 5.64).

Pheophytin passes the electron on to protein-bound plastoquinones. The first is known as PQ_A. PQ_A hands the electron off to a second plastoquinone (PQ_B), which waits for a second electron and collects two protons to become PQH_2, also known as plastoquinol (Figure 5.65). PQH_2

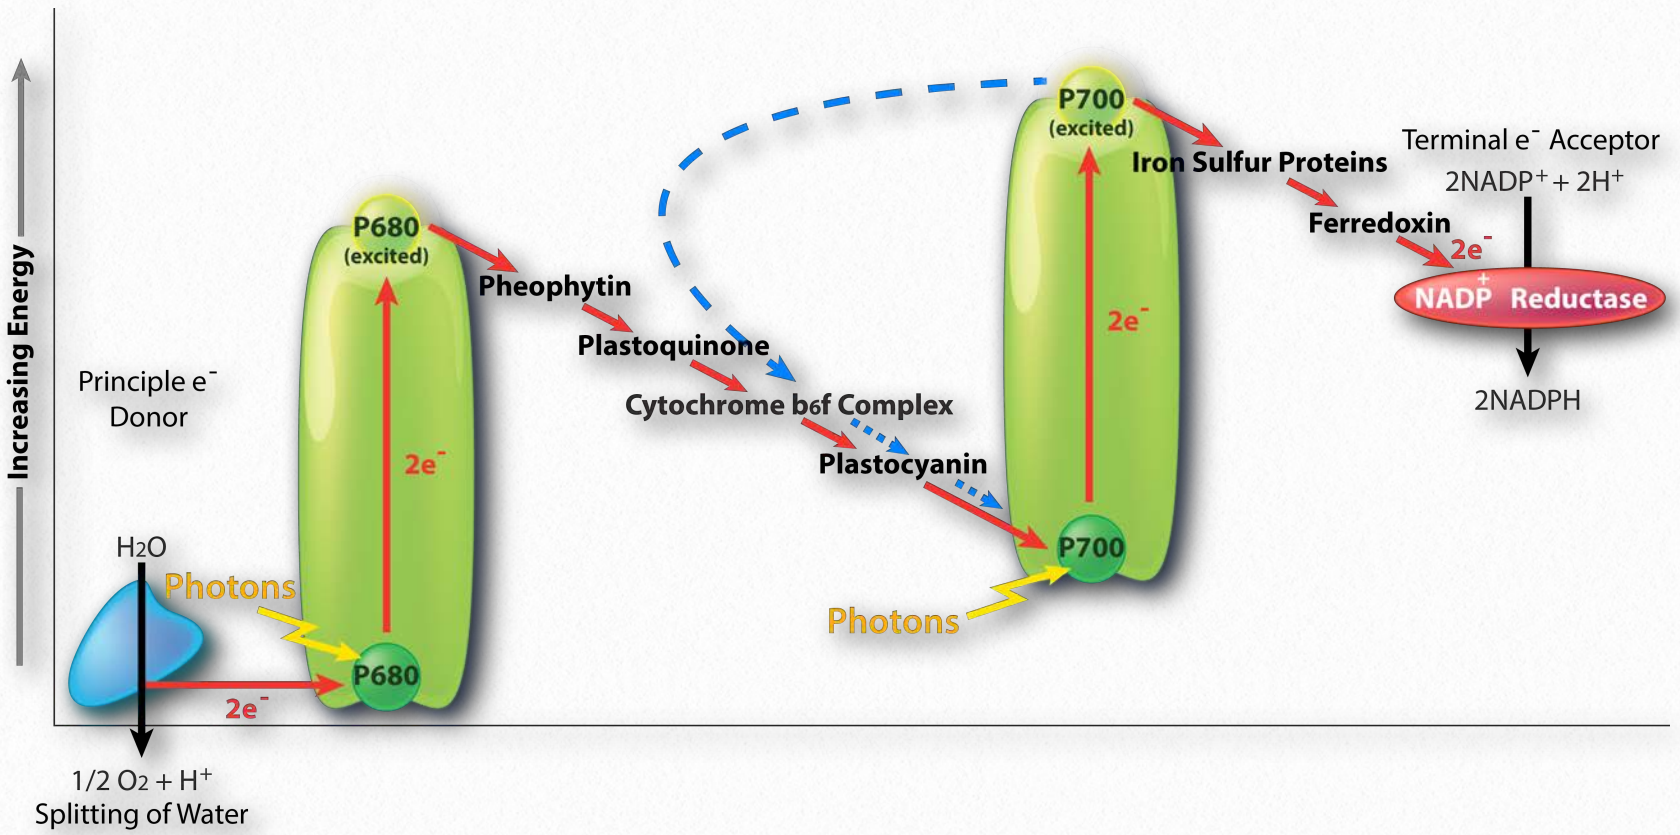

Figure 5.63 - Movement of electrons through photosystems. Cyclic photophosphorylation shown by blue dashed line

Image by Aleia Kim and Pehr Jacobson

passes these to the Cytochrome b_6f complex (Cb_6f) which uses passage of electrons through it to pump protons into the thylakoid space. ATP synthase makes ATP from the proton gradient created in this way. Cb6f drops the electron off at plastocyanin, which holds it until the next excitation process begins with absorption of another photon of light at 700 nm by PS I.

Absorption of light at PS I

With absorption of a photon of light by PS I, a process begins, that is similar to the process in PS II. PS I gains a positive charge as a result of the loss of an excited electron and pulls the electron in plastocyanin away from it. Meanwhile, the excited electron from PS I passes through an iron-sulfur protein, which gives the electron to ferredoxin (another iron sulfur protein). Ferredoxin then passes the electron off to the last protein in the system known as Ferredoxin:$NADP^+$ oxidoreductase, which gives the electron and a proton to $NADP^+$, creating NADPH.

Note that reduction of $NADP^+$ to NADPH requires two electrons and one proton, so the four electrons and two protons from oxidation of water will result in production of two molecules of NADPH. At this point, the light cycle is complete - water has been oxidized, ATP has been created, and NADPH has been made. The electrons have made their way from water to NADPH via carriers in the thylakoid membrane and their movement has released sufficient energy to make ATP. En-

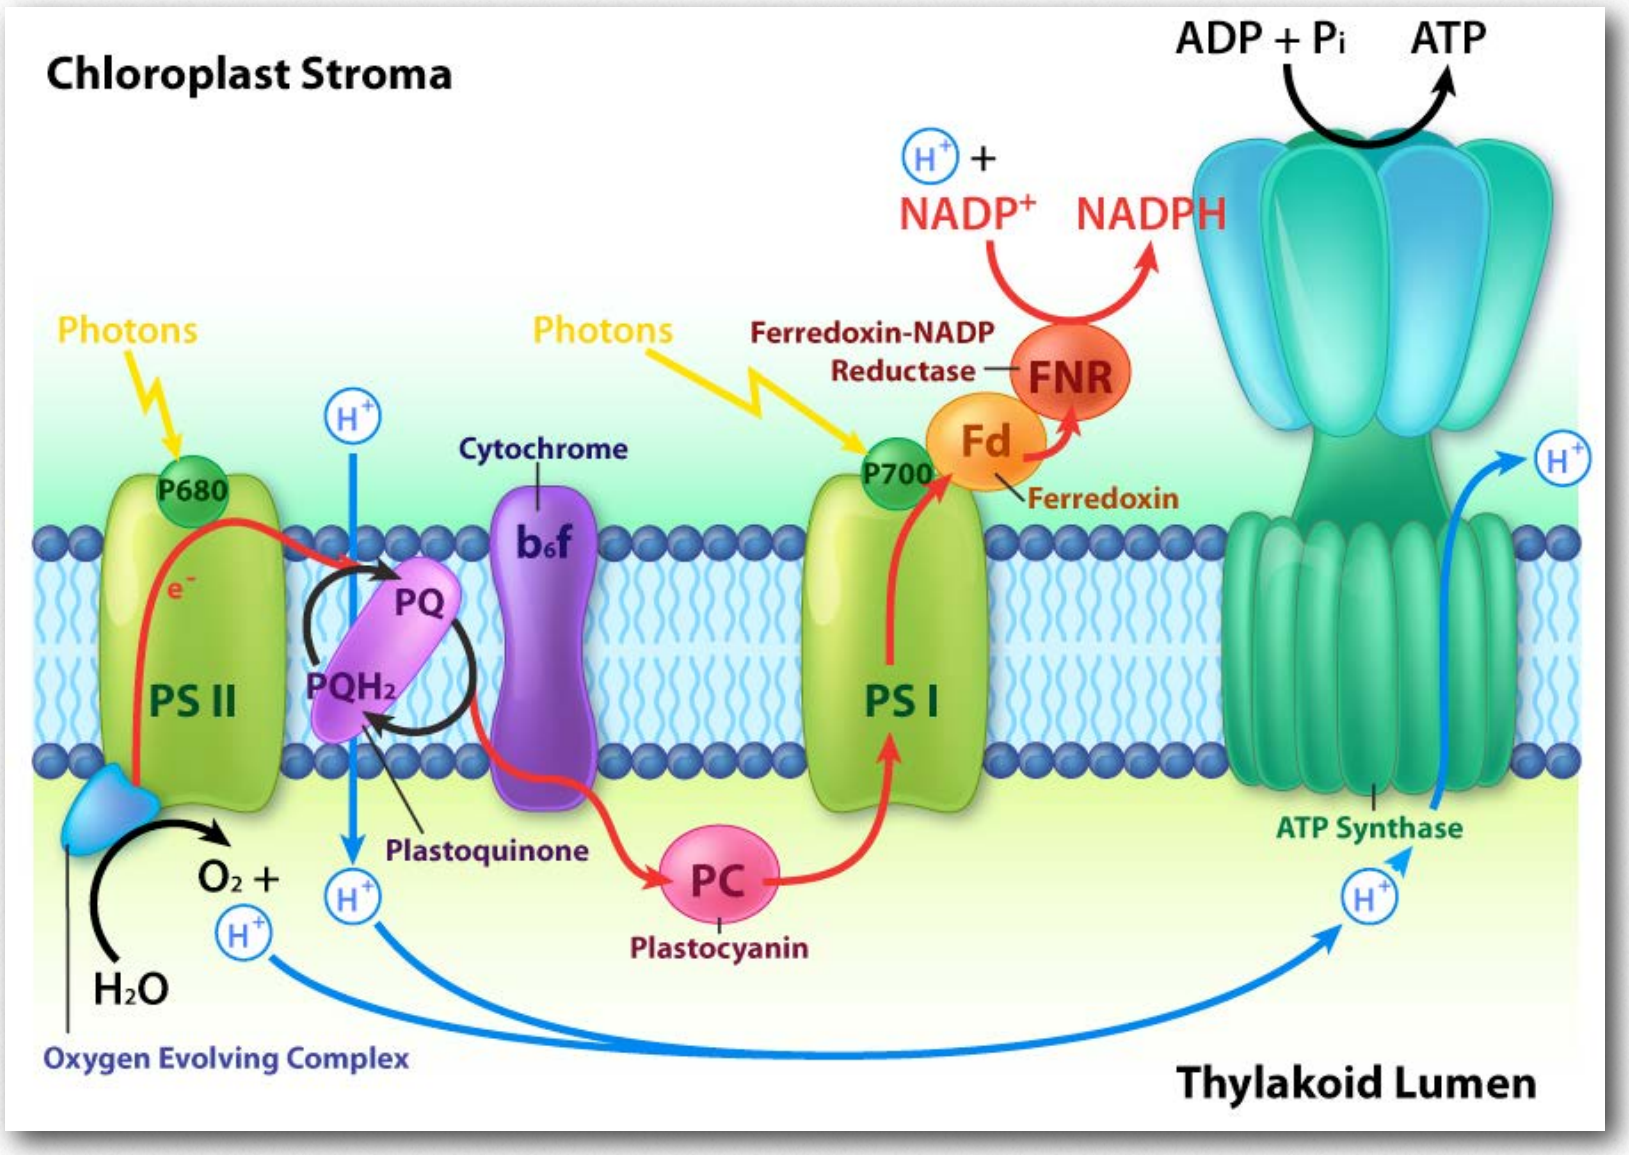

Figure 5.64 - Movement of electrons and protons through the thylakoid membrane

Image by Aleia Kim

ergy for the entire process came from four photons of light.

The two photosystems performing all of this magic are protein complexes that are similar in structure and means of operation. They absorb photons with high efficiency so that whenever a pigment in the photosynthetic reaction center absorbs a photon, an electron from the pigment is excited and transferred to another molecule almost instantaneously. This reaction is called photo-induced charge separation and it is a unique means of transforming light energy into chemical forms.

YouTube Lectures by Kevin
HERE & HERE

Cyclic photophosphorylation

Besides the path described above for movement of electrons through PS I, plants have an alternative route that electrons can take. Instead of electrons going through ferredoxin to form NADPH, they instead take a backwards path through the the proton-pumping b6f complex. This system, called cyclic photophosphorylation (Figure 5.64) which generates more ATP and no

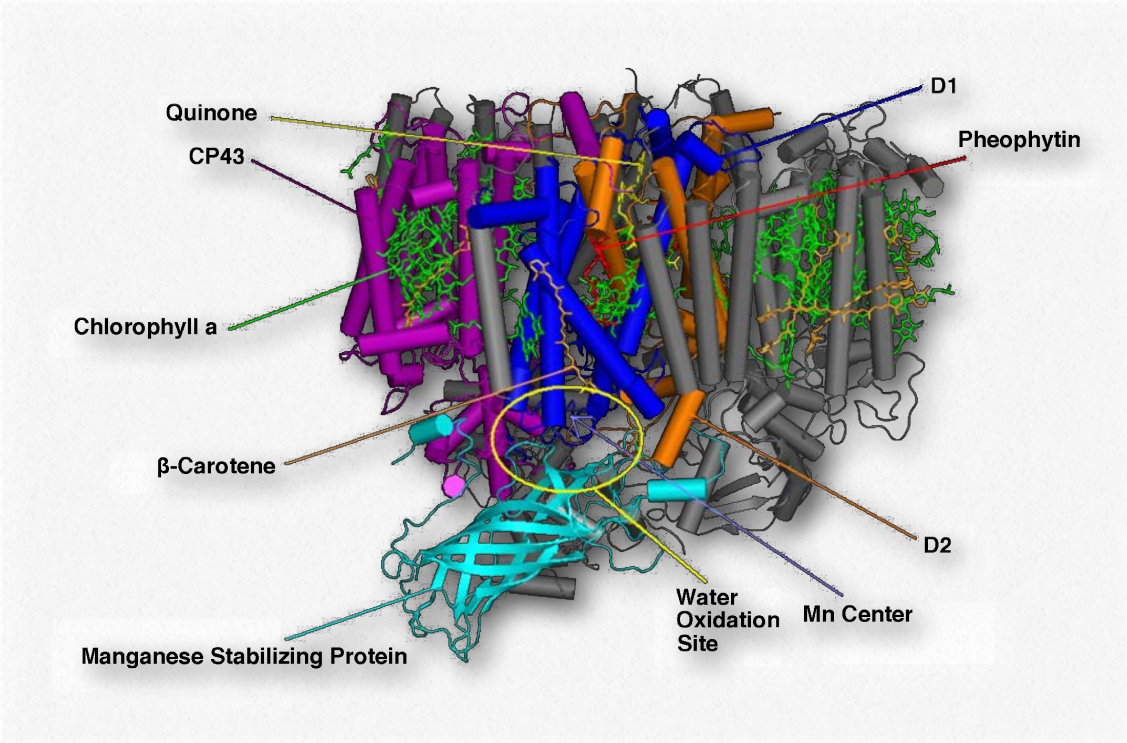

Figure 5.65 - Photosystem II of cyanobacteria

Wikipedia

NADPH, is similar to a system found in green sulfur bacteria. The ability of plants to switch between non-cyclic and cyclic photosystems allows them to make the proper ratio of ATP and NADPH they need for assimilation of carbon in the dark phase of photosynthesis. This ratio turns out to be 3 ATPs to 2 NADPHs.

Photosynthetic energy

The output of the photophosphorylation part of photosynthesis (O_2, NADPH, and ATP), of course, is not the end of the process of photosynthesis. For the growing plant, the NADPH and ATP are used to capture carbon dioxide from the atmosphere and convert it (ultimately) into glucose and other important carbon compounds. This, as noted previously, occurs in the Calvin Cycle (see HERE) in what is called the dark phase of the process. The oxygen liberated in the process is a necessary for respiration of all aerobic life forms on Earth. Indeed, it is believed that essentially all of the oxygen in the atmosphere today is the result the splitting of water in photosynthesis over the many eons that the process has existed.

Metabolism

"The true sign of intelligence is not knowledge but imagination."

- Albert Einstein

The term 'metabolism' (from the Greek, to change) is defined as sum total of all the chemical processes occurring within a living cell or organism that are necessary for the maintenance of life. In metabolism some substances are broken down to yield energy for vital processes (catabolism) while other substances, necessary for life, are synthesized (anabolism).

Studying the entire set of chemical processes necessary for life may seem intimidating, but in fact, there are two factors that make the study of metabolism much simpler than might be expected. The first is the unity of biochemical processes across species. Carl Sagan noted that “when you look more generally at life on Earth, you find that it is all the same kind of life. There are not many different kinds; there's only one kind. It uses about fifty fundamental biological building blocks, organic molecules.” This means that what we learn in one organism will help us understand the biochemistry of all other organisms.

The second reassuring fact, in the words of Sir Frederick Gowland Hopkins, is that "in the study of the intermediate processes of metabolism we have to deal not with complex substances which elude ordinary chemical methods, but with the simple substances undergoing comprehensible reactions.

With that as our starting point . . . . . .

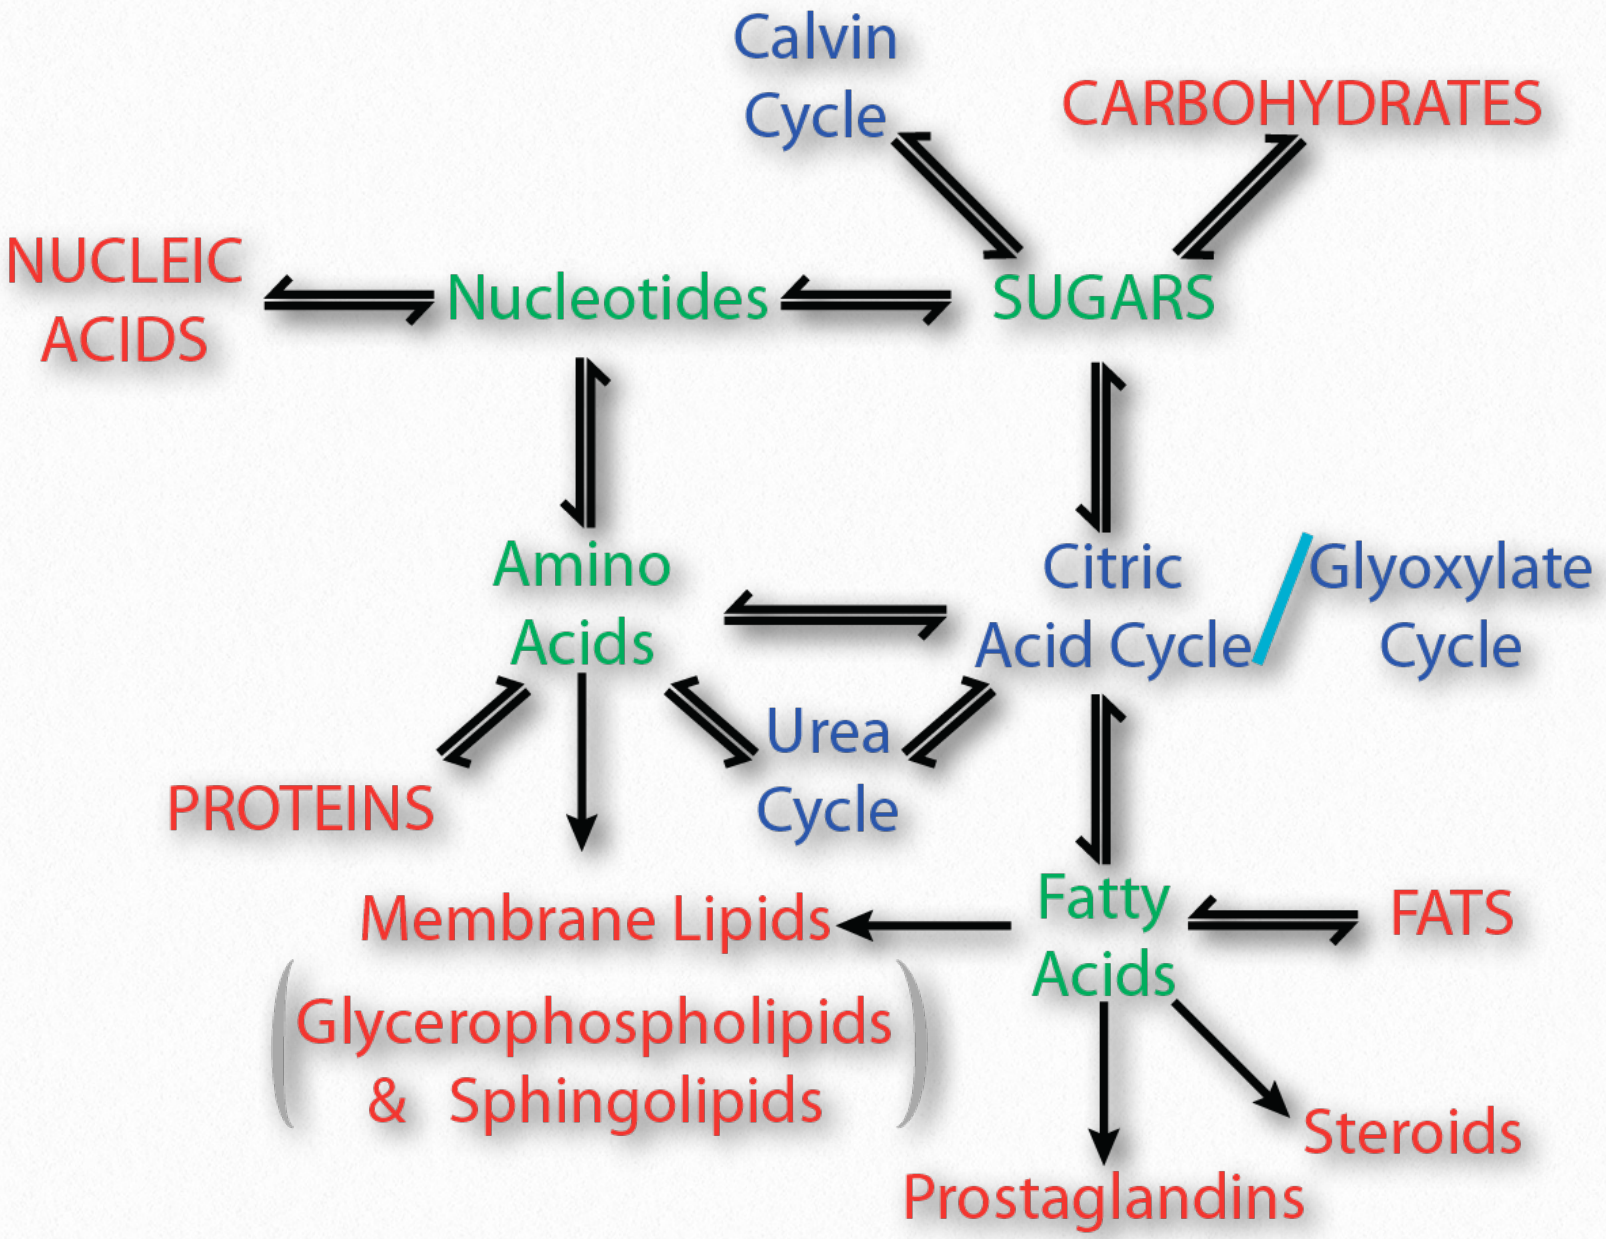

Figure 6.1 - Overview of metabolism

Image by Aleia Kim

Metabolism: Sugars

Glycolysis

Carbohydrates, whether synthesized by photosynthetic organisms, stored in cells as glycogen, or ingested by heterotrophs, must be broken down to obtain energy for the cell's activities as well as to synthesize other molecules required by the cell. Starch and glycogen, polymers of glucose, are the main energy storage forms of carbohydrates in plants and animals, respectively. To use these sources of energy, cells must first break down the polymers to yield glucose. The glucose is then taken up by cells through transporters in cell membranes. The metabolism of glucose, as well as other six carbon sugars (hexoses) begins with the catabolic pathway called glycolysis. In this pathway, sugars are oxidized and broken down into pyruvate molecules. The corresponding anabolic pathway by which glucose is synthesized is termed gluconeogenesis. Neither glycolysis nor gluconeogenesis is a major oxidative/reductive process, with one step in each one involving loss/gain of elec-

Your cells may have a mounting crisis
Should they not go through glyco-lye-sis
No glucose energy releases
Until it's fractured into pieces

trons, but the product of glycolysis, pyruvate, can be completely oxidized to carbon dioxide (Figure 6.2). Indeed, without production of pyruvate from glucose in glycolysis, a major energy source for the cell would not be available.

Glucose is the most abundant hexose in nature and is traditionally used to illustrate the reactions of glycolysis, but fructose (in the form of fructose-6-phosphate) is also readily metabolized, while galactose can easily be converted into glucose for catabolism in the pathway as well. The end metabolic products of glycolysis are two molecules of ATP, two molecules of NADH and two molecules of pyruvate (Figure 6.3), which, in turn, can be oxidized further in the citric acid cycle.

Entry points for glycolysis

Glucose and fructose are the sugar 'funnels' serving as entry points to the glycolytic pathway. Other sugars must be converted to either of these forms to be metabolized in glycolysis. Some pathways, including the Calvin

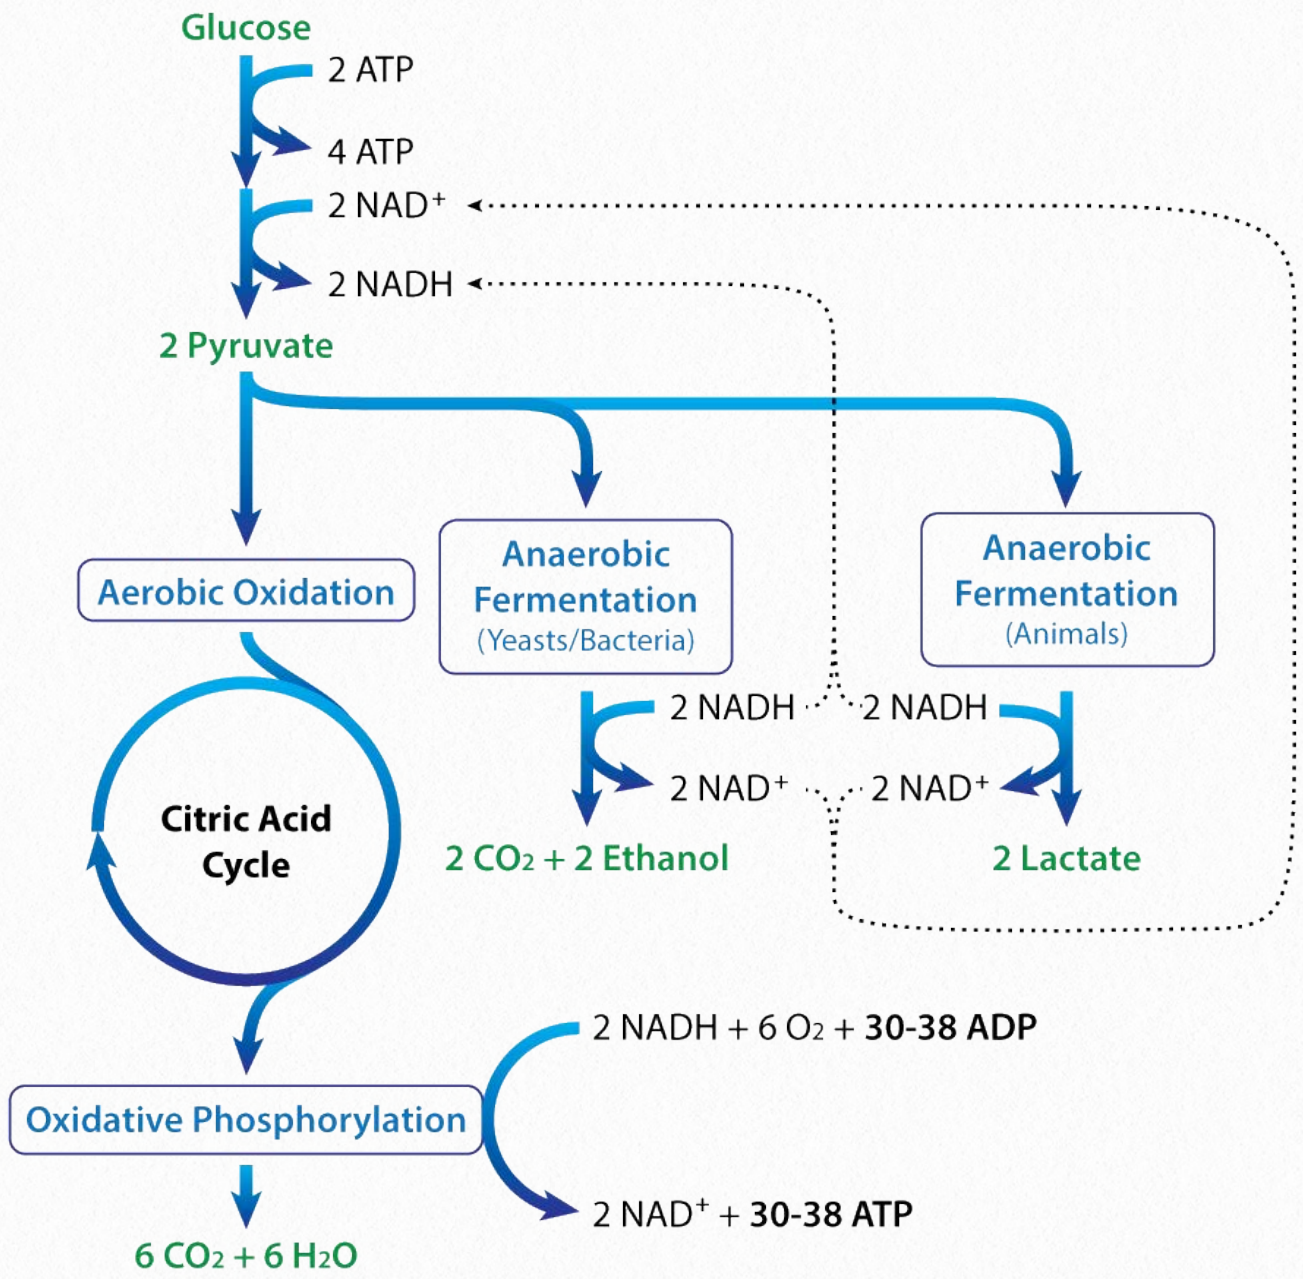

Figure 6.2 - Metabolic fates of glucose

Image by Aleia Kim

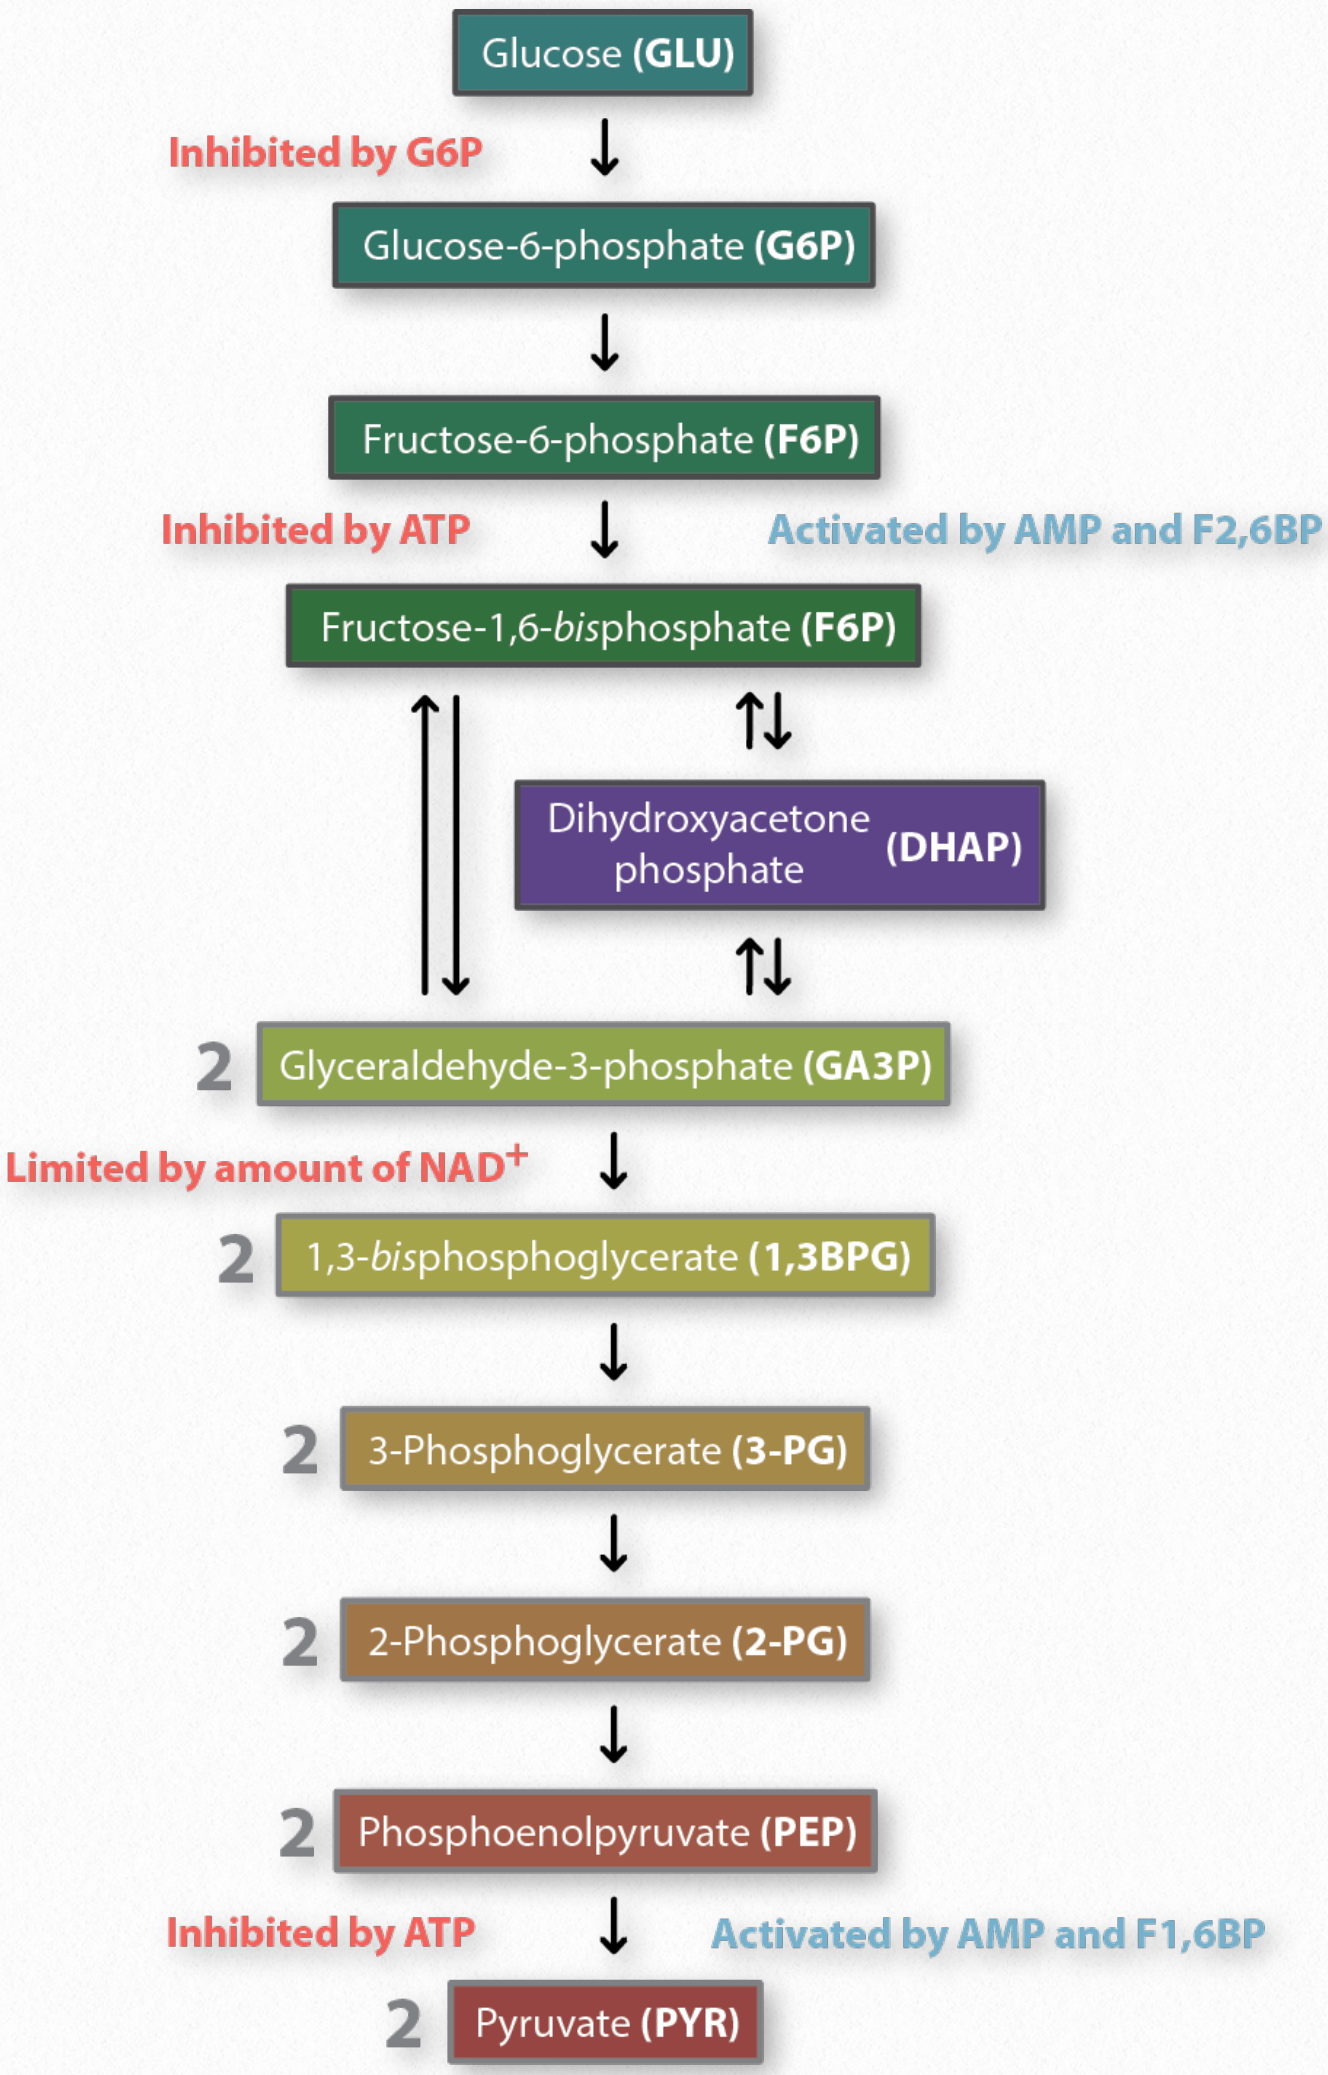

Figure 6.3 - Glycolysis and its Regulators

Image by Ben Carson

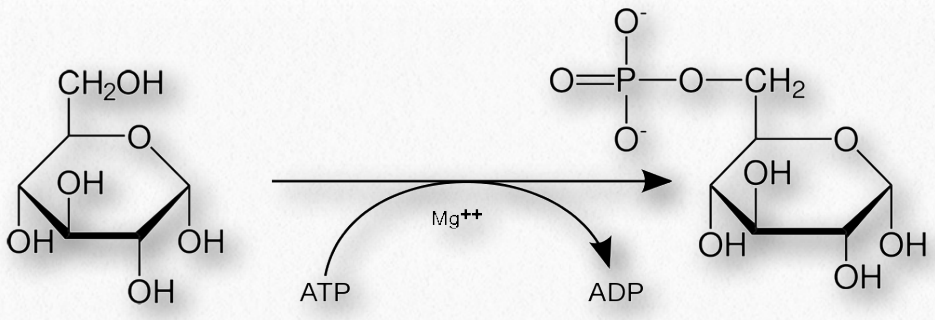

Figure 6.4 - Reaction #1 - Phosphorylation of glucose - catalyzed by hexokinase

Cycle and the Pentose Phosphate Pathway (PPP) contain intermediates in common with glycolysis, so in that sense, almost any cellular sugar can be metabolized here.

Other pathways

Intermediates of glycolysis and gluconeogenesis that are common to other pathways include glucose-6-phosphate (PPP, glycogen metabolism), Fructose-6-phosphate (Calvin Cycle, PPP), Glyceraldehyde-3-phosphate (Calvin Cycle, PPP), dihydroxyacetone phosphate (PPP, glycerol metabolism, Calvin Cycle), 3-phosphoglycerate (Calvin Cycle, PPP), phosphoenolpyruvate (C4 plant metabolism, Calvin Cycle), and pyruvate (fermentation, acetyl-CoA genesis, amino acid metabolism). It is worth noting that glycerol from the breakdown of fat can readily be metabolized to dihydroxyacetone phosphate (DHAP) and thus enter the glycolysis pathway. It is the only part of a fat that is used in these pathways.

Reaction 1

Glucose gets a phosphate from ATP to make glucose-6-phosphate (G6P) in a reaction catalyzed by the enzyme hexokinase, a transferase enzyme.

$$\text{Glucose} + \text{ATP} \rightleftarrows \text{G6P} + \text{ADP} + \text{H}^+$$

Hexokinase is one of three regulated enzymes in glycolysis and is inhibited by one of the products of its action - G6P. Hexokinase has flexibility in its substrate binding and is able to phosphorylate a variety of hexoses, including fructose, mannose, and galactose.

Why phosphorylate glucose?

Phosphorylation of glucose serves two important purposes. First, the addition of a phosphate group to glucose effectively traps it in the cell, as G6P cannot diffuse across the lipid bilayer. Second, the reaction decreases the concentration of free glucose, favoring additional import of the molecule. G6P is a substrate for the pentose phosphate pathway and can also be converted to glucose-1-phosphate (G1P) for use in glycogen synthesis and galactose metabolism (Figure 6.5).

It is worth noting that the liver has an enzyme like hexokinase called glucokinase, which

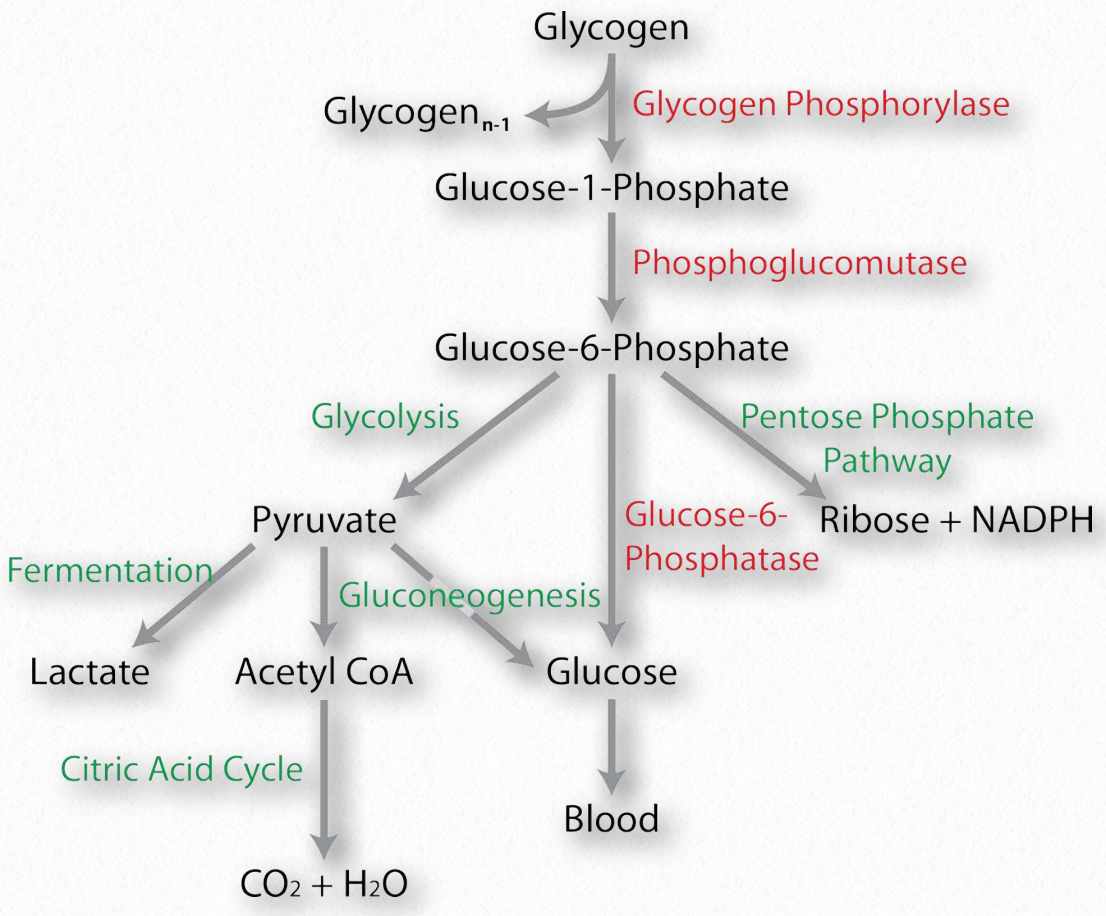

Figure 6.5 - The centrality of glucose-6-phosphate in metabolism

Image by Aleia Kim

where cellular concentrations of glucose can be relatively high. With a lower affinity glucose phosphorylating enzyme, glucose is not converted to G6P unless glucose concentrations get high, so the liver is able to release the glucose it makes into the bloodstream for the rest of the body to use.

Reaction 2

Next, G6P is converted to fructose-6-phosphate (F6P), in a reaction catalyzed by the enzyme phosphoglucoisomerase.

G6P ⇄ F6P

has a much higher K_m (lower affinity) for glucose. This is important, because the liver is a site of glucose synthesis (gluconeogenesis)

The reaction has a low $\Delta G°'$, so it is readily favorable in either direction with

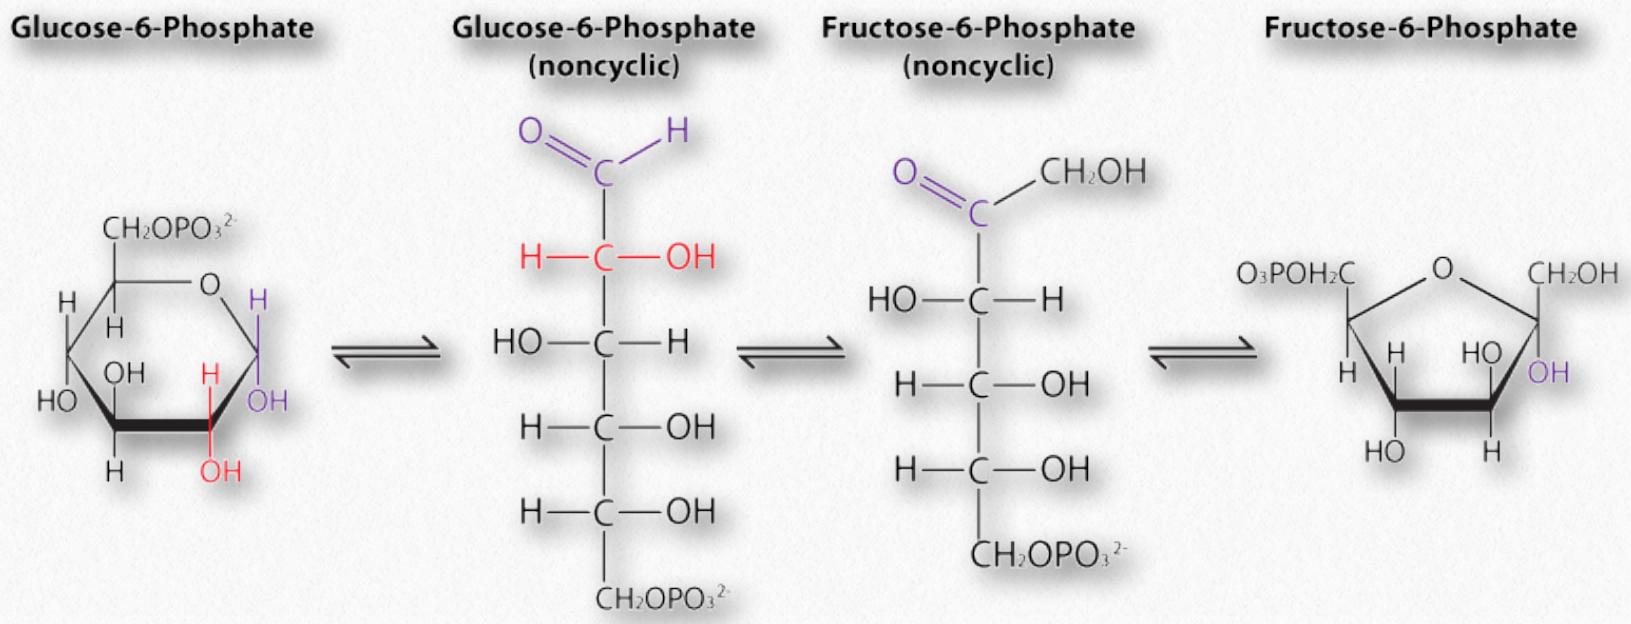

Figure 6.6 - Mechanism of conversion of G6P to F6P in reaction #2

only slight changes in concentration of reactants.

Reaction 3

F6P + ATP ⇄ F1,6BP + ADP + H^+

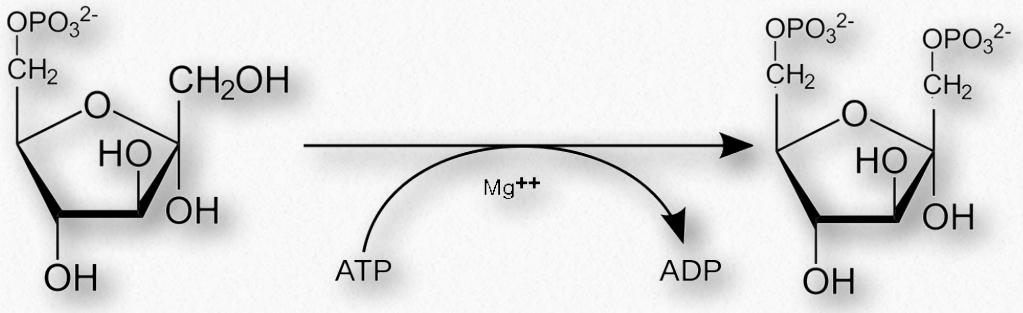

Figure 6.7 - Reaction #3 - Conversion of F6P to F1,6BP by PFK

Wikipedia

The second input of energy occurs when F6P gets another phosphate from ATP in a reaction catalyzed by the enzyme phosphofructokinase-1 (PFK-1 - another transferase) to make fructose-1,6-bisphosphate (F1,6BP). PFK-1 is a very important enzyme regulating glycolysis, with several allosteric activators and inhibitors (see HERE).

YouTube Lectures by Kevin HERE & HERE

Like the hexokinase reaction the energy from ATP is needed to make the reaction energetically favorable.

PFK-1 is the most important regulatory enzyme in the pathway and this reaction is the rate-limiting step. It is also one of three essentially irreversible reactions in glycolysis.

A variant enzyme found in plants and some bacterial uses pyrophosphate rather than ATP as the energy source and due to the lower energy input from hydrolysis of the pyrophosphate, that reaction is reversible.

Reaction 4

F1,6BP ⇄ D-GLYAL3P + DHAP

With the glycolysis pump thus primed, the pathway proceeds to split the F1,6BP into two 3-carbon intermediates. This reaction catalyzed by the lyase known as aldolase is energetically a “hump” to overcome in the glycolysis direction ($\Delta G^{\circ\prime}$ = +24 kJ/mol

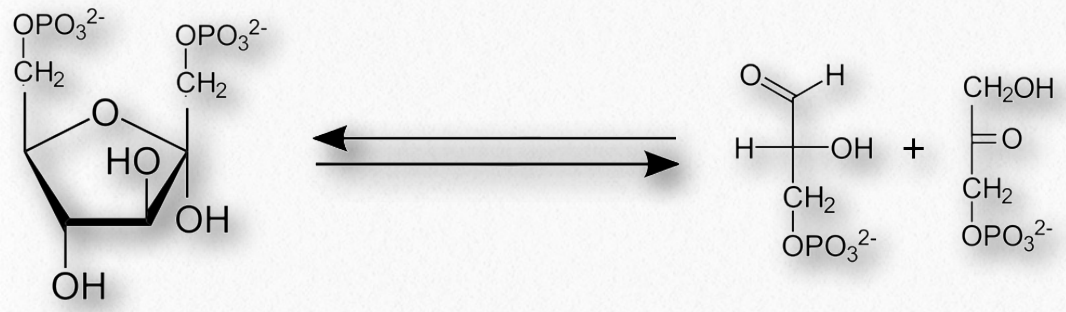

Figure 6.8 - Reaction #4 - Breakdown of F1,6BP into GLYAL3P (left) and DHAP (right) by aldolase

°K) so to get over the energy hump, cells must increase the concentration the reactant (F1,6BP) and decrease the concentration of the products, which are D-glyceraldehyde-3-phosphate (D-GLYAL3P) and dihydroxyacetone phosphate (DHAP).

A novel scheme facilitates decreasing concentration of the products (see below). Aldolases cut the ketose ring by two different mechanisms and these enzymes are grouped as Class I (in animals and plants) and Class II (in fungi and bacteria).

Reaction 5

DHAP ⇄ D-GLYAL3P

In the next step, DHAP is converted to D-GLYAL3P in a reaction catalyzed by the enzyme triosephosphate isomerase. At this point, the six carbon glucose molecule has been broken down to two units of three carbons each - D-GLYAL3P. From this point forward each reaction of glycolysis contains two of each molecule. Reaction #5 is fairly readily reversible in cells.

The enzyme is of note because it is one example of a "perfect enzyme." Enzymes in this category have very high ratios of K_{cat}/K_m that approach a theoretical maximum limited only by the diffusion of substrate into the active site of the enzyme. The apparent reason for the enzyme evolving in this way is that the mechanism of the reaction produces an unstable, toxic intermediate (Figure 6.9). With the reaction proceeding as rapidly as it does, there is less chance of the intermediate escaping and causing damage in the cell.

Reaction 6

D-GLYAL3P + NAD^+ + P_i ⇅ D-1,3BPG + NADH + H^+

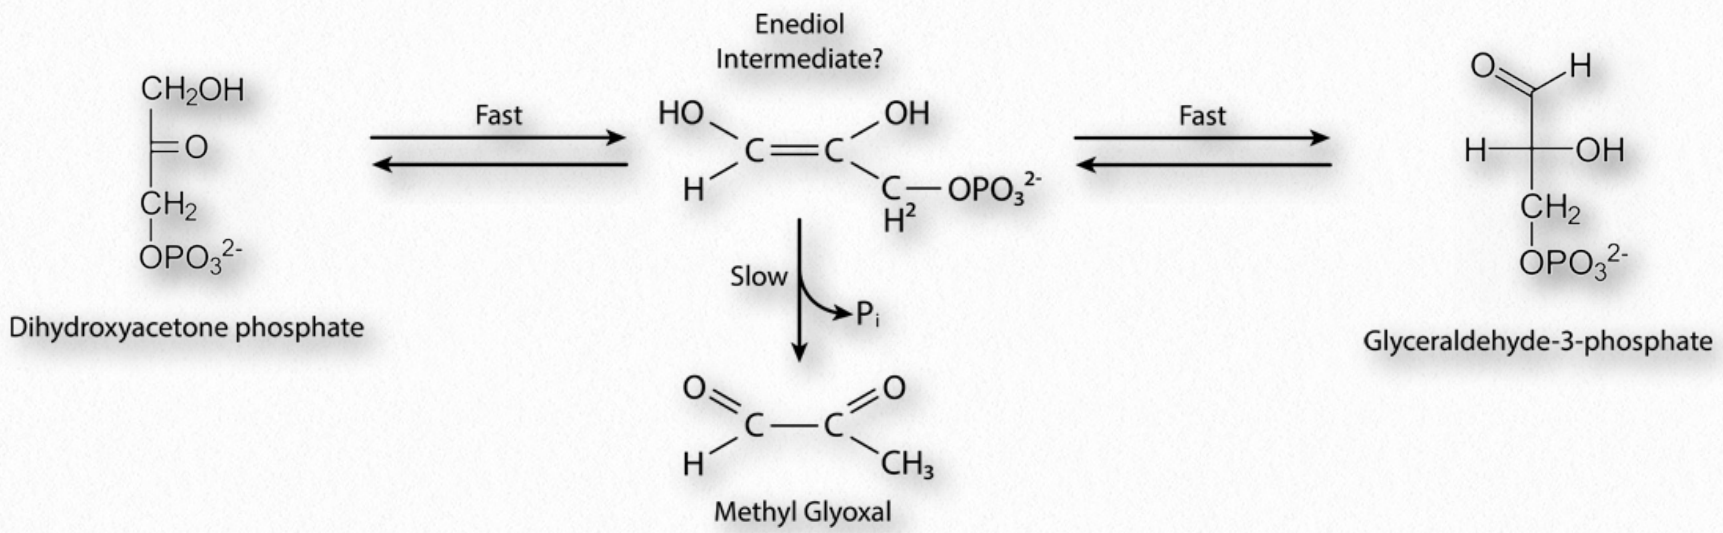

Figure 6.9 - Reaction #5 - Triose phosphate isomerase with unstable, toxic intermediate (methyl glyoxal)

Image by Ben Carson

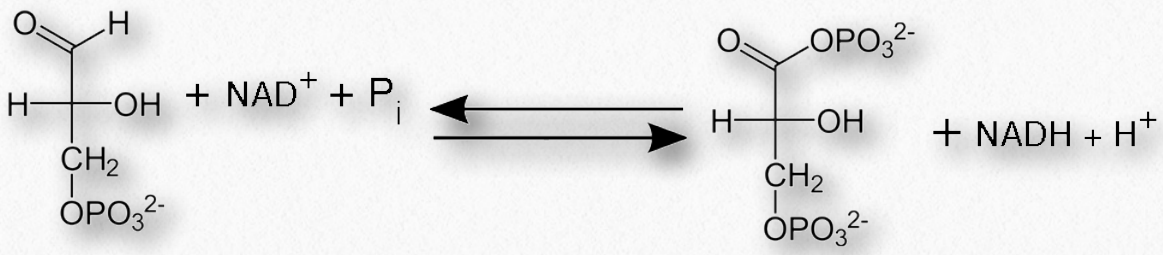

Figure 6.10 - Reaction #6 - Oxidation of GLYAL3P, catalyzed by glyceraldehyde-3-phosphate dehydrogenase

In this reaction, D-GLYAL3P is oxidized in the only oxidation step of glycolysis catalyzed by the enzyme glyceraldehyde-3-phosphate dehydrogenase, an oxidoreductase. The aldehyde in this reaction is oxidized, then linked to a phosphate to make an ester - D-1,3-bisphospho-glycerate (D-1,3BPG). Electrons from the oxidation are donated to NAD^+, creating NADH.

NAD^+ is a critical constituent in this reaction and is the reason that cells need a fermentation option at the end of the pathway (see below).

Note here that ATP energy was not required to put the phosphate onto the oxidized D-GLYAL3P. The reason for this is because the energy provided by the oxidation reaction is sufficient for adding the phosphate.

Reaction 7

D-1,3BPG + ADP ⇄ 3PG + ATP

The two phosphates in the tiny 1,3BPG molecule repel each other and give the molecule high potential energy. This energy is utilized by the enzyme phosphoglycerate kinase (another transferase) to phosphorylate ADP and make ATP, as well as the product, 3-phosphoglycerate (3-PG). This is an example of a substrate-level phosphorylation. Such mechanisms for making ATP require an intermediate with a high enough energy to phosphorylate ADP to make ATP.

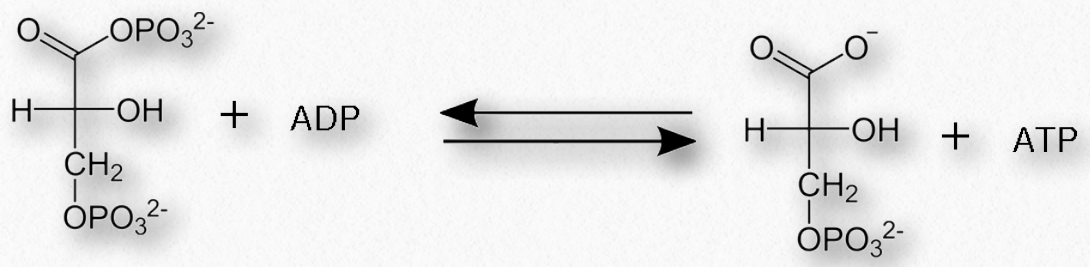

Figure 6.11 - Reaction #7 - Substrate-level Phosphorylation by 1,3-BPG

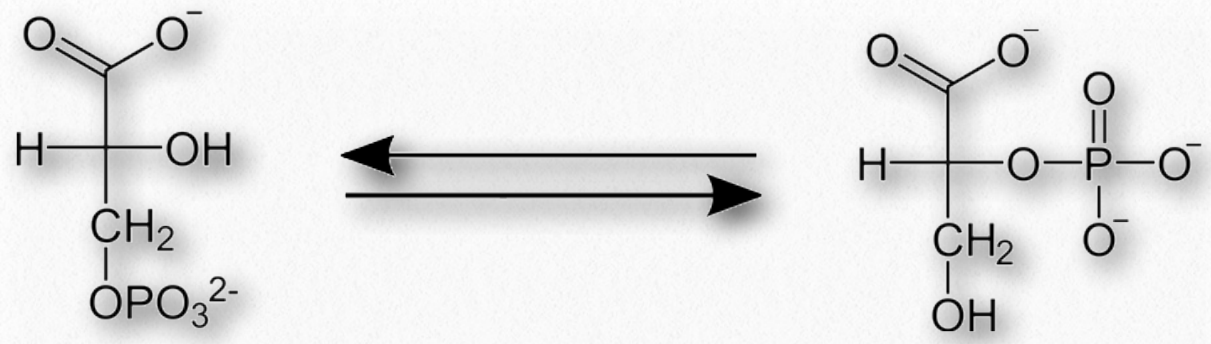

Figure 6.12 - **Reaction #8 - Conversion of 3-PG to 2-PG**

Reaction 8

3-PG ⇄ 2-PG

Conversion of the 3-PG intermediate to 2-PG (2-phosphoglycerate) occurs by an important mechanism. An intermediate in this readily reversible reaction (catalyzed by phosphoglycerate mutase - a mutase enzyme) is 2,3-BPG. This intermediate, which is stable, is released with low frequency by the enzyme instead of being con-

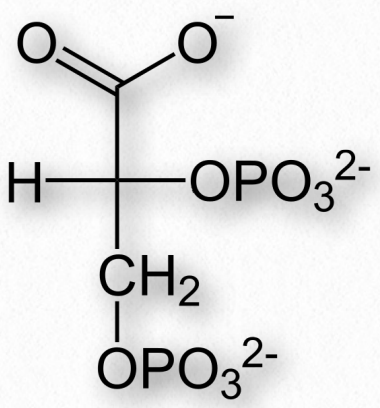

Figure 6.14 - **2,3-Bisphosphoglycerate (2,3-BPG)**

Though there are a few substrate level phosphorylations in cells (including another one at the end of glycolysis), the vast major of ATP is made by oxidative phosphorylation in the mitochondria (in animals). In addition to oxidative phosphorylation, plants also make ATP by photophosphorylation in their chloroplasts. Since there are two 1,3 BPGs produced for every glucose, the two ATPs produced in this reaction replenish the two ATPs used to start the cycle and the net ATP count at this point of the pathway is zero.

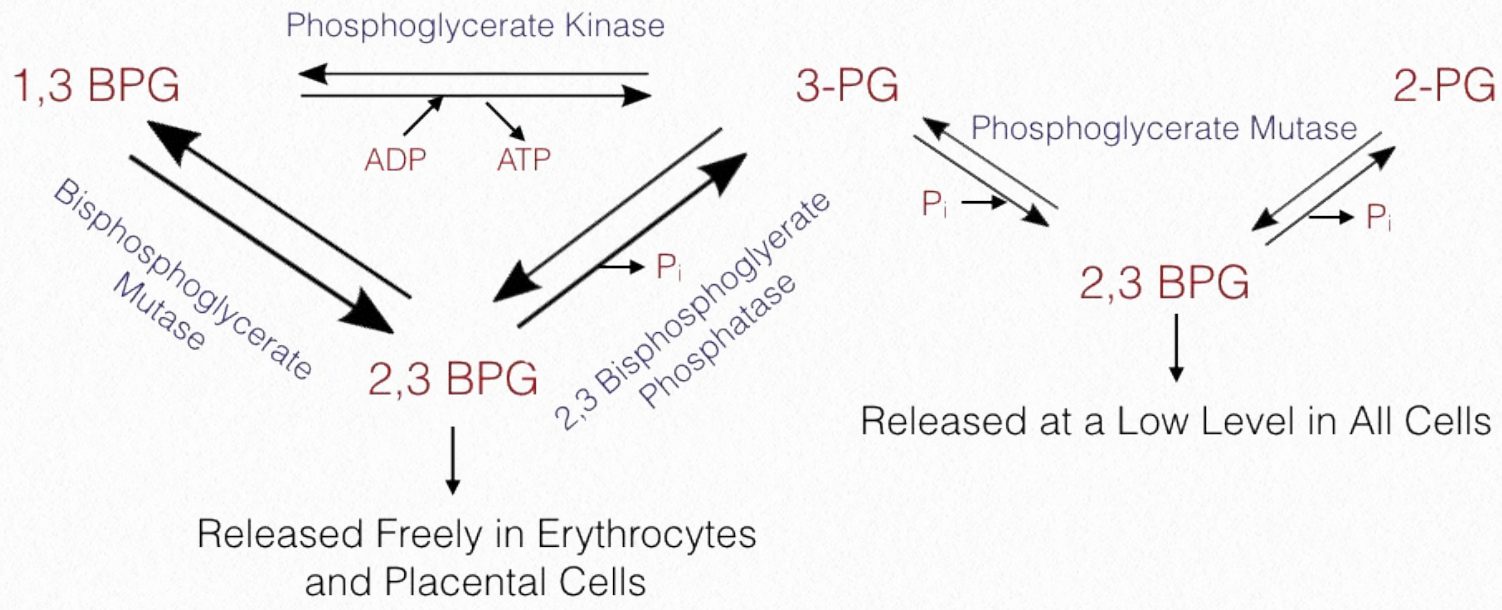

Figure 6.13 - **Two routes to formation of 2,3-BPG**

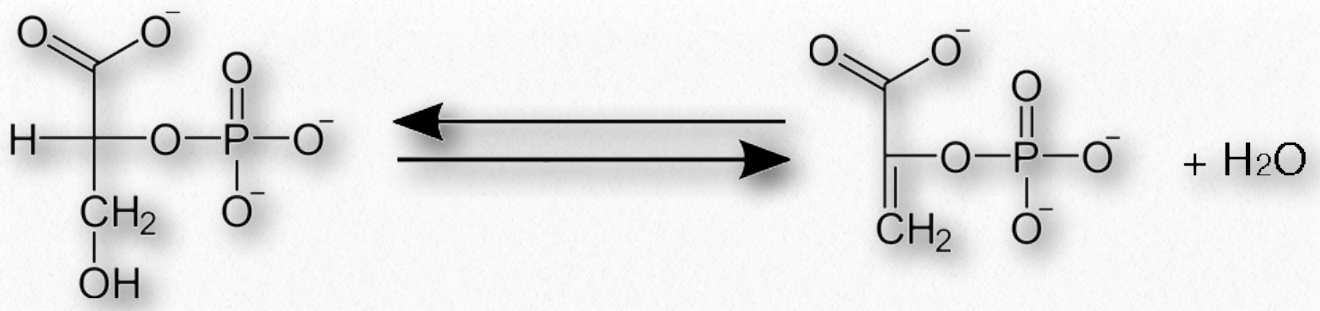

Figure 6.15 - **Reaction #9 - Enolase-catalyzed removal of water**

Wikipedia

verted to 2-PG.

2,3BPG is important because it binds to hemoglobin and stimulates release of oxygen. The molecule can also be made from 1,3-BPG as a product of a reaction catalyzed by bisphophglycerate mutase (Figure 6.13). Cells which are metabolizing glucose rapidly release more 2,3-BPG and, as a result, get more oxygen, supporting their needs. Notably, cells which are metabolizing rapidly are using oxygen more rapidly and are more likely to be deficient in it.

Reaction 9

$$\text{2-PG} \rightleftarrows \text{PEP} + H_2O$$

2-PG is converted by enolase (a lyase) to phosphoenolpyruvate (PEP) by removal of water, creating a very high energy intermediate. The reaction is readily reversible, but with PEP, the cell has one of its highest energy molecules and that is important for the next reaction.

Reaction 10

$$\text{PEP} + \text{ADP} + H+ \rightleftarrows \text{PYR} + \text{ATP}$$

Conversion of PEP to pyruvate by pyruvate kinase is the second substrate level phosphorylation of glycolysis, creating ATP. This reaction is what some refer to as the “Big Bang” of glycolysis because there is almost enough energy in PEP to stimulate production of a second ATP ($\Delta G°’ = 31.6$ kJ/mol), but it is not used. Consequently, this energy is lost as heat. If you wonder why you get hot when you exercise, the heat produced in the breakdown of glucose is a prime contributor and the pyruvate kinase reaction is a major source.

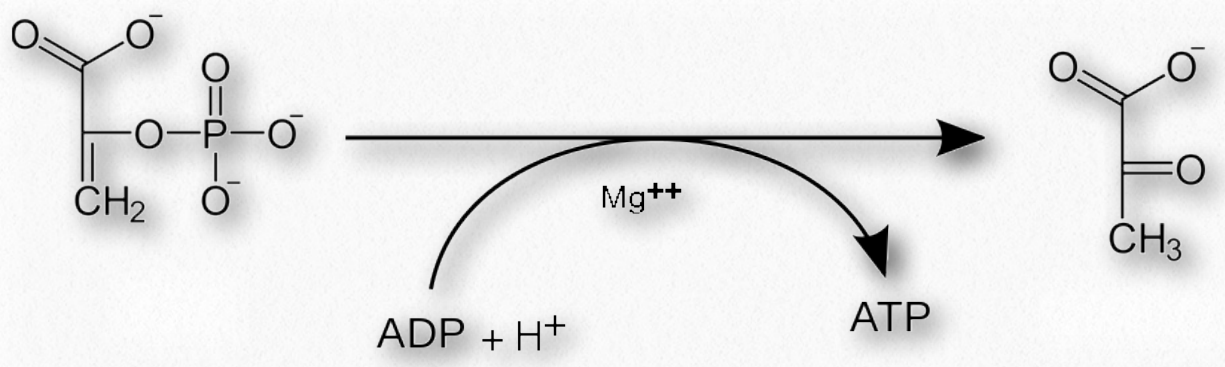

Figure 6.16 - **Reaction #10 - The big bang - PEP phosphorylates ADP with a lot of energy to spare**

Wikipedia

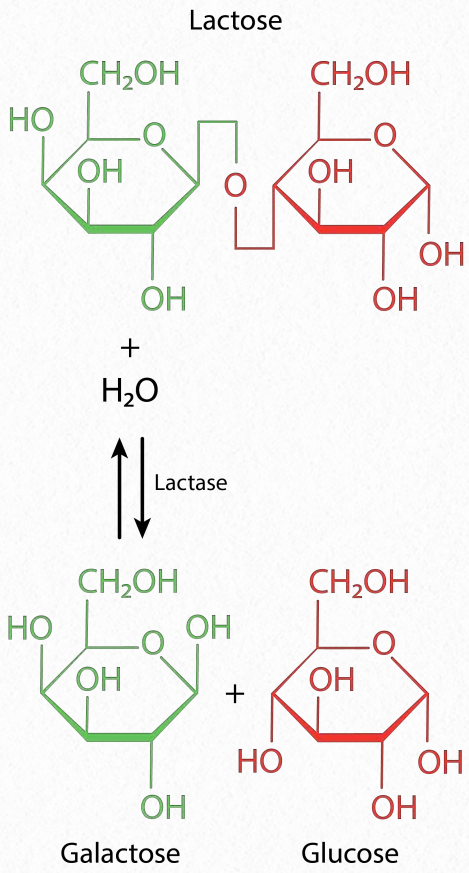

Figure 6.17 - Breakdown of lactose to glucose and galactose by lactase

Image by Pehr Jacobson

Pyruvate kinase is the third and last enzyme of glycolysis that is regulated (see below). The primary reason this is the case is to be able to prevent this reaction from occurring when cells are making PEP while going through gluconeogenesis (see more HERE).

Catabolism of other sugars

Though glycolysis is a pathway focused on the metabolism of glucose and fructose, the fact that other sugars can be readily metabolized into glucose means that glycolysis can be used for extracting energy from them as well. Galactose is a good example. It is commonly produced in the produced in the body as a result of hydrolysis of lactose, catalyzed by the enzyme known as lactase (Figure 6.17). Deficiency of lactase is the cause of lactose intolerance.

Galactose begins preparation for entry into glycolysis by being converted to galactose-1-phosphate (catalyzed by galactokinase - Figure 6.18). Galactose-1-phosphate swaps with glucose-1-phosphate from UDP-glucose to make UDP-galactose (Figure 6.19). An epimerase converts UDP-galactose back to UDP-glucose and the cycle is complete. Each turn of the cycle thus takes in one galactose-1-phosphate and releases one glucose-1-phosphate.

Deficiency of galactose conversion enzymes results in accumulation of galactose (from breakdown of lactose). Excess galactose is converted to galactitol, a sugar alcohol. Galactitol in the human eye lens causes it to absorb water and this may be a factor in formation of cataracts.

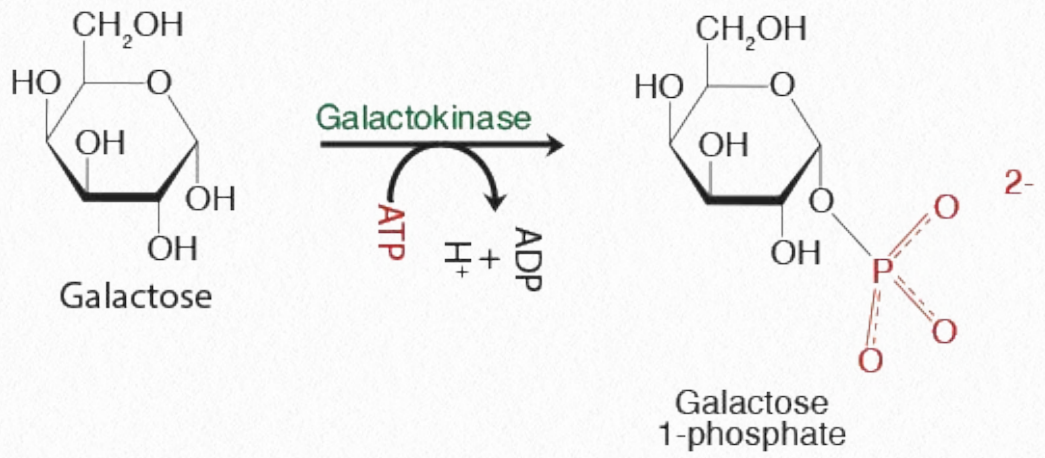

Figure 6.18 - Galactokinase Reaction

Image by Penelope Irving

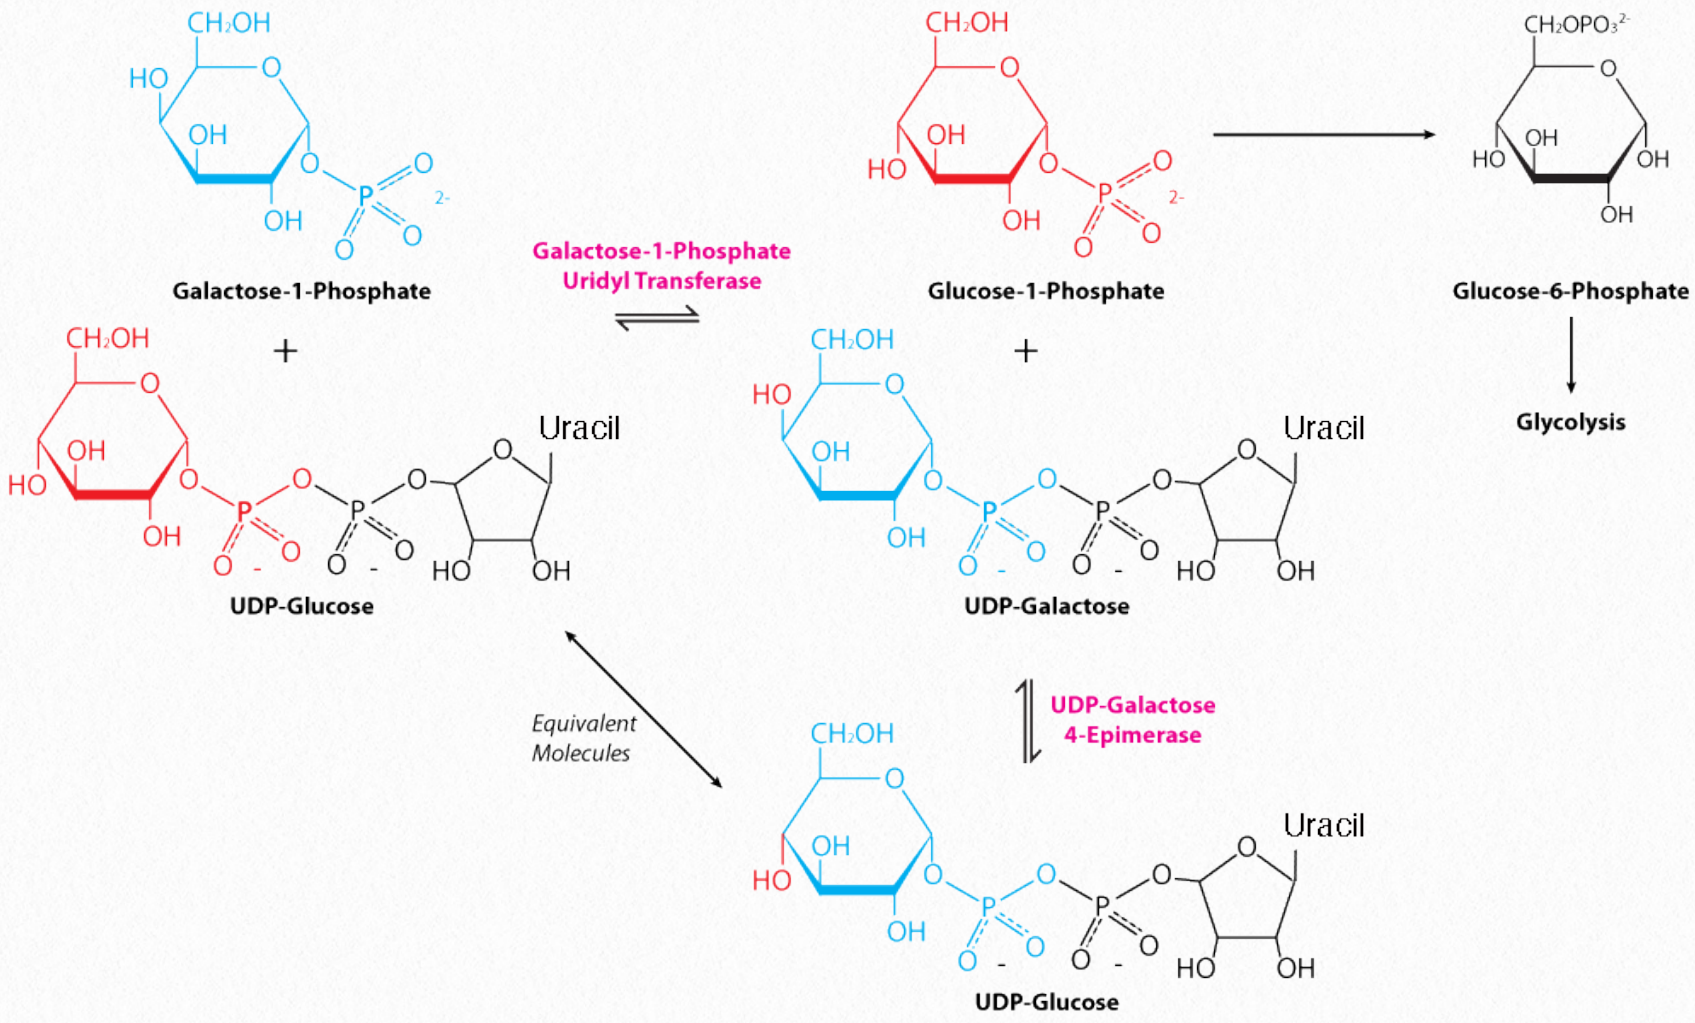

Figure 6.19 - Conversion of galactose-1-phosphate into glucose-6-phosphate

Image by Aleia Kim

Free fructose can also enter glycolysis by two mechanisms. First, it can be phosphorylated to fructose-6-phosphate by hexokinase. A more interesting alternate entry point is that shown in Figure 6.20. Phosphorylation of fructose by fructokinase produces fructose-1-phosphate and cleavage of that by fructose-1-phosphate aldolase yields DHAP and glyceraldehyde.

Phosphorylation of glyceraldehyde by triose kinase yields GLYAL3P. This alternative entry means for fructose may have important implications because DHAP and GLYAL3P are introduced into the glycolysis pathway while bypassing PFK-1 regulation. Some have proposed this may be important when considering metabolism of high fructose corn syrup, since it forces production of pyruvate, a precursor of acetyl-CoA, which is itself a precursor of fatty acids when ATP levels are high.

YouTube Lectures by Kevin HERE & HERE

Mannose metabolism

Mannose can also be metabolized in glycolysis. In this case, it enters via fructose by the following two-step process - 1) phosphoryla-

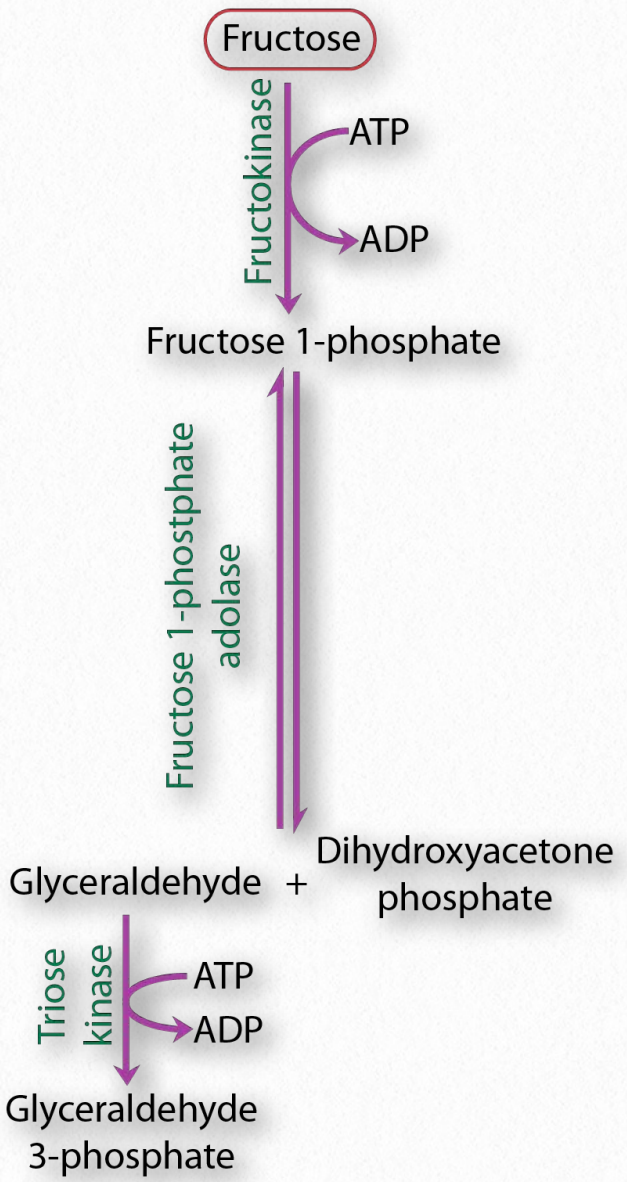

Figure 6.20 - Entry of fructose into glycolysis, bypassing PFK-1

Image by Penelope Irving

tion by hexokinase to make mannose-6-phosphate followed by its conversion to fructose-6-phosphate, catalyzed by phosphomannoisomerase (Figure 6.21).

Glycerol metabolism

Glycerol is an important molecule for the synthesis of fats, glycerophospholipids, and other membrane lipids. Most commonly it is made into glycerol-3-phosphate (Figure 6.22) and the glycolysis/gluconeogenesis pathways are important both for producing the compound and for metabolizing it. The relevant intermediate in these pathways both for producing and for using glycerol-3-phosphate is DHAP. The enzyme glycerol-3-phosphate dehydrogenase reversibly converts glycerol-3-phosphate into DHAP (Figure 6.22).

This reaction, which is an oxidation, transfers electrons to NAD^+ to produce NADH. In the reverse reaction, production of glycerol-3-phosphate from DHAP, of course, requires electrons from NADH for the reduction. Both glycolysis and gluconeogenesis are sources DHAP, meaning when the cell needs glycerol-3-phosphate that it can use sugars (glucose, fructose, mannose, or galactose) as sources in glycolysis. For gluconeogenesis, sources include pyruvate, alanine and

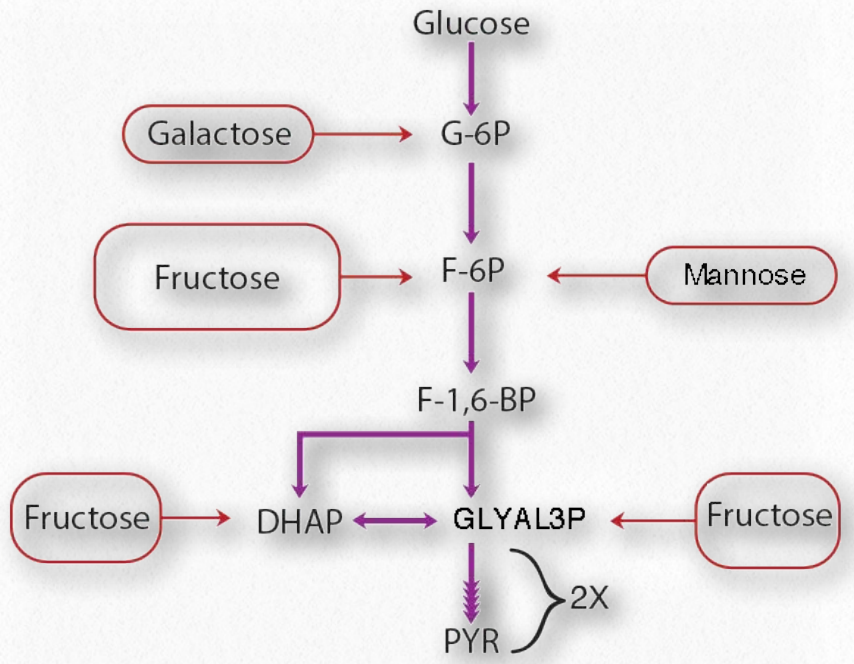

Figure 6.21 - Entry of other sugars into glycolysis

Image by Penelope Irving

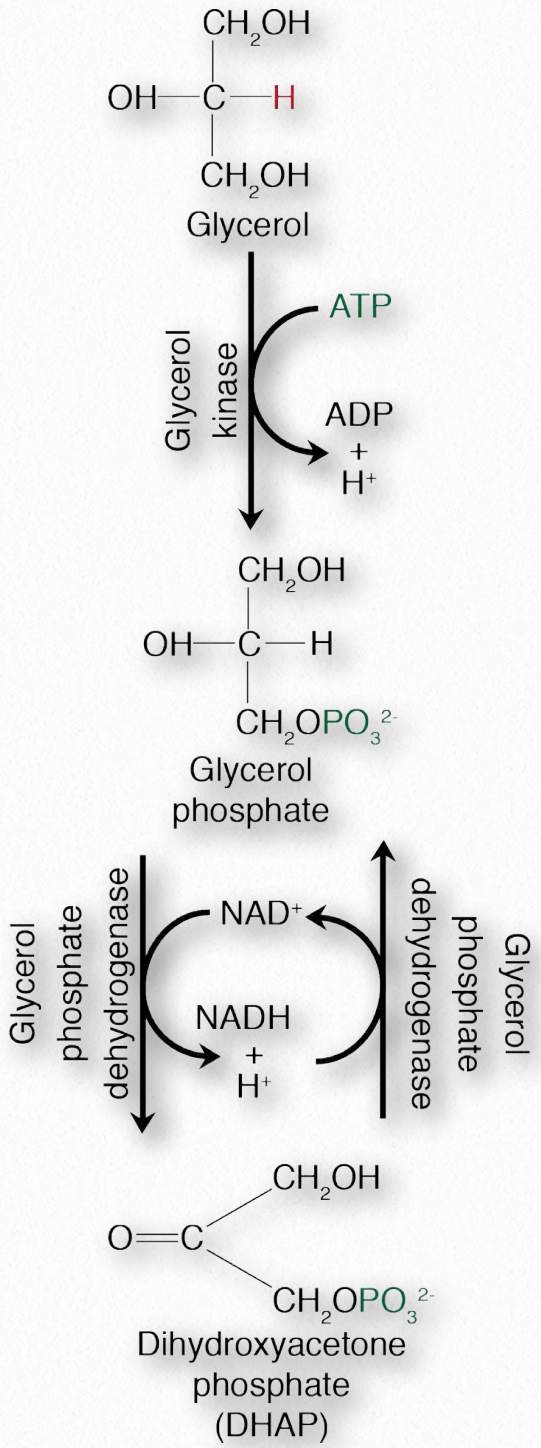

Figure 6.22 - Reactions in glycerol metabolism

Image by Penelope Irving

lactate (both can easily be made into pyruvate), oxaloacetate, aspartic acid (which can be made into oxaloacetate by transamination), and others. All of the intermediates of the citric acid cycle (and glyoxylate cycle) can be converted ultimately to oxaloacetate, which is a gluconeogenesis intermediate, as well.

It is worth noting that animals are unable to use fatty acids as materials for gluconeogenesis in net amounts, but they can, in fact, use glycerol in both glycolysis and gluconeogenesis. It is the only part of the fat molecule that can be so used.

Pyruvate metabolism

As noted, pyruvate produced in glycolysis can be oxidized to acetyl-CoA, which is itself oxidized in the citric acid cycle to carbon dioxide. That is not the only metabolic fate of pyruvate, though (Figure 6.23).

Pyruvate is a "starting" point for gluconeogenesis, being converted to oxaloacetate in the mitochondrion in the first step. Pyruvate in animals can also be reduced to lactate by adding electrons from NADH (Figure 6.24). This reaction produces NAD^+ and is critical for generating the latter molecule to keep the glyceraldehyde-3-phosphate dehydrogenase reaction of glycolysis (reaction #6) going under conditions when there is no oxygen.

This is because oxygen is necessary for the electron transport system (ETS) to operate and it performs the important function of converting NADH back to NAD^+. When the ETS is running, NADH donates electrons to Complex I and is oxidized to NAD^+ in the process, generating the intermediate needed for oxidizing GLYAL-3P. In the absence of oxygen, however, NADH cannot be converted to

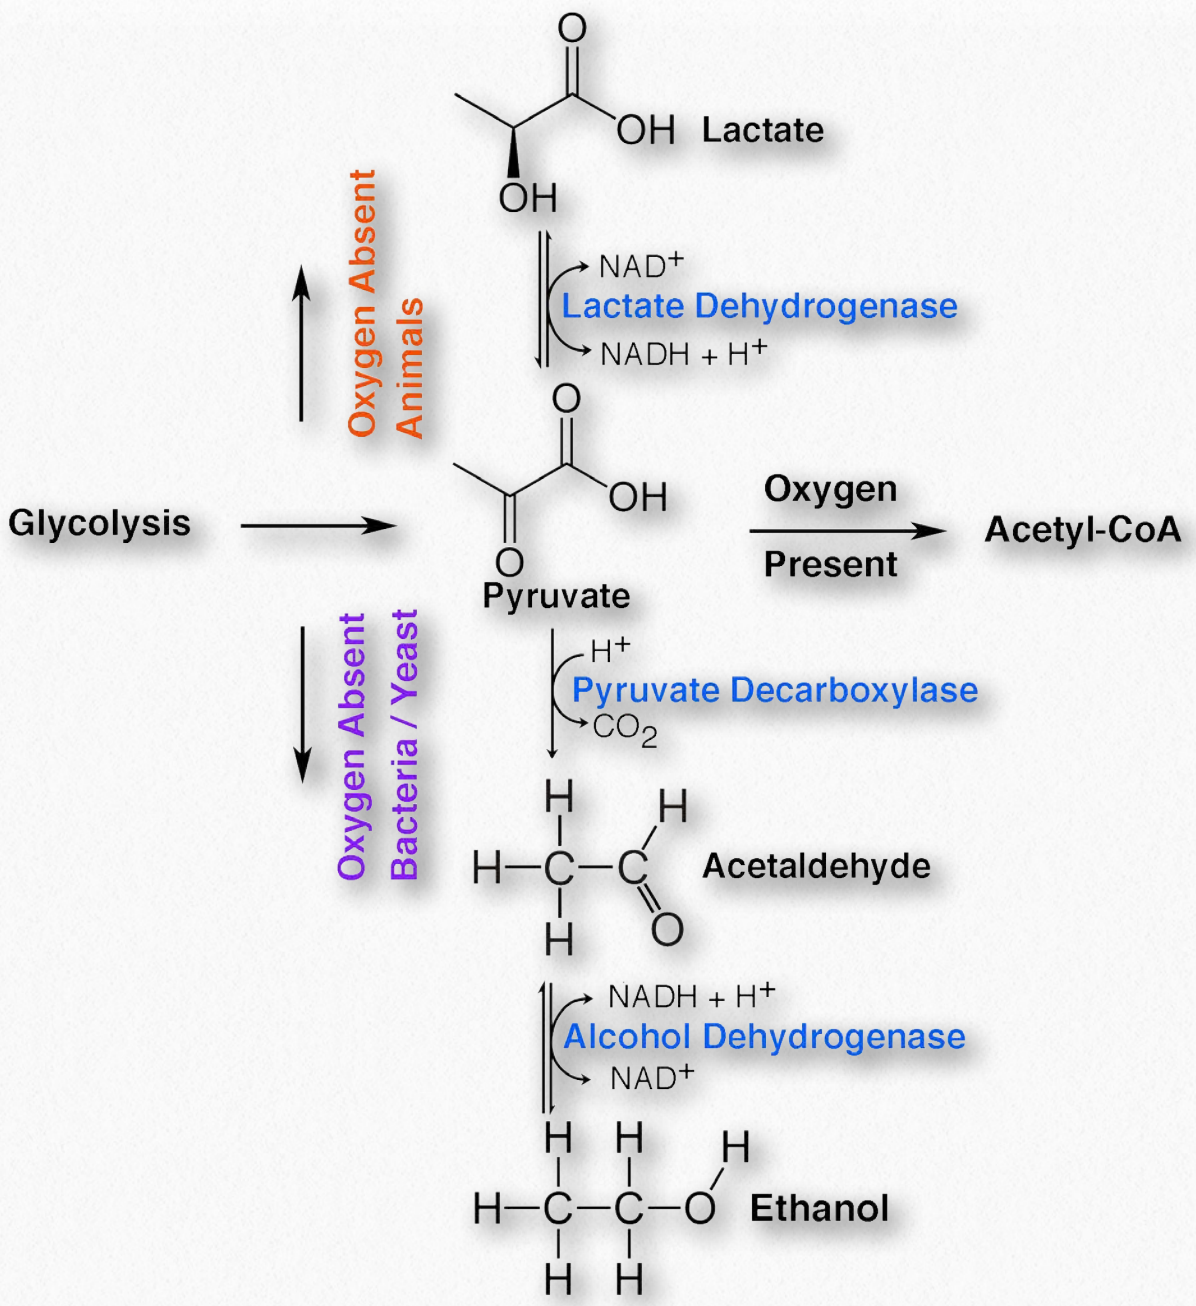

Figure 6.23 - Pyruvate metabolism. When oxygen is absent, pyruvate is converted to lactate (animals) or ethanol (bacteria and yeast). When oxygen is present, pyruvate is converted to acetyl-CoA. Not shown - Pyruvate transamination to alanine or carboxylation to form oxaloacetate.

NAD^+ by the ETS, so an alternative means of making NAD^+ is necessary for keeping glycolysis running under low oxygen conditions (fermentation).

Bacteria and yeast generate NAD^+ under oxygen deprived conditions by doing fermentation in a different way (Figure 6.25). They use NADH-requiring reactions that regenerate NAD^+ while producing ethanol from pyruvate instead of making lactate. Thus, fermentation of pyruvate is essential to keep glycolysis operating when oxygen is limiting. It is also for these reasons that brewing of beer (using yeast) involves depletion of oxygen and muscles low in oxygen produce lactic acid (animals).

Pyruvate is a precursor of alanine which can be easily synthesized by transfer of a nitrogen from an amine donor, such as glutamic acid. Pyruvate can also be converted into oxaloacetate by carboxylation in the process of gluconeogenesis (see below).

The enzymes involved in pyruvate metabolism include pyruvate dehydrogenase (makes acetyl-CoA), lactate dehydrogenase (makes lactate), transaminases (make alanine), pyruvate carboxylase (makes ox-

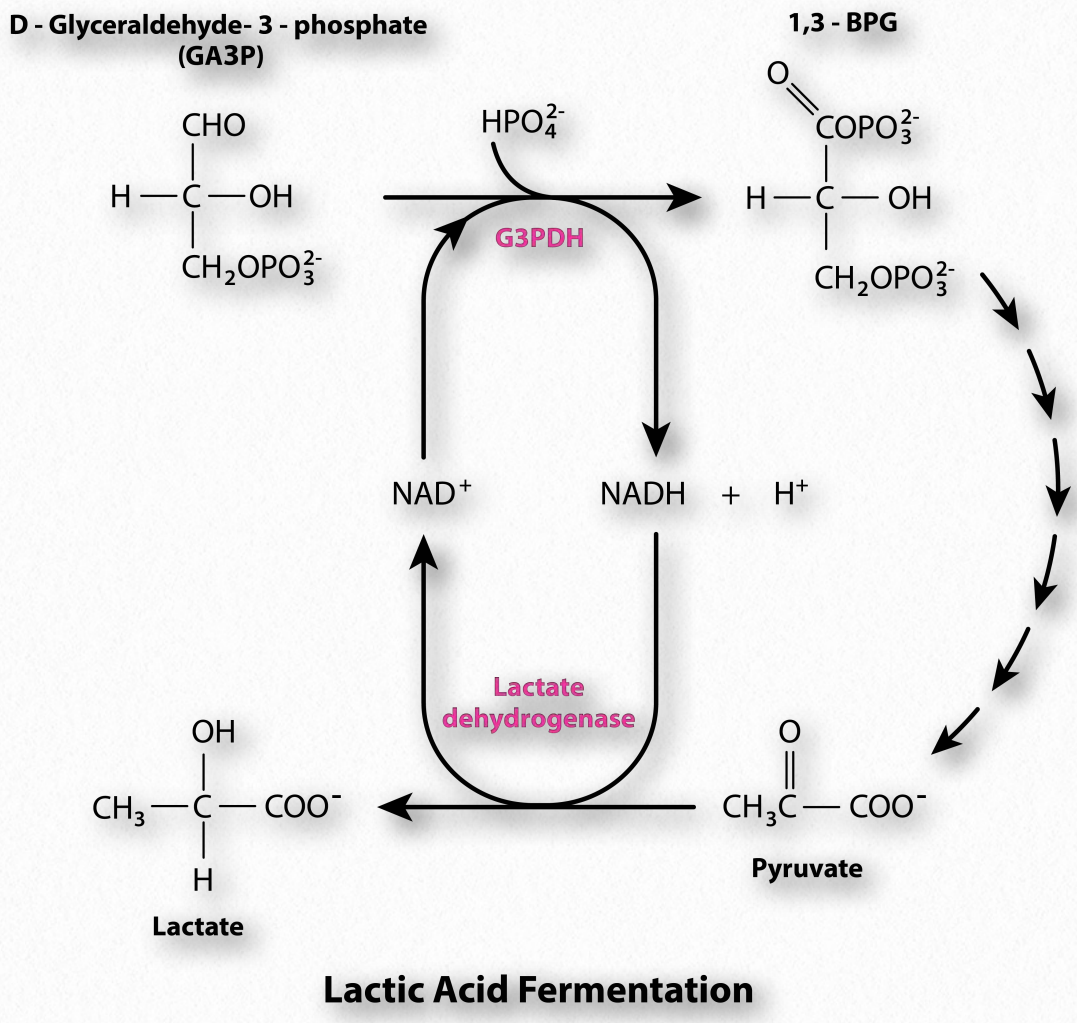

Figure 6.24 - Formation of lactate in animal fermentation produces NAD⁺ for G3PDH

Image by Ben Carson

aloacetate), and pyruvate decarboxylase (a part of pyruvate dehydrogenase that makes acetaldehyde in bacteria and yeast).

Catalytic action and regulation of the pyruvate dehydrogenase complex is discussed in the section on the citric acid cycle (HERE).

Gluconeogenesis

The anabolic counterpart to glycolysis is gluconeogenesis (Figure 6.26), which occurs mostly in the cells of the liver and kidney and virtually no other cells in the body. In seven of the eleven reactions of gluconeogenesis (starting from pyruvate), the same enzymes are used as in glycolysis, but the reaction directions are reversed. Notably, the ΔG values of these reactions in the cell are typically near zero, meaning their direction can be readily controlled by changing substrate and product concentrations by small amounts.

The three regulated enzymes of glycolysis all catalyze reactions whose cellular ΔG values are not close to zero, making manipulation of reaction direction for their reac-

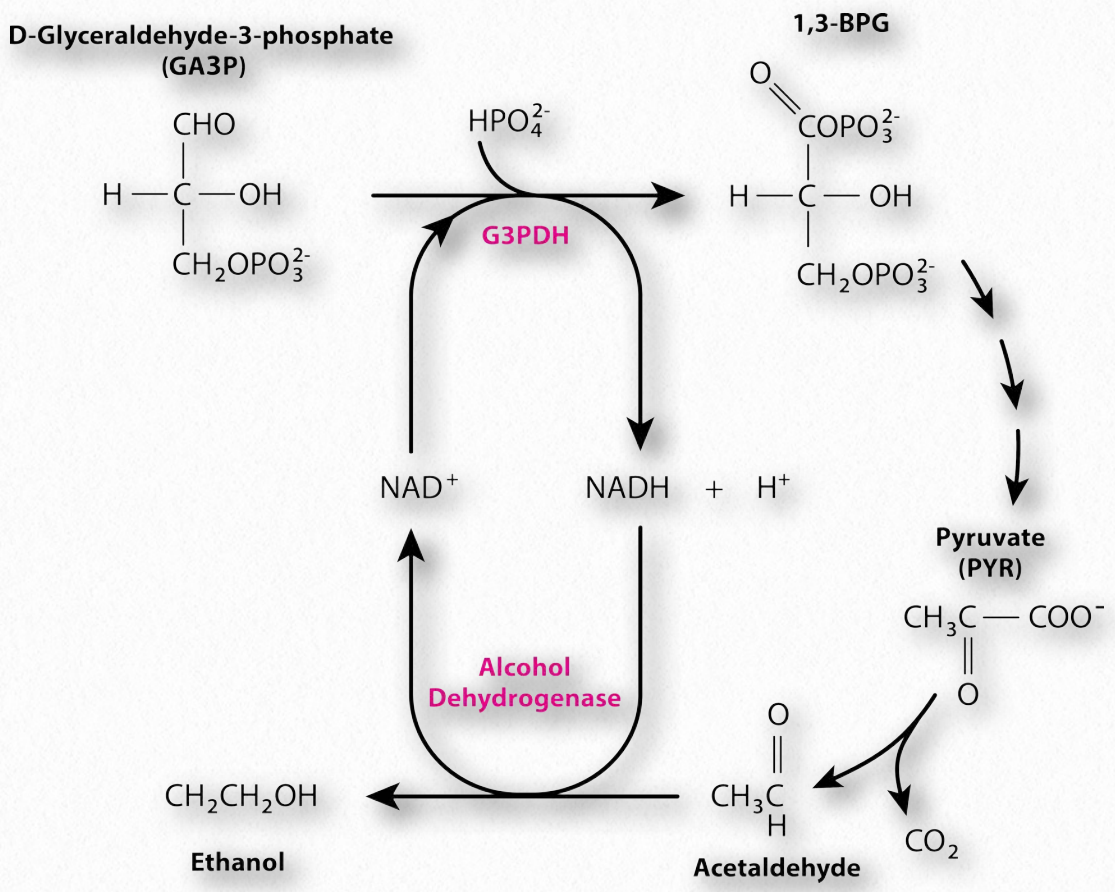

Figure 6.25 - Formation of ethanol in microbial fermentation produces NAD⁺ for G3PDH

Image by Ben Carson

tions non-trivial. Consequently, cells employ "work-around" reactions catalyzed by four different enzymes to favor gluconeogenesis, when appropriate.

Bypassing pyruvate kinase

Two of the enzymes (pyruvate carboxylase and PEP carboxykinase - PEPCK) catalyze reactions that bypass pyruvate kinase. F1,6BPase bypasses PFK-1 and G6Pase bypasses hexokinase. Notably, pyruvate carboxylase and G6Pase are found in the mitochondria and endoplasmic reticulum, respectively, whereas the other two are found in the cytoplasm along with all of the enzymes of glycolysis.

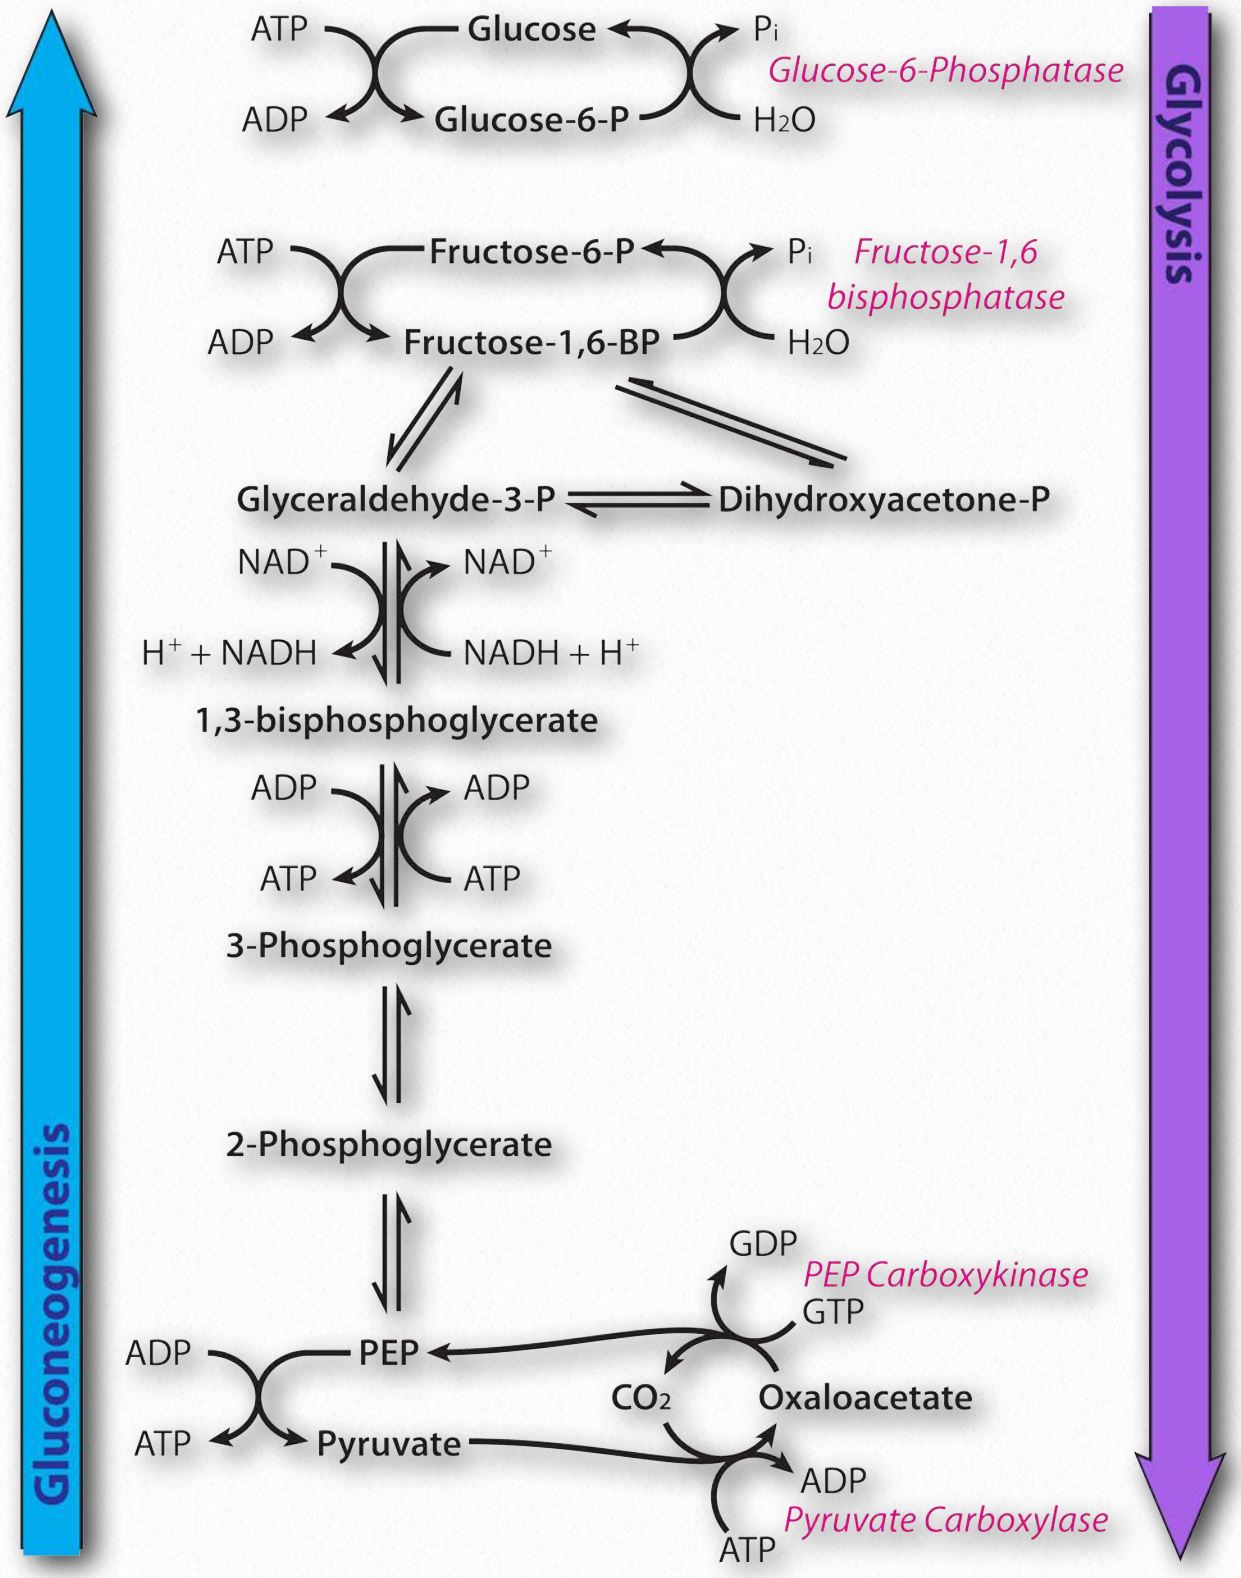

Figure 6.26 - Gluconeogenesis and glycolysis. Only the enzymes differing in gluconeogenesis are shown

Image by Aleia Kim

Biotin

An important coenzyme used by pyruvate carboxylase is biotin (Figure 6.27). Biotin is commonly used by carboxylases to carry CO_2 to incorporate into the substrate.

YouTube Lectures by Kevin HERE & HERE

Also known as vitamin H, biotin is a water soluble B vitamin (B_7) needed for many metabolic processes, including fatty acid synthesis, gluconeogenesis, and amino acid metabolism. Deficiency of the vitamin is rare, since it is readily produced by gut bac-

teria. There are many claims of advantages of taking biotin supplements, but there is no strong indication of benefits in most cases. Deficiencies are associated with inborn genetic errors, alcoholism, burn patients, and people who have had a gastrectomy. Some pregnant and lactating women may have reduced levels due to increased biotin catabolism.

Wikipedia

Reciprocal regulation

All of the enzymes of glycolysis and nine of the eleven enzymes of gluconeogenesis are all in the cytoplasm, necessitating a coordinated means of controlling them. Cells generally need to minimize the extent to which paired anabolic and catabolic pathways are occurring simultaneously, lest they produce a futile cycle, resulting in wasted energy with no tangible product except heat. The mechanisms of controlling these pathways have opposite effects on catabolic and anabolic processes. This method of control is called reciprocal regulation (see above).

Reciprocal regulation is a coordinated means of simultaneously controlling metabolic pathways that do opposite things. In reciprocal regulation, a single molecule (allosteric regulation) or a single covalent modification (phosphorylation/dephosphorylation,

Allosteric Regulation of Glycolysis & Gluconeogenesis

> If glycolysis is flowing
> Glucose synthesis awaits
> But when the latter is a-going
> Sugar breakdown then abates

Reciprocal allosteric effects

For example, in glycolysis, the enzyme known as phosphofructokinase (PFK-1) is allosterically activated by AMP and a molecule known as F2,6BP (Figure 6.28). The corresponding enzyme from gluconeogenesis catalyzing a reversal of the glycolysis reaction is known as F1,6BPase. F1,6BPase is inhibited by both AMP and F2,6BP.

Reciprocal covalent effects

In glycogen metabolism, the enzymes phosphorylase kinase and glycogen phosphorylase catalyze reactions important for the breakdown of glycogen. The enzyme glycogen synthase catalyzes the synthesis of glyco-

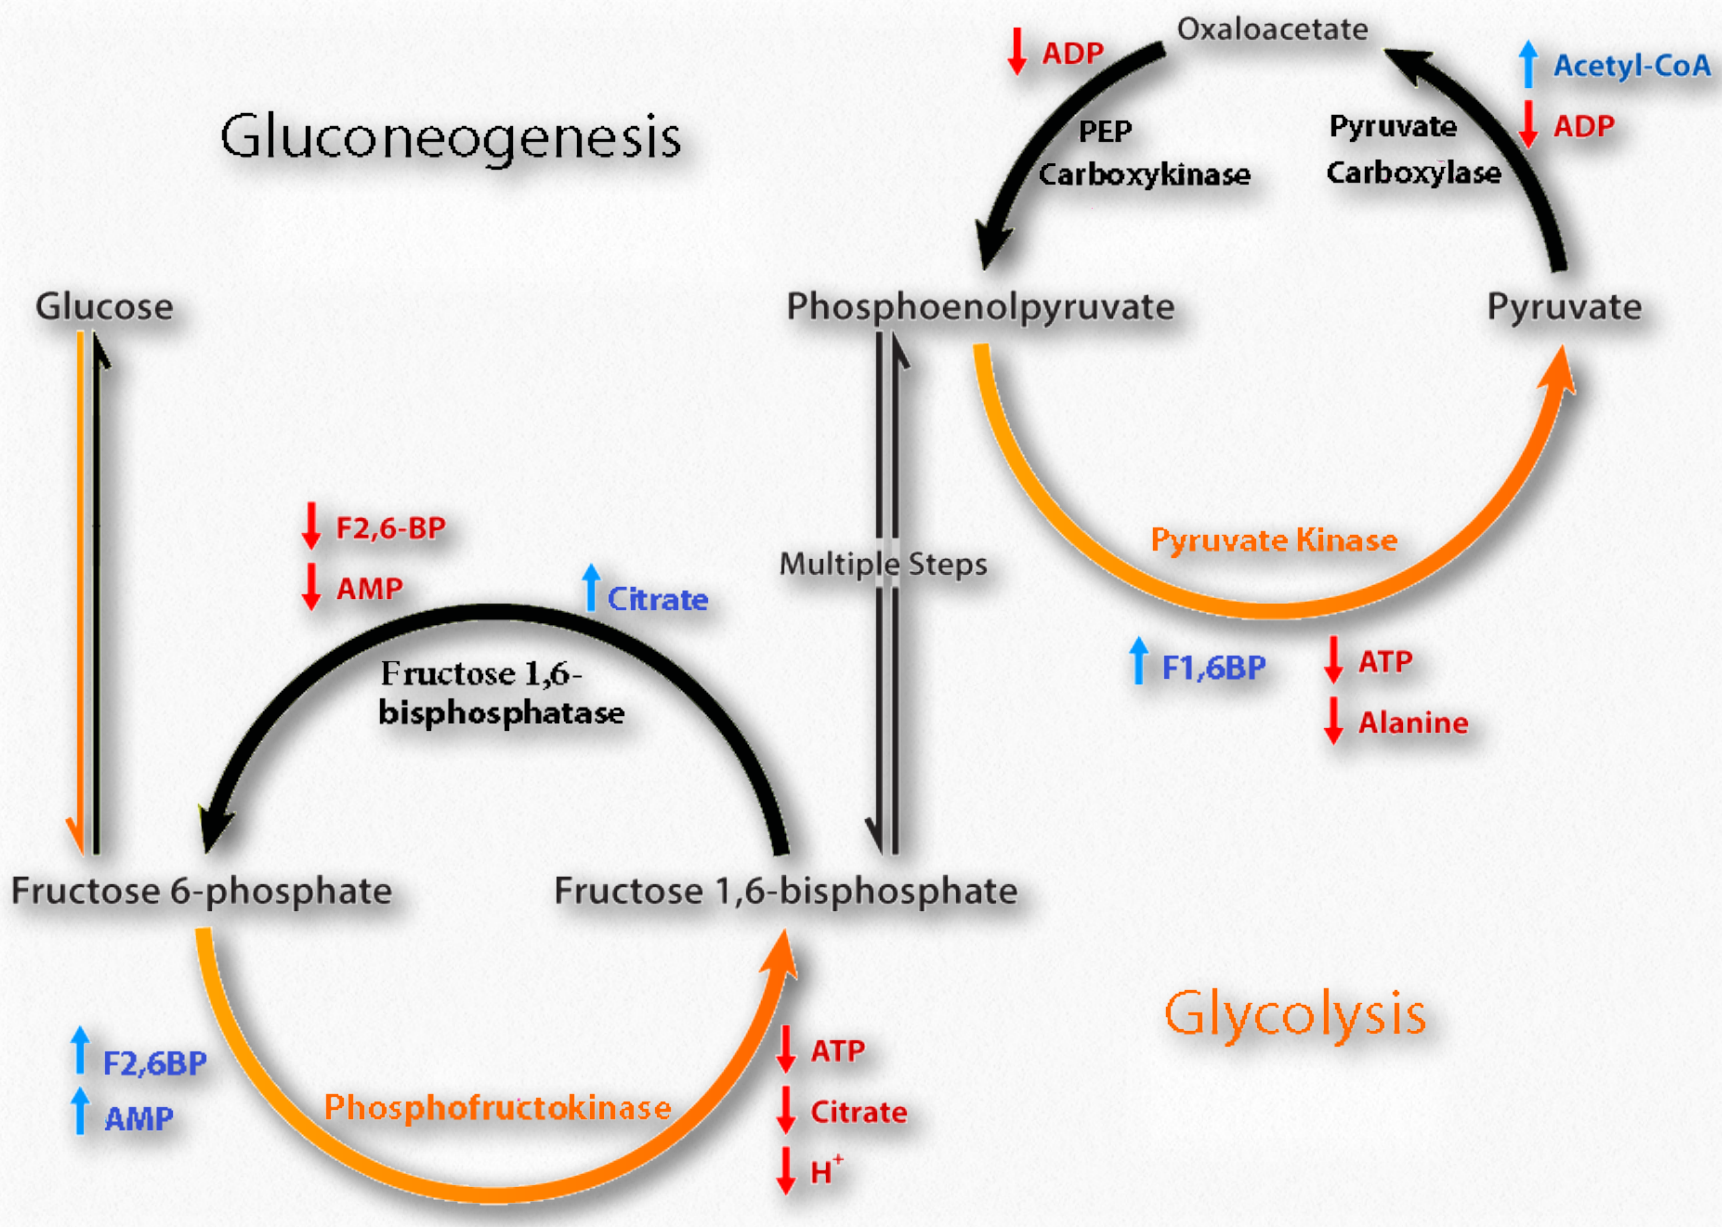

Figure 6.28 - Regulation of glycolysis (orange path) and gluconeogenesis (black path)

Image by Aleia Kim

gen. Each of these enzymes is, at least partly, regulated by attachment and removal of phosphate.

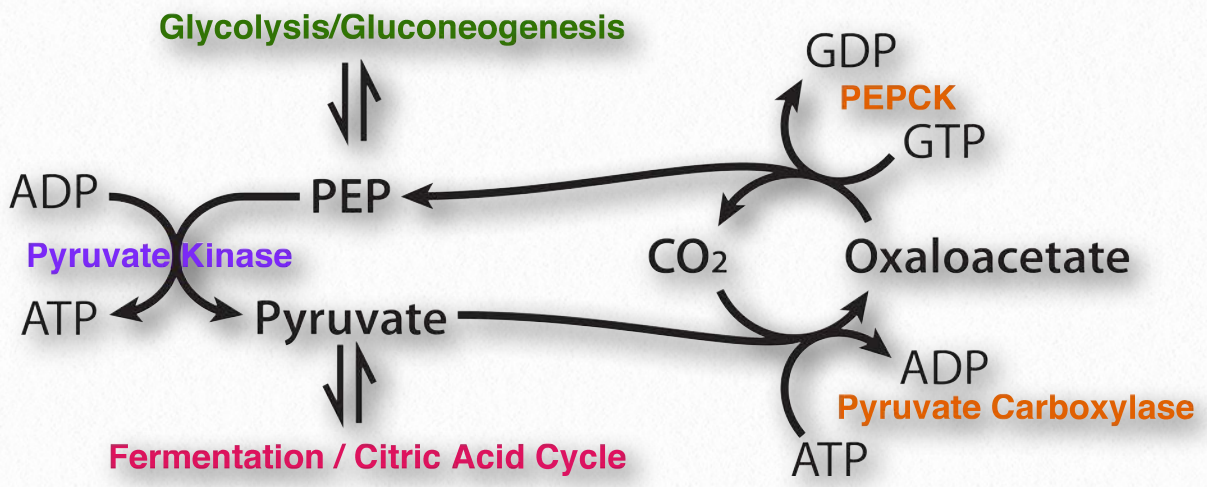

Figure 6.29 - A simple futile cycle - follow the black lines

Image by Aleia Kim

Phosphorylation of phosphorylase kinase and glycogen phosphorylase has the effect of making them more active, whereas phosphorylation of glycogen synthase makes it less active. Conversely, dephosphorylation has the reverse effects on these enzymes - phosphorylase kinase and glycogen phosphorylase become less active and glycogen synthase becomes more active.

Interactive Learning Module HERE

Simple and efficient

The advantage of reciprocal regulation schemes is that they are very efficient. It doesn't take separate molecules or separate treatments to control two pathways simultaneously. Further, its simplicity ensures that when one pathway is turned on, the other is turned off.

This is especially important with catabolic/anabolic regulation, because having both pathways going on simultaneously in a cell is not very productive, leading only to production of heat in a futile cycle. A simple futile cycle is shown on Figure 6.29. If unregulated, the cyclic pathway in the figure (shown in black) will make ATP in creating pyruvate from PEP and will use ATP to make oxaloacetate from pyruvate.

It will also use GTP to make PEP from oxaloacetate. Thus, each turn of the cycle will make one ATP, use one ATP and use one GTP for a net loss of energy. The process will start with pyruvate and end with pyruvate, so there is no net production of molecules. (see HERE for one physiological use of a futile cycle).

Specific gluconeogenesis controls

Besides reciprocal regulation, other mechanisms help control gluconeogenesis. First, PEPCK is controlled largely at the level of synthesis. Overexpression of PEPCK (stimulated by glucagon, glucocorticoid hormones, and cAMP and inhibited by insulin) produces symptoms of diabetes.

Pyruvate carboxylase is sequestered in the mitochondrion (one means of regulation)

and is sensitive to acetyl-CoA, which is an allosteric activator. Acetyl-CoA concentrations increase as the citric acid cycle activity decreases. Glucose-6-phosphatase is present in low concentrations in many tissues, but is found most abundantly and importantly in the major gluconeogenic organs – the liver and kidney cortex.

Specific glycolysis controls

Control of glycolysis and gluconeogenesis is unusual for metabolic pathways, in that regulation occurs at multiple points. For glycolysis, this involves three enzymes:

1. Hexokinase (Glucose ⇄ G6P)

2. Phosphofructokinase-1 (F6P ⇄ F1,6BP)

3. Pyruvate kinase (PEP ⇄ Pyruvate).

Regulation of hexokinase is the simplest of these. The enzyme is unusual in being inhibited by its product, glucose-6-phosphate. This ensures when glycolysis is slowing down hexokinase is also slowing down to reduce feeding the pathway.

Pyruvate kinase

It might also seem odd that pyruvate kinase, the last enzyme in the pathway, is regulated (Figure 6.30), but the reason is simple. Pyruvate kinase catalyzes the most energetically rich reaction of glycolysis. The reaction is favored so strongly in the forward direction that cells must do a 'two-step' around it in the reverse direction when making glucose in the gluconeogenesis pathway.

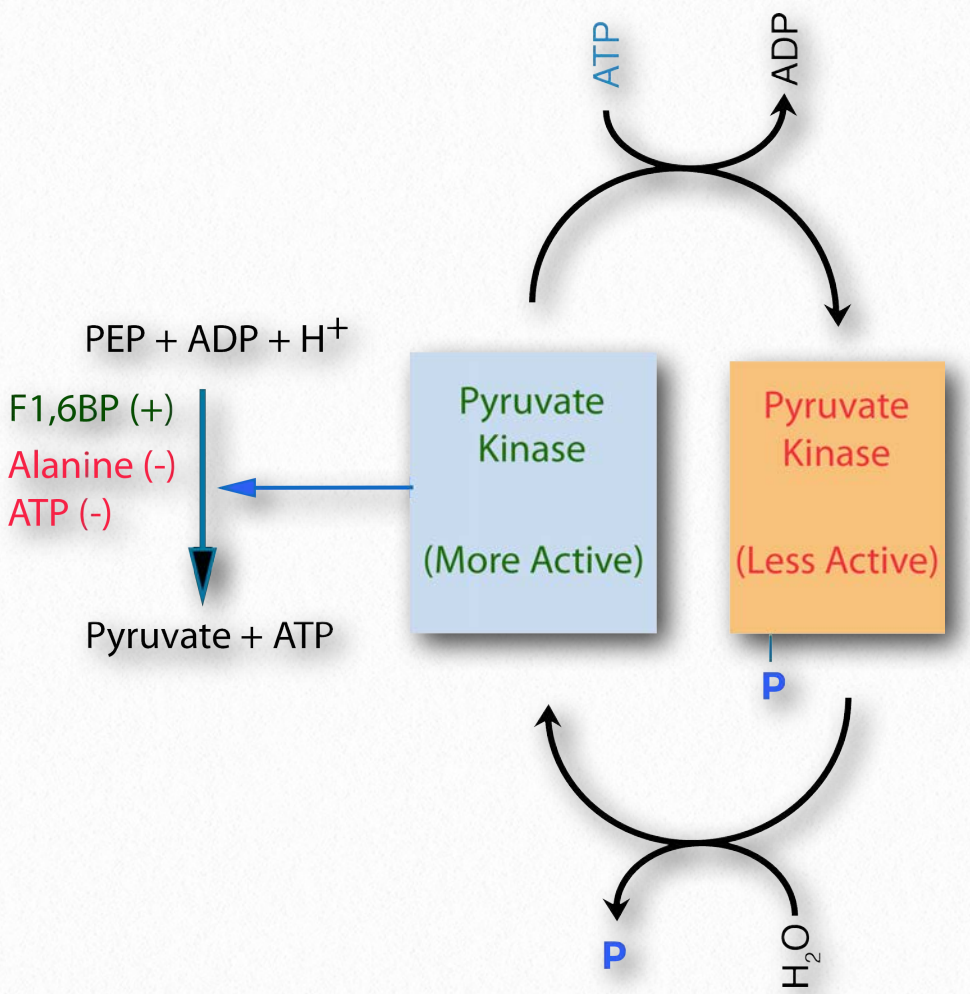

Figure 6.30 - Regulation of pyruvate kinase

For cells a glucose cycling's cost
Is energy in reams
Four ATPs each time is lost
From breaking/making schemes

So use for metabolic heat
To make it warm inside your feet
Else it's of no utility
To practice such futility

In other words, it takes two enzymes, two reactions, and two triphosphates (ATP and GTP) to go from one pyruvate back to one PEP in gluconeogenesis. When cells are needing to make glu-

cose, they can't be sidetracked by having the PEP they have made in gluconeogenesis be converted directly back to pyruvate by pyruvate kinase. Consequently, pyruvate kinase must be inhibited during gluconeogenesis or a futile cycle will occur and no glucose will be made.

Another interesting control mechanism called feedforward activation involves pyruvate kinase. Pyruvate kinase is activated allosterically by the glycolysis intermediate, F1,6BP. This molecule is a product of the PFK-1 reaction and a substrate for the aldolase reaction.

Reactions pulled

As noted above, the aldolase reaction is energetically unfavorable (high positive $\Delta G°'$), thus allowing F1,6BP to accumulate. When this happens, some of the excess F1,6BP binds to pyruvate kinase, which activates and jump-

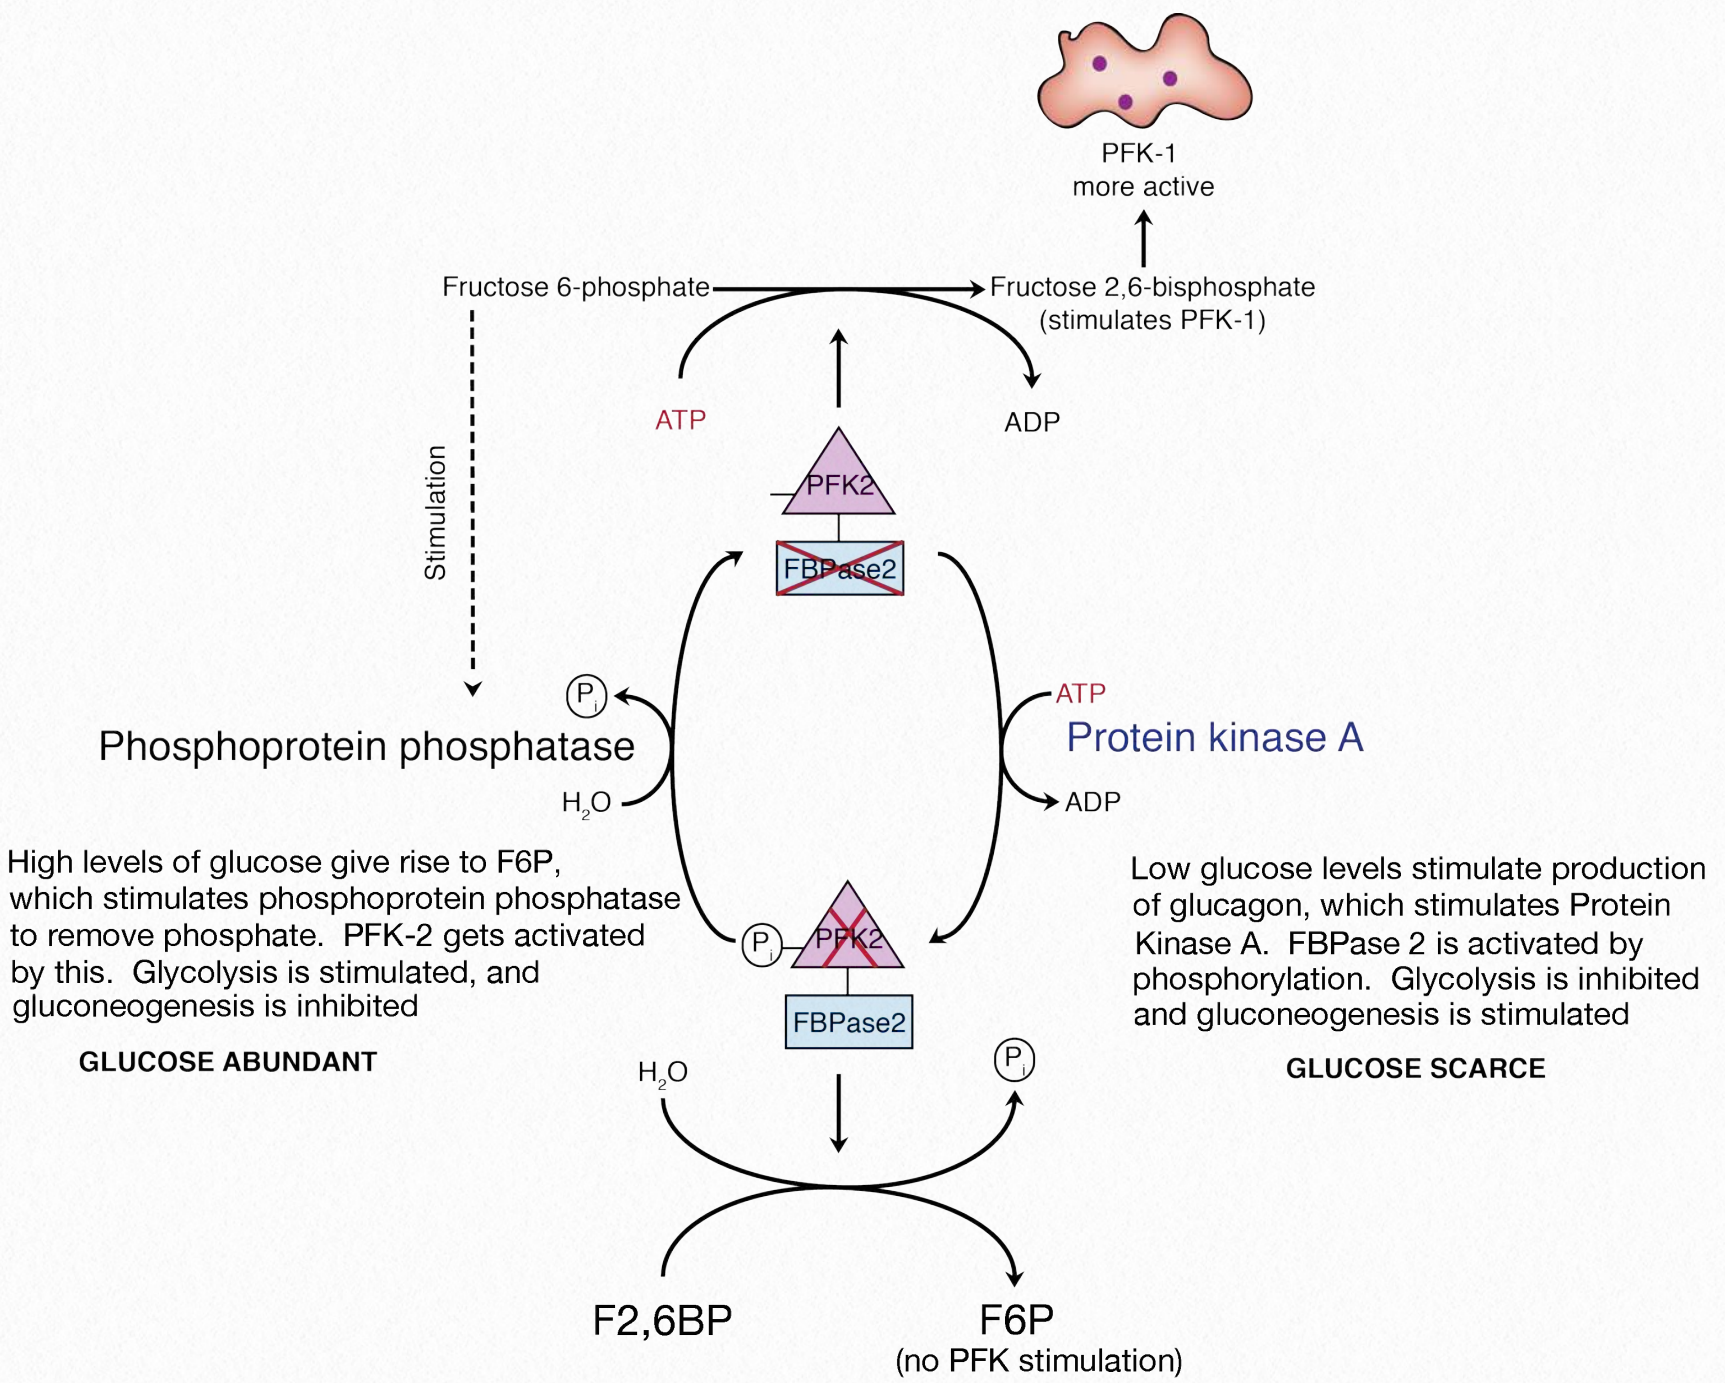

Figure 6.31 - Regulation of Synthesis and Breakdown of F2,6BP

Image by Penelope Irving

starts the conversion of PEP to pyruvate. The resulting drop in PEP levels has the effect of "pulling" on the reactions preceding pyruvate kinase. As a consequence, the concentrations of GLYAL3P and DHAP fall, helping to pull the aldolase reaction forward.

YouTube Lectures by Kevin HERE & HERE

PFK-1 regulation

PFK-1 has a complex regulation scheme. First, it is reciprocally regulated (relative to F1,6BPase) by three molecules. F2,6BP activates PFK-1 and inhibits F1,6BPase. PFK-1 is also allosterically activated by AMP, whereas F1,6BPase is inhibited. On the other hand, citrate inhibits PFK-1, but activates F1,6BPase.

PFK-1 is also inhibited by ATP and is exquisitely sensitive to proton concentration, easily losing activity when the pH drops only slightly. PFK-1's inhibition by ATP is noteworthy and odd at first glance because ATP is also a substrate whose increasing concentration should favor the reaction instead of inhibit it. The root of this conundrum is that PFK-1 has two ATP binding sites - one at an allosteric site that binds ATP relatively inefficiently and one that the active site that binds ATP with high affinity. Thus, only when ATP concentration is high is binding at the allosteric site favored and only then can ATP turn off the enzyme.

F2,6BP regulation

Regulation of PFK-1 by F2,6BP is simple at the PFK-1 level, but more complicated at the level of synthesis of F2,6BP. Despite having a name sounding like a glycolysis/gluconeogenesis intermediate (F1,6BP), F2,6BP is not an intermediate in either pathway. Instead, it is made from fructose-6-phosphate and ATP by the enzyme known as phosphofructokinase-2 (PFK-2 - Figure 6.31).

Cori cycle

With respect to energy, the liver and muscles act complementarily. The liver is the major or-

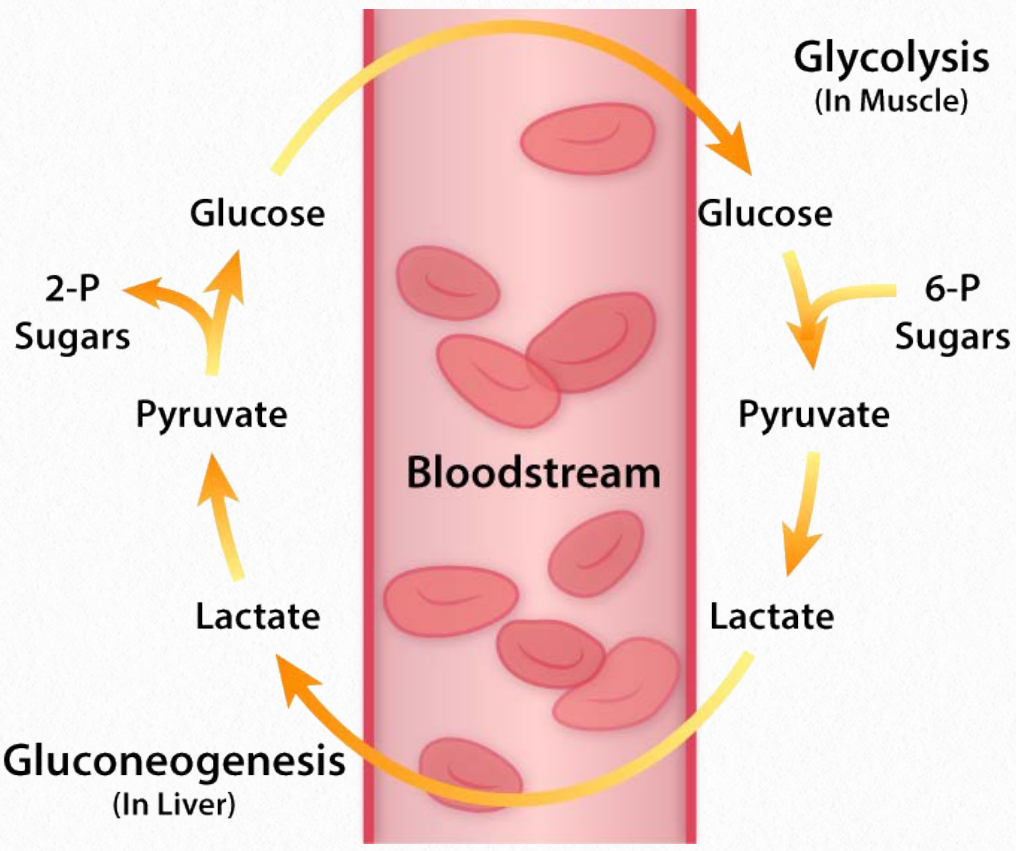

Figure 6.32 - The Cori cycle

Image by Aleia Kim

gan in the body for the synthesis of glucose. Muscles are major users of glucose to make ATP. Actively exercising muscles use oxygen faster than the blood can deliver it. As a consequence, the muscles go anaerobic and produce lactate. This lactate is of no use to muscle cells, so they dump it into the blood. Lactate travels in the blood to the liver, which takes it up and reoxidizes it back to pyruvate, catalyzed by the enzyme lactate dehydrogenase (Figure 6.32).

Pyruvate in the liver is then converted to glucose by gluconeogenesis. The glucose thus made by the liver is dumped into the bloodstream where it is taken up by muscles and used for energy, completing the important intercellular pathway known as the Cori cycle.

Glucose alanine cycle

The glucose alanine cycle (also known as the Cahill Cycle), has been described as the amine equivalent of the Cori cycle (Figure 6.33). The Cori cycle, of course, exports lac-

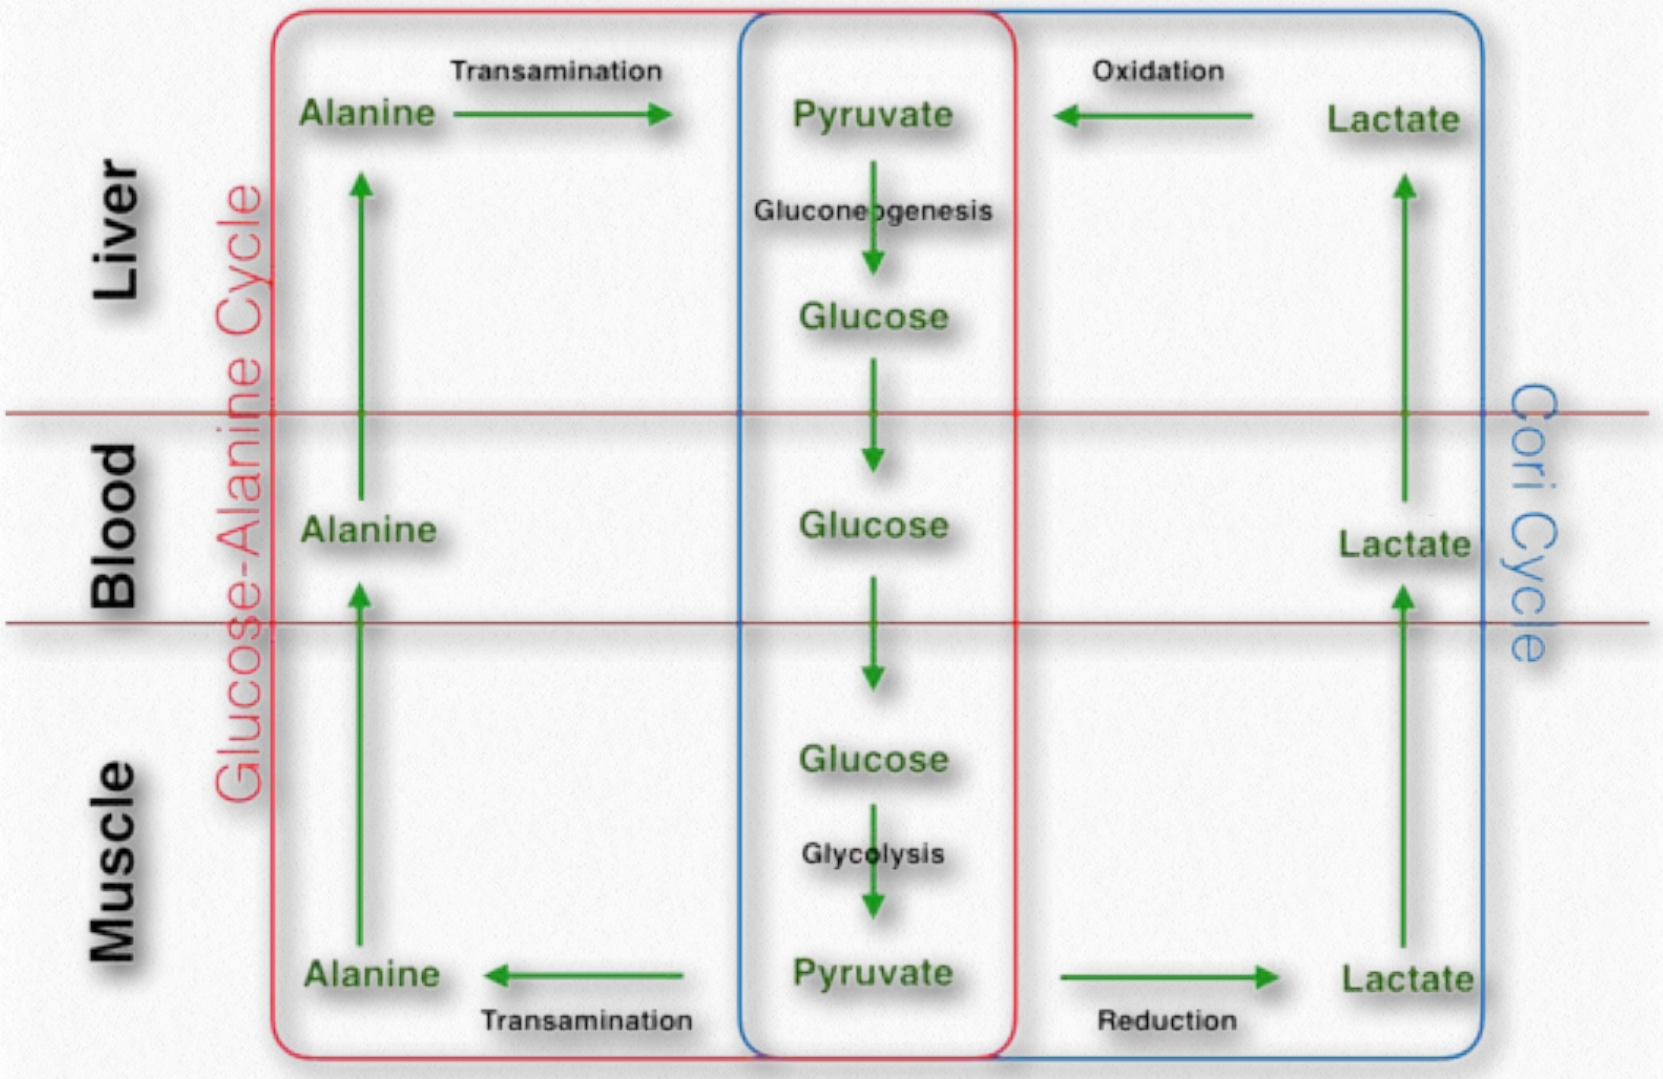

Figure 6.33 - Overlap between the Cori cycle and the glucose alanine cycle

tate from muscles (when oxygen is limiting) to the liver via the bloodstream. The liver, in turn, converts lactate to glucose, which it ships back to the muscles via the bloodstream. The Cori Cycle is an essential source of glucose energy for muscles during periods of exercise when oxygen is used faster than it can be delivered.

In the glucose-alanine cycle, cells are generating toxic amines and must export them. This is accomplished by transaminating pyruvate (the product of glycolysis) to produce the amino acid alanine.

The glucose-alanine process requires the enzyme alanine aminotransferase, which is found in muscles, liver, and intestines. Alanine is exported in the process to the blood and picked up by the liver, which deaminates it to release the amine for synthesis of urea and excretion. The pyruvate left over after the transamination is a substrate for gluconeogenesis. Glucose produced in the liver is then exported to the blood for use by cells, thus completing the cycle.

Polysaccharide metabolism

Sugars are metabolized rapidly in the body and that is one of the primary reasons they are used. Managing levels of glucose in the body is very important - too much leads to complications related to diabetes and too little gives rise to hypoglycemia (low blood sugar). Sugars in the body are maintained by three processes - 1) diet; 2) synthesis (gluconeogenesis); and 3) storage. The storage forms of sugars are, of course, the polysaccharides and their metabolism is our next topic of discussion.

Amylose and amylopectin

The energy needs of a plant are much less dynamic than those of animals. Muscular contraction, nervous systems, and information processing in the brain require large amounts of quick energy. Because of this, the polysaccharides stored in plants are somewhat less complicated than those of animals. Plants store glucose for energy in the form of amylose (Figure 6.34 and see HERE) and amylopectin and for structural integrity in the form of cellulose (see HERE). These structures differ in that cellulose contains glucose units solely joined by β-1,4 bonds, whereas amylose has only α-1,4 bonds and amylopectin has α-1,4 and α-1,6 bonds.

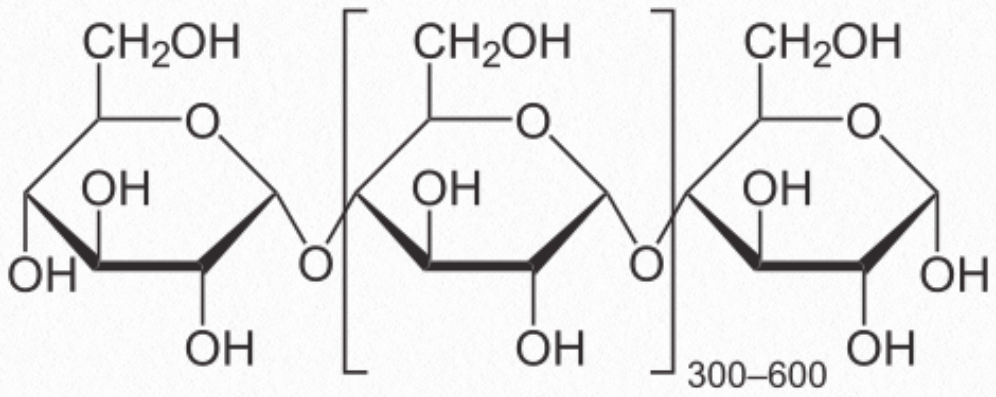

Figure 6.34 Amylose, a polymer of glucose in plants

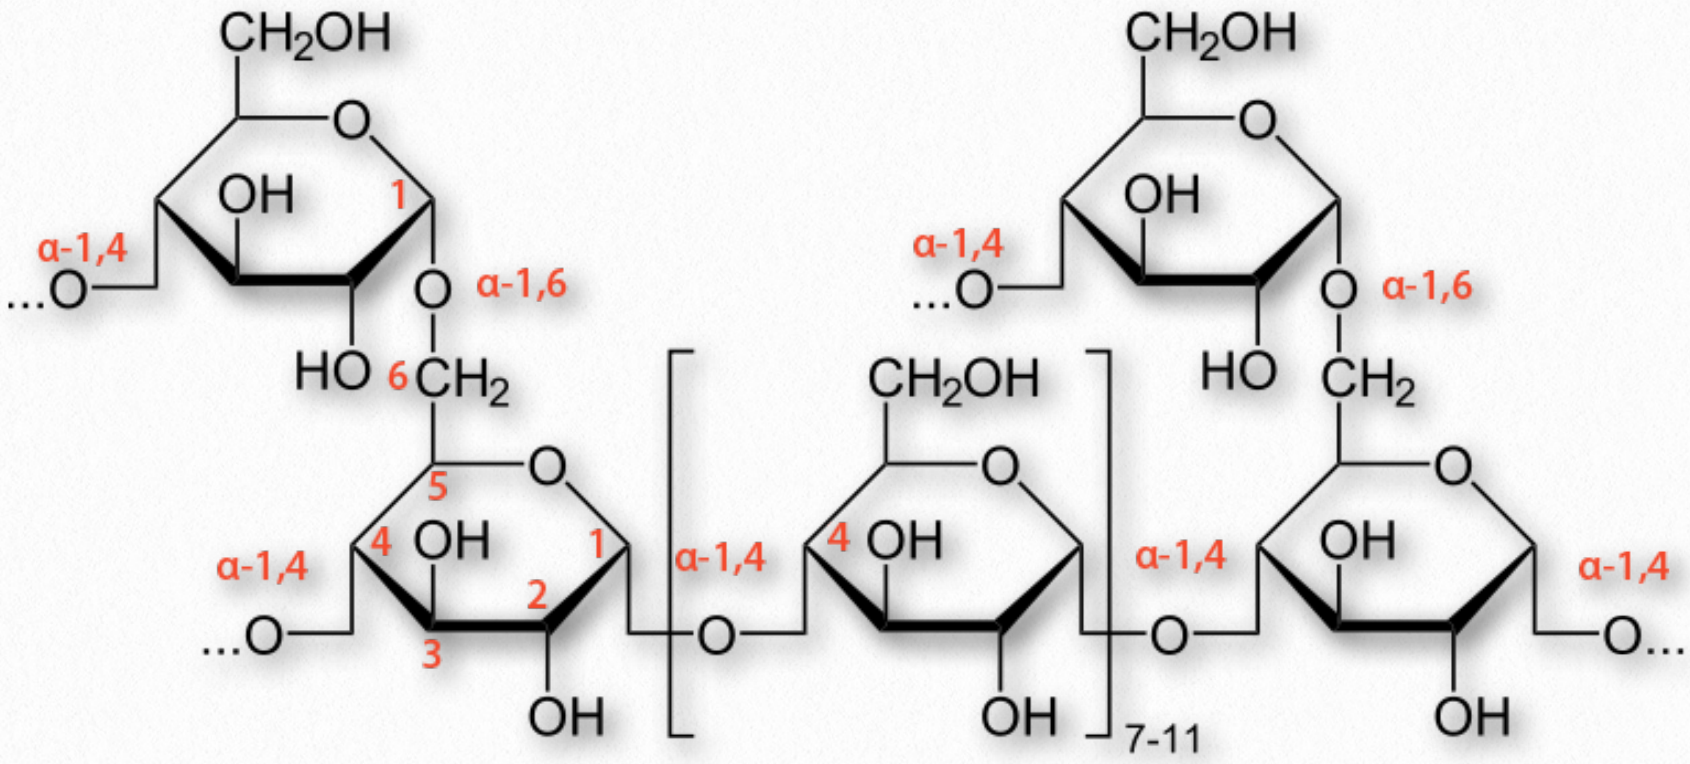

Figure 6.35 - Glycogen Structure - α-1,4 links with α-1,6 branches every 7-10 residues

Glycogen

Animals store glucose primarily in liver and muscle in the form of a compound related to amylopectin known as glycogen. The structural differences between glycogen and amylopectin are solely due to the frequency of the α-1,6 branches of glucoses. In glycogen they occur about every 10 residues instead of every 30-50, as in amylopectin (Figure 6.35).

Glycogen provides an additional source of glucose besides that produced *via* gluconeogenesis. Because glycogen contains so many glucoses, it acts like a battery backup for the body, providing a quick source of glucose when needed and providing a place to store excess glucose when glucose concentrations in the blood rise.

YouTube Lectures by Kevin HERE & HERE

The branching of glycogen is an important feature of the molecule metabolically as well. Since glycogen is broken down from the "ends" of the molecule, more branches translate to more ends, and more glucose that can be released at once.

Just as in gluconeogenesis, the cell has a separate mechanism for glycogen synthesis that is distinct from glycogen breakdown. As noted previously, this allows the cell to separately control the reactions, avoiding futile cycles, and enabling a process to occur efficiently (synthesis of glycogen) that would not occur if

it were simply the reversal of glycogen breakdown.

Glycogen breakdown

Breakdown of glycogen involves 1) release of glucose-1-phosphate (G1P), 2) rearranging the remaining glycogen (as necessary) to permit continued breakdown, and 3) conversion of G1P to G6P for further metabolism. G6P can be 1) used in glycolysis, 2) converted to glucose by gluconeogenesis, or 3) oxidized in the pentose phosphate pathway.

Glycogen phosphorylase (sometimes simply called phosphorylase) catalyzes breakdown of glycogen into glucose-1-Phosphate (G1P - Figure 6.36). The reaction that produces G1P from glycogen is a phosphorolysis, not a hydrolysis reaction. The distinction is that hydrolysis reactions use water to cleave bigger molecules into smaller ones, but phosphorolysis reactions use phosphate instead for the same purpose. Note that the phosphate is just that - it does NOT come from ATP. Since ATP is *not* used to put phosphate on G1P, the reaction saves the cell energy.

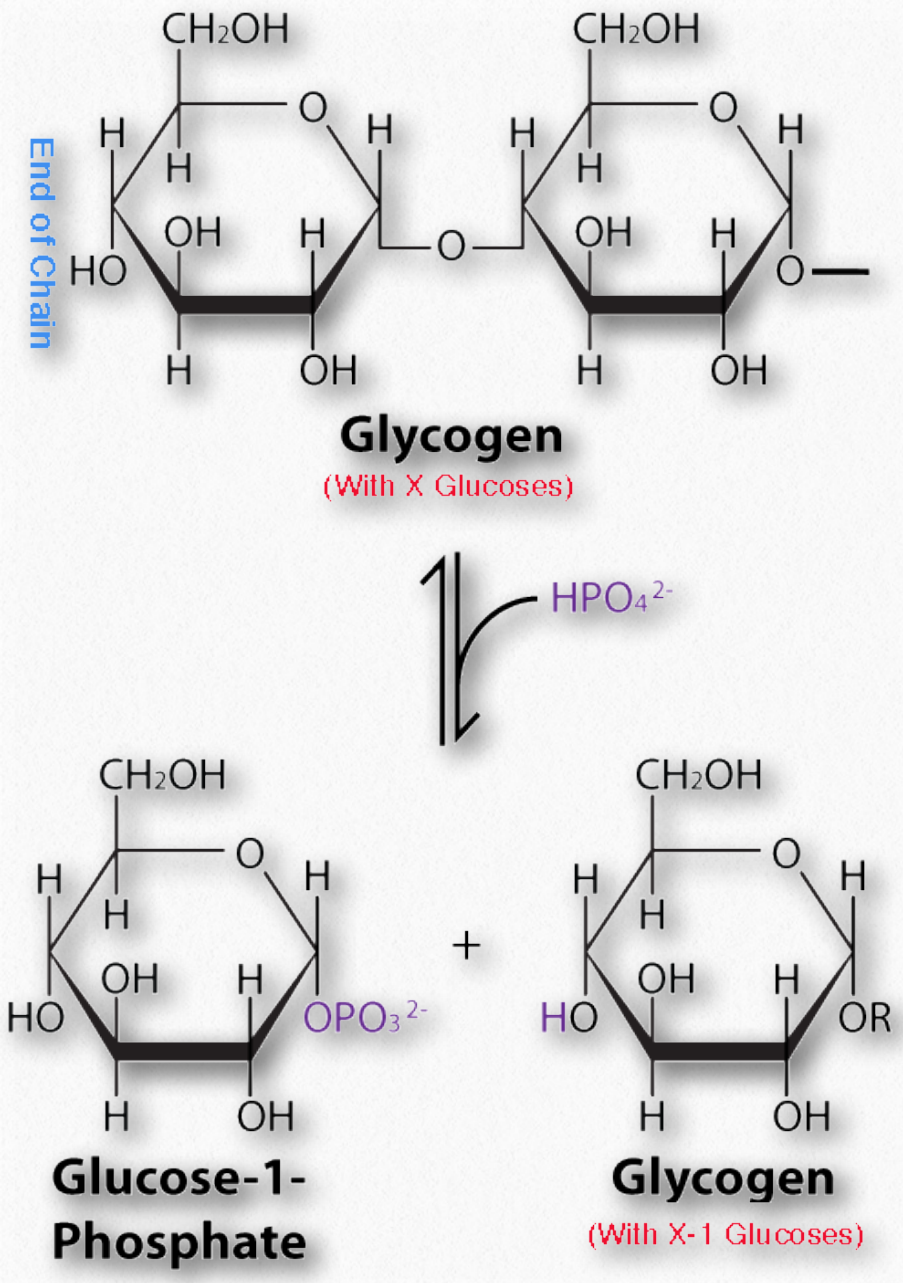

Figure 6.36 - Breaking of α-1,4 bonds of glycogen by glycogen phosphorylase

Image by Aleia Kim

Glycogen debranching enzyme

Glycogen phosphorylase will only act on non-reducing ends of a glycogen chain that are at least 5 glucoses away from a branch point. A second enzyme, Glycogen Debranching Enzyme (GDE) (also called debranching enzyme), is therefore needed to convert α (1-6) branches to α (1-4) branches. GDE acts on glycogen branches that have reached their limit of phosphorylysis with glycogen phosphorylase.

Interactive Learning Module HERE

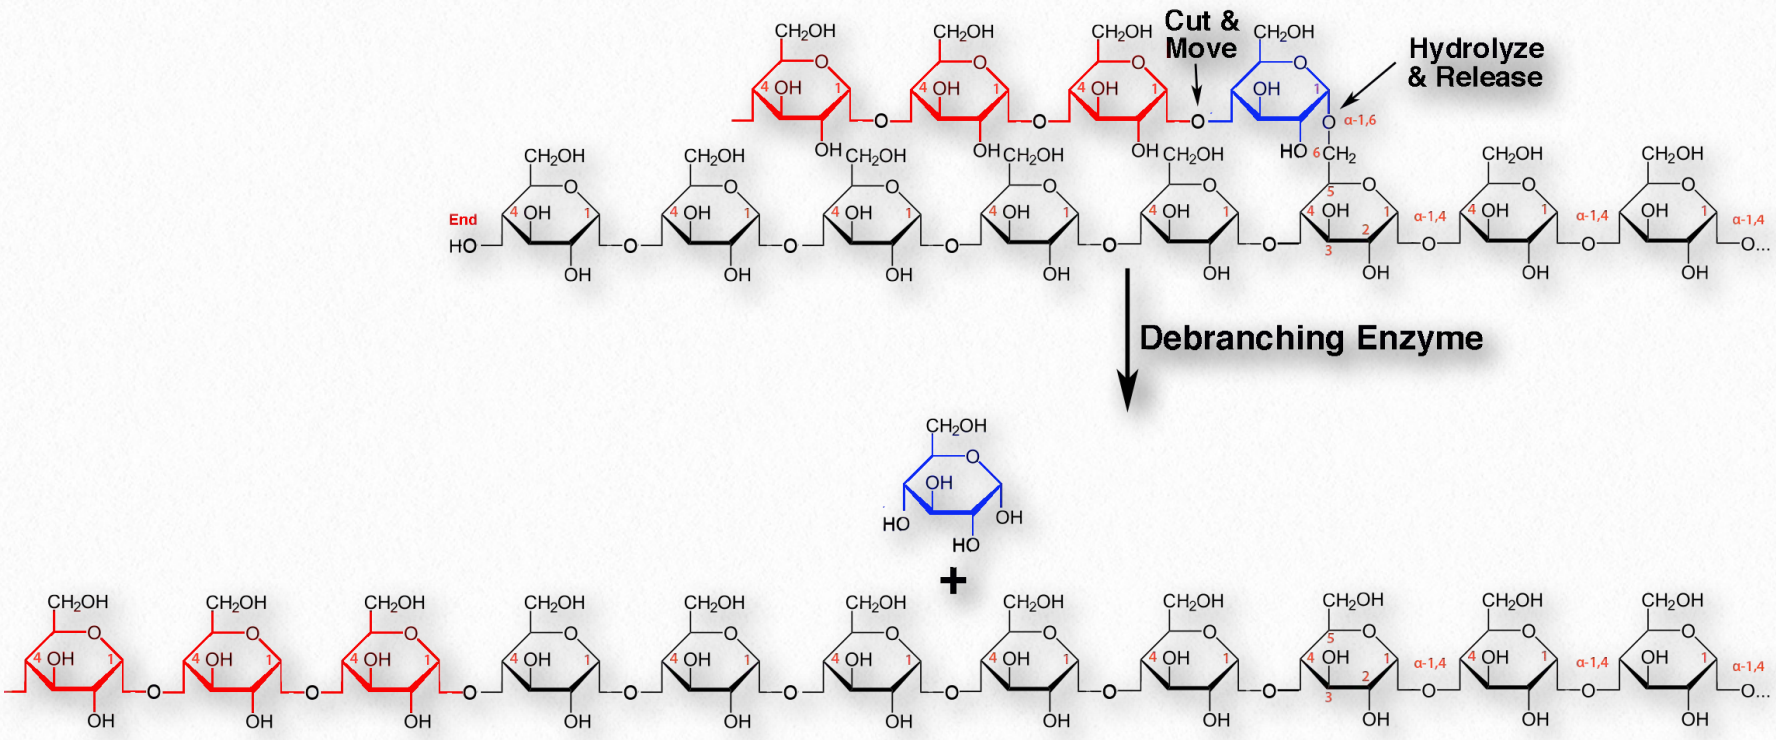

Figure 6.37 - Catalytic activity of debranching enzyme

GDE acts to transfer a trisaccharide from an α-1,6 branch onto an adjacent α-1,4 branch, leaving a single glucose at the 1,6 branch. Note that the enzyme also catalyzes the hydrolysis of the remaining glucose at the 1,6 branch point (Figure 6.37). Thus, the breakdown products from glycogen are G1P and glucose (mostly G1P). Glucose can, of course, be converted to Glucose-6-Phosphate (G6P) as the first step in glycolysis by either hexokinase or glucokinase.

G1P can be converted to G6P by action of an enzyme called phosphoglucomutase. This reaction is readily reversible, allowing G6P and G1P to be interconverted as the concentration of one or the other increases. This is important, because phosphoglucomutase is needed to form G1P for glycogen synthesis.

Regulation of glycogen metabolism

Regulation of glycogen metabolism is complex, occurring both allosterically and *via* hormone-receptor controlled events that result in protein phosphorylation or dephosphorylation. In order to avoid a futile cycle of glycogen synthesis and breakdown simultaneously, cells have evolved an elaborate set of controls that ensure only one pathway is primarily active at a time.

Regulation of glycogen metabolism is managed by the enzymes glycogen phosphorylase and glycogen synthase. Glycogen phosphorylase is regulated by both allosteric factors (ATP, G6P, AMP, and glucose) and by covalent modification (phosphorylation / dephosphorylation). Its regulation is consistent with the energy needs of the cell. High energy molecules (ATP, G6P, glucose) al-

losterically inhibit glycogen phosphorylase, while the low energy molecule AMP allosterically activates it.

GP_a/GP_b allosteric regulation

Glycogen phosphorylase exists in two different covalent forms – one form with phosphate (called GP_a here) and one form lacking phosphate (GP_b here). GP_b is converted to GP_a by phosphorylation by an enzyme known as phosphorylase kinase. GP_a and GP_b can each exist in an 'R' state and a 'T' state (Figure 6.38). For both GP_a and GP_b, the R state is the more active form of the enzyme. GP_a's negative allosteric effector (glucose) is usually not abundant in cells, so GP_a does not flip into the T state often. There is no positive allosteric effector of GP_a. When glucose is absent, GP_a automatically flips into the R (more active) state (Figure 6.39). It is for this reason that people tend to think of GP_a as being the more active covalent form of the enzyme.

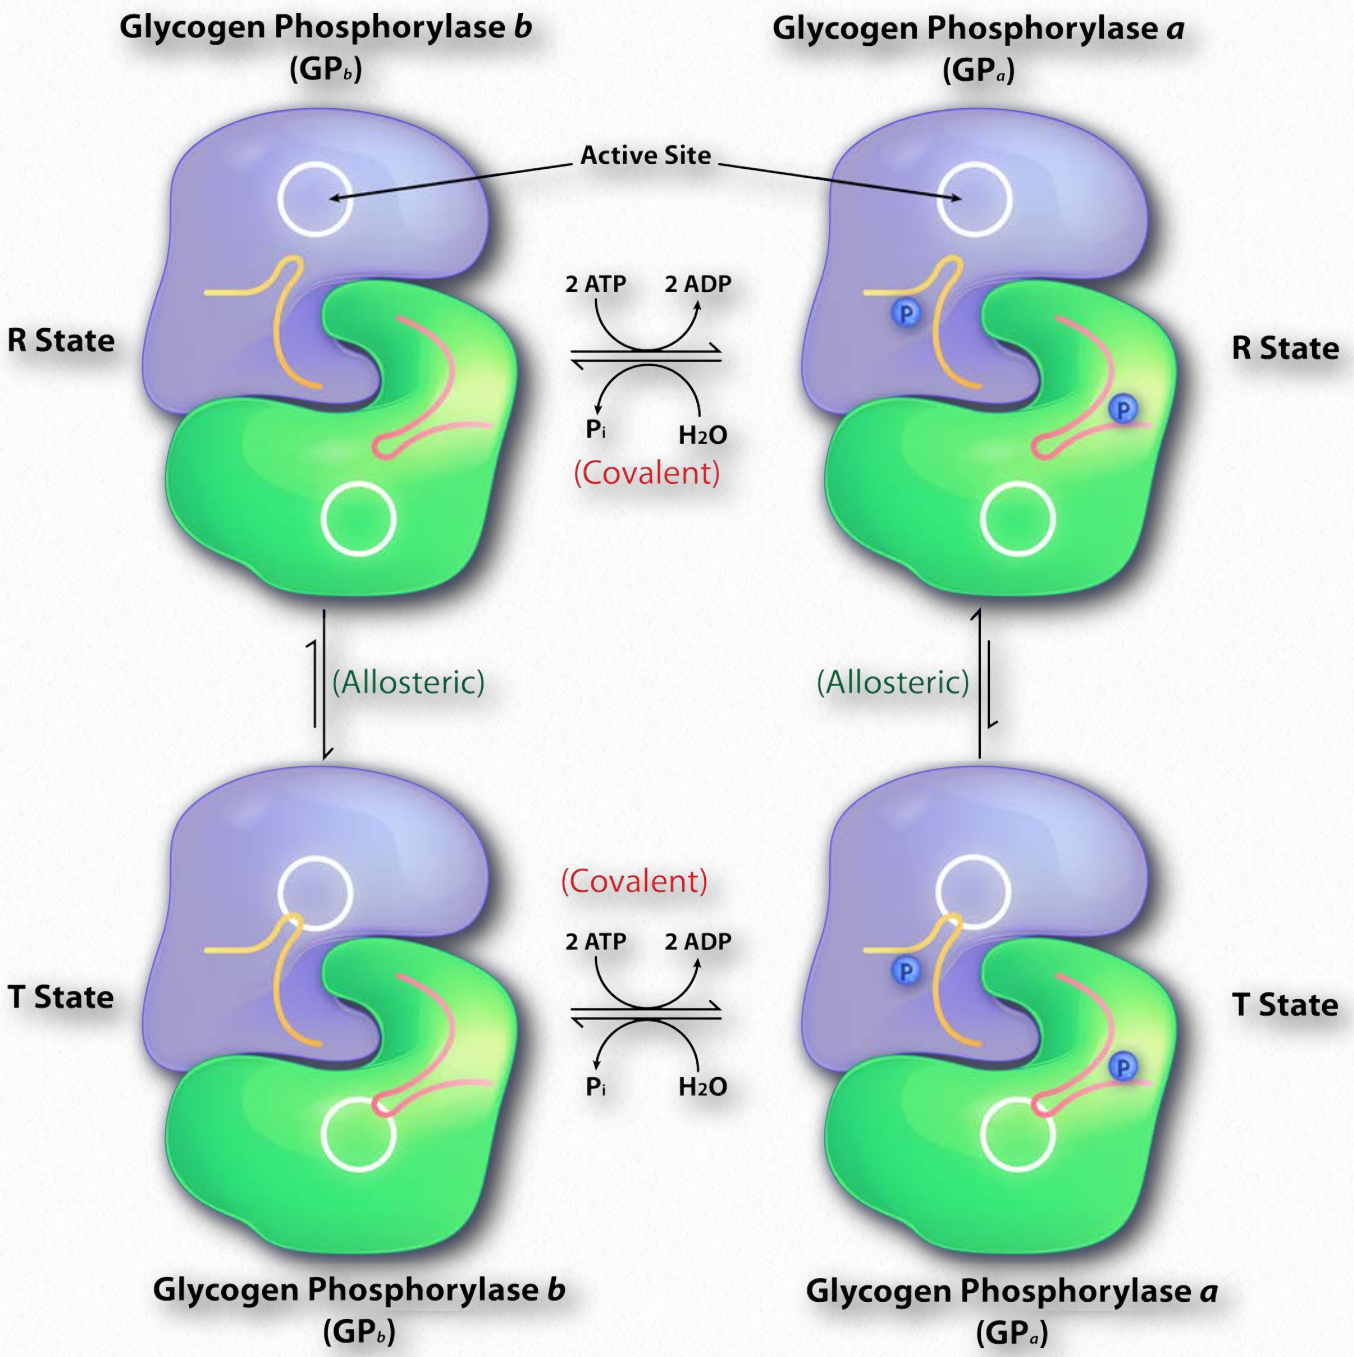

Figure 6.38 - Glycogen phosphorylase regulation - covalent (horizontal) and allosteric (vertical)

Image by Aleia Kim

YouTube Lectures by Kevin HERE & HERE

GP_b can convert from the GP_b T state to the GP_b R state by binding AMP. Unless a cell is low in energy, AMP concentration is low. Thus GP_b is not converted

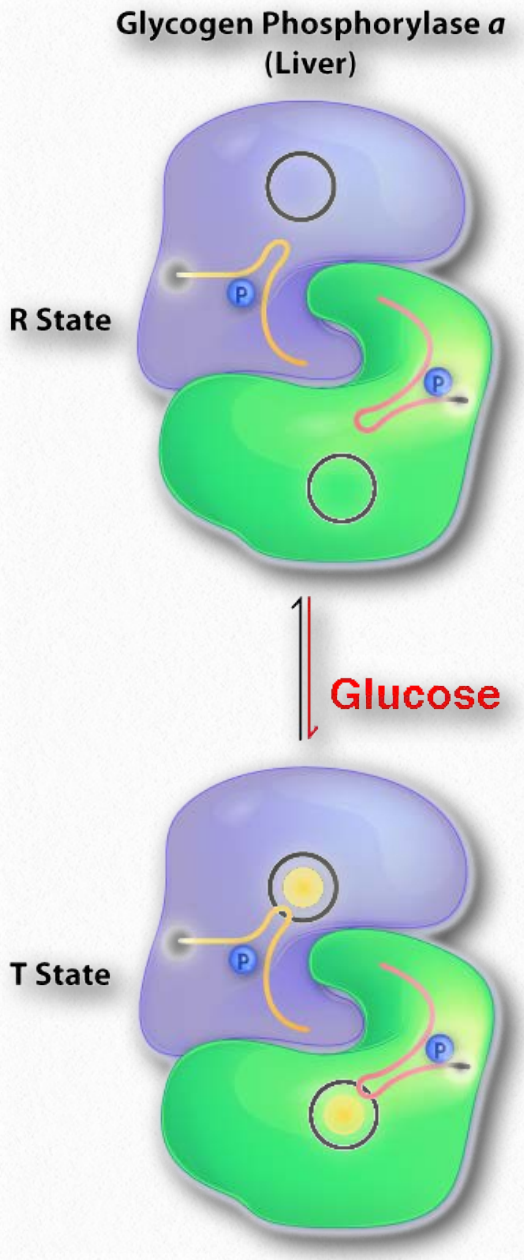

Figure 6.39 - Allosteric regulation of GP_a

Image by Aleia Kim

to the R state very often. This is why people think of the GP_b form as less active than GP_a. On the other hand, ATP and/or G6P are usually present at high enough concentration in cells that GP_b is readily flipped into the T state (Figure 6.40).

GP_a/GP_b covalent regulation

The relative amounts of GP_a and GP_b largely govern the overall process of glycogen breakdown, since GP_a tends to be active more often than GP_b. It is important, therefore, to understand the controls on the enzymes that interconvert GP_a and GP_b. This is accomplished by the enzyme phosphorylase kinase, which transfers phosphates from 2 ATPs to GP_b to form GP_a.

Phosphorylase kinase itself has two covalent forms – phosphorylated (active) and dephosphorylated (inactive). It is phosphorylated by the enzyme Protein Kinase A (PKA -). Another way to activate the enzyme is allosterically with calcium (Figure 6.41). Phosphory-

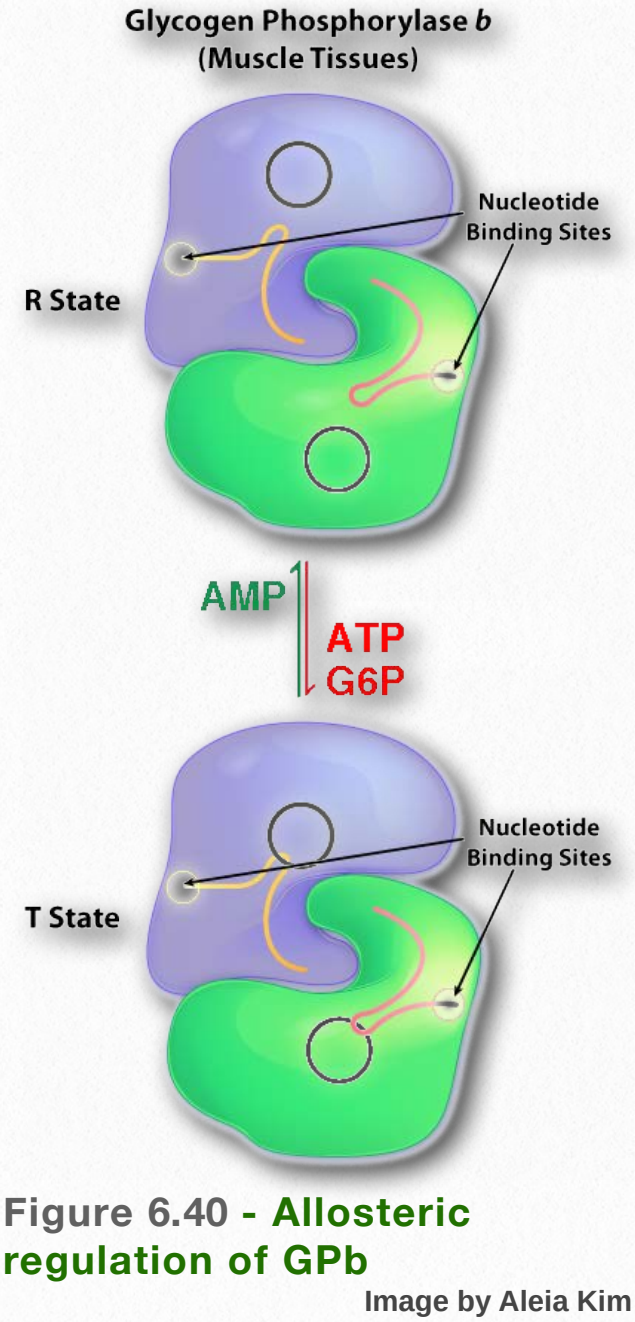

Figure 6.40 - Allosteric regulation of GPb

Image by Aleia Kim

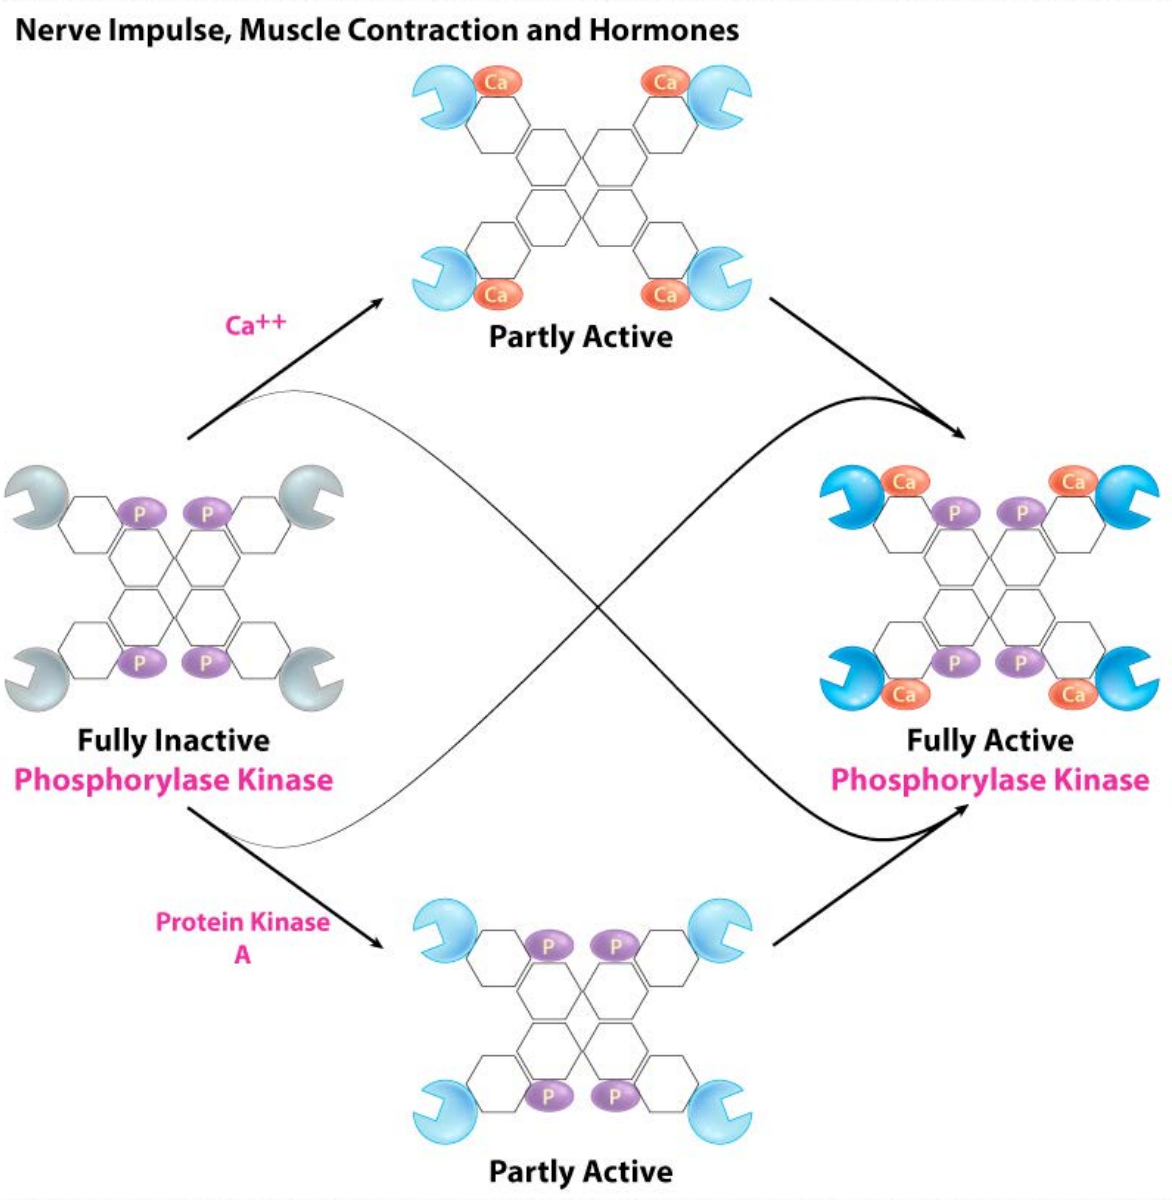

Figure 6.41 - Activation of phosphorylase kinase

Image by Aleia Kim

lase kinase is dephosphorylated by phosphoprotein phosphatase, the same enzyme that removes phosphate from GP_a.

PKA and cAMP

PKA is activated by cAMP, which is, in turn, produced by adenylate cyclase after activation by a G-protein (See HERE for overview). G-proteins are activated ultimately by binding of ligands to specific membrane receptors called 7-TM receptors, also known as G-protein coupled receptors. These are discussed in greater detail HERE. Common ligands for 7-TM receptors include epinephrine (binds β-adrenergic receptor) and glucagon (binds glucagon receptor). Epinephrine exerts its greatest effects on muscle and glucagon works preferentially on the liver. Thus, epinephrine and glucagon can activate glycogen breakdown by stimulating synthesis of cAMP followed by the cascade of events described above.

Turning off glycogen breakdown

Turning off signals is as important, if not more so, than turning them on. Glycogen is a precious resource. If its breakdown is not controlled, a lot of energy used in its synthesis is wasted. The steps in the glycogen breakdown regulatory pathway can be reversed at every level. First, the ligand (epinephrine or glucagon) can leave the receptor, turning off the stimulus. Second, the G-proteins have an inherent GTPase activity. GTP, of course, is what activates G-proteins, so a GTPase activity converts the GTP it is carrying to GDP and the G-protein becomes inactive. Thus, G-proteins turn off

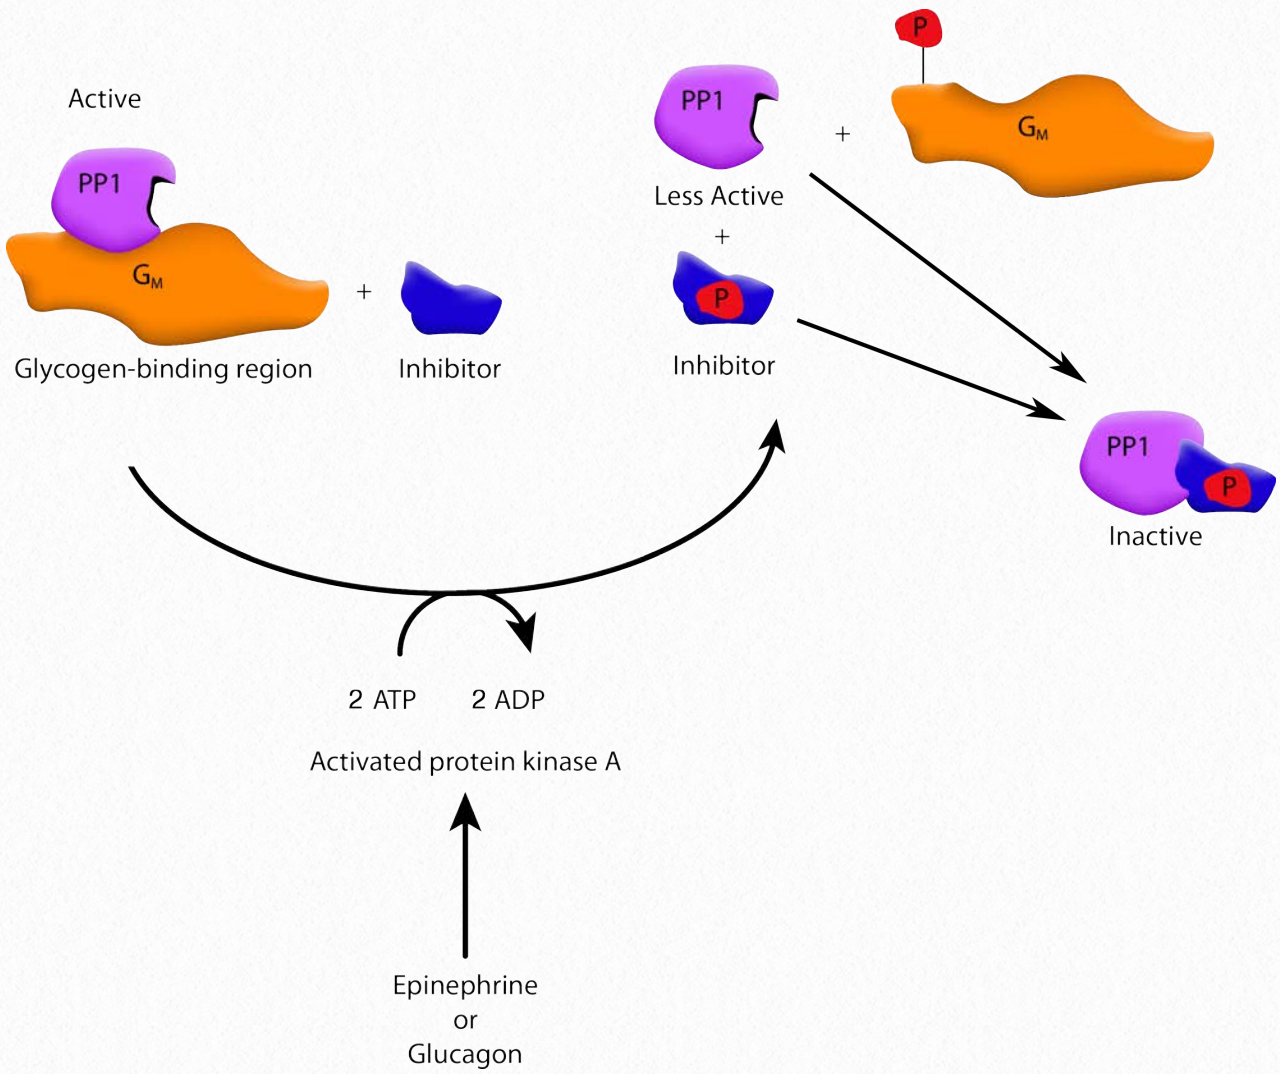

Figure 6.42 - Inactivation of phosphoprotein phosphatase by protein kinase A via phosphorylation of PI-1 (Inhibitor) and the G_M binding protein

Image by Pehr Jacobson

their own activity. Interfering with their ability to convert GTP to GDP can have dire consequences, including cancer in some cases.

Third, cells have phosphodiesterase enzymes (inhibited by caffeine) for breaking down cAMP. cAMP is needed to activate PKA, so breaking it down stops PKA from activating phosphorylase kinase. Fourth, the enzyme known as phosphoprotein phosphatase (also called PP1) plays a major role. It can remove phosphates from phosphorylase kinase (inactivating it) and form GP_a, converting it to the less likely to be active GP_b. Regulation of phosphoprotein phosphatase activity occurs at several levels. Two of these are shown in Figures 6.42 & 6.43.

In Figure 6.42, phosphoprotein phosphatase is shown being inactivated by phosphorylation of an inhibitor (called PI-1 - see below). This happens as a result of cascading actions from binding of epinephrine (or glucagon) to a cell's β-adrenergic receptor. Reversal of these actions occurs when insulin binds to the cell's insulin receptor, resulting in activation of phosphoprotein phosphatase.

Interactive Learning Module HERE

PI-1

The inhibitor PI-1 can block activity of phosphpoprotein phosphatase only if it (PI-1) is phosphorylated. When PI-1 gets dephosphorylated, it no longer functions as an inhibitor, so phosphoprotein phosphatase be-

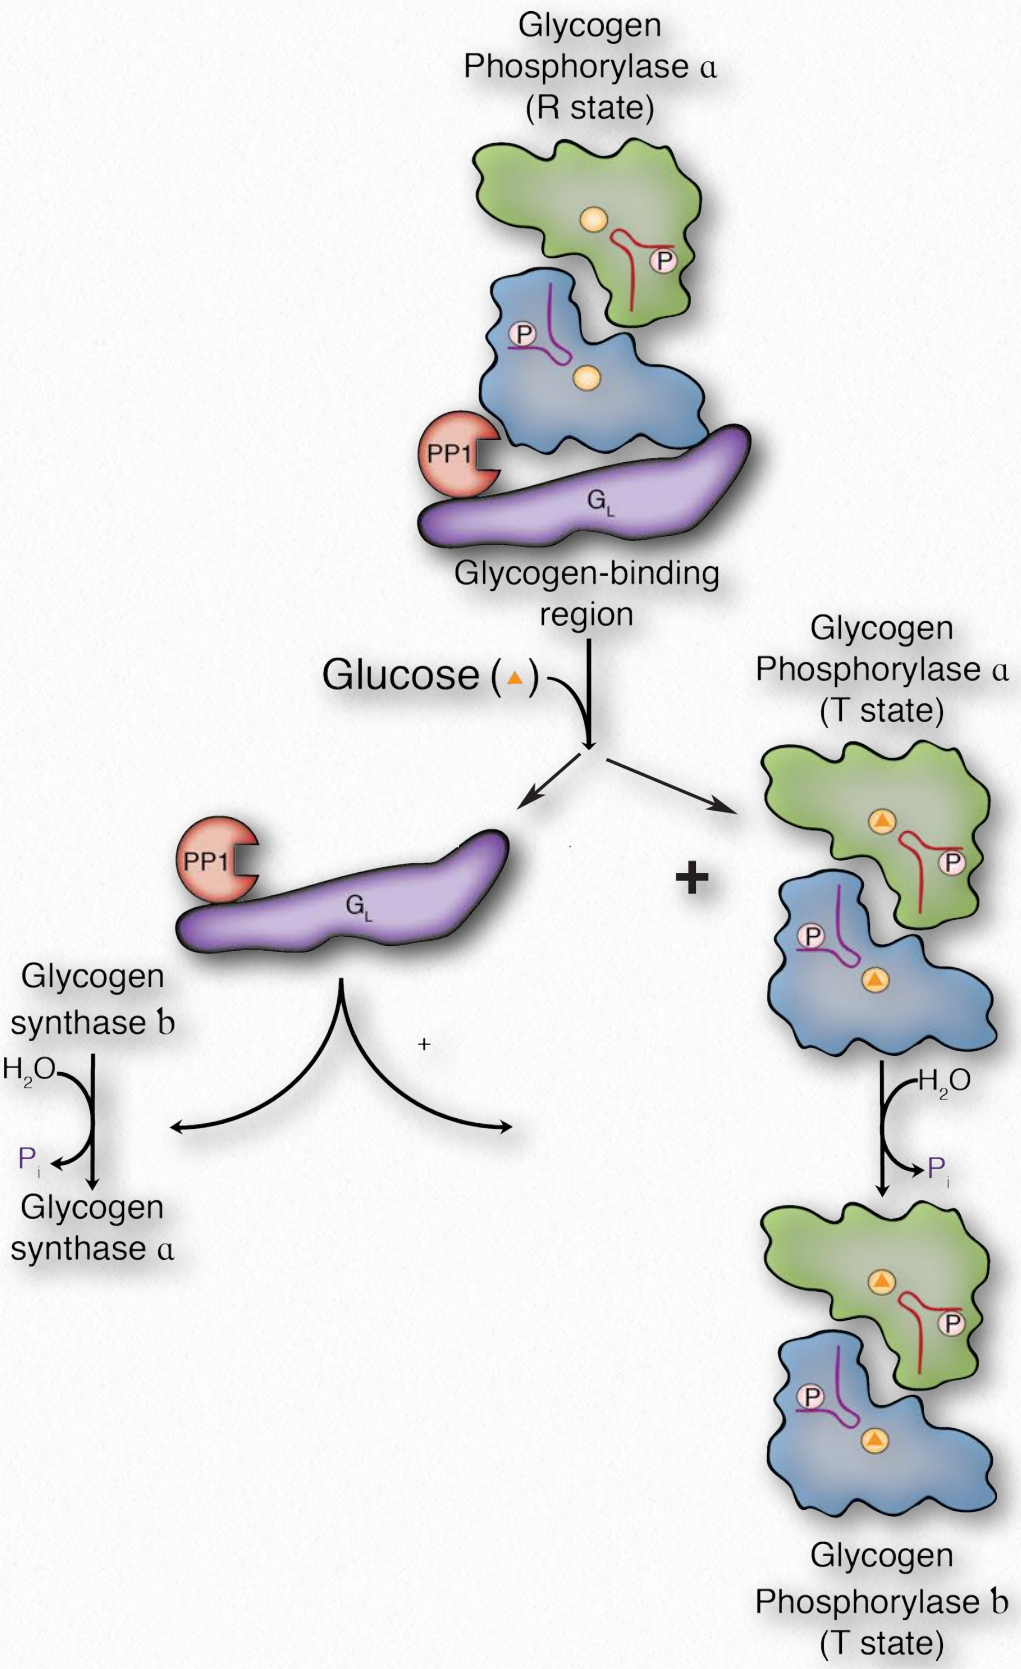

Figure 6.43 - Regulation of phosphoprotein phosphatase (PP-1) activity by GPa

Image by Penelope Irving

comes active. Now, here is the clincher - PI-1 gets phosphorylated by PKA (thus, when epinephrine or glucagon binds to a cell) and gets dephosphorylated when insulin binds to a cell.

Another regulatory mechanism

Another way to regulate phosphoprotein phosphatase in the liver involves GP_a directly (Figure 6.43). In liver cells, phosphoprotein phosphatase is bound to a protein called G_L. GL can also bind to GPa. As shown in the figure, if the three proteins are complexed together (top of figure), then PP1 (phosphoprotein phosphatase) is inactive. When glucose is present (such as when the liver has made too much glucose), then the free glucose binds to the GP_a and causes GP_a to be released from the G_L.

This has the effect of activating phosphoprotein phosphatase, which begins dephosphorylating enzymes. As shown in the figure, two such enzymes are GP_a (making GP_b) and glycogen synthase b, making glycogen synthase a. These dephosphorylations have opposite effects on the two enzymes, making GP_b, which is less active and glycogen synthase a, which is much more active.

Glycogen synthesis

The anabolic pathway opposing glycogen breakdown is that of glycogen synthesis. Just

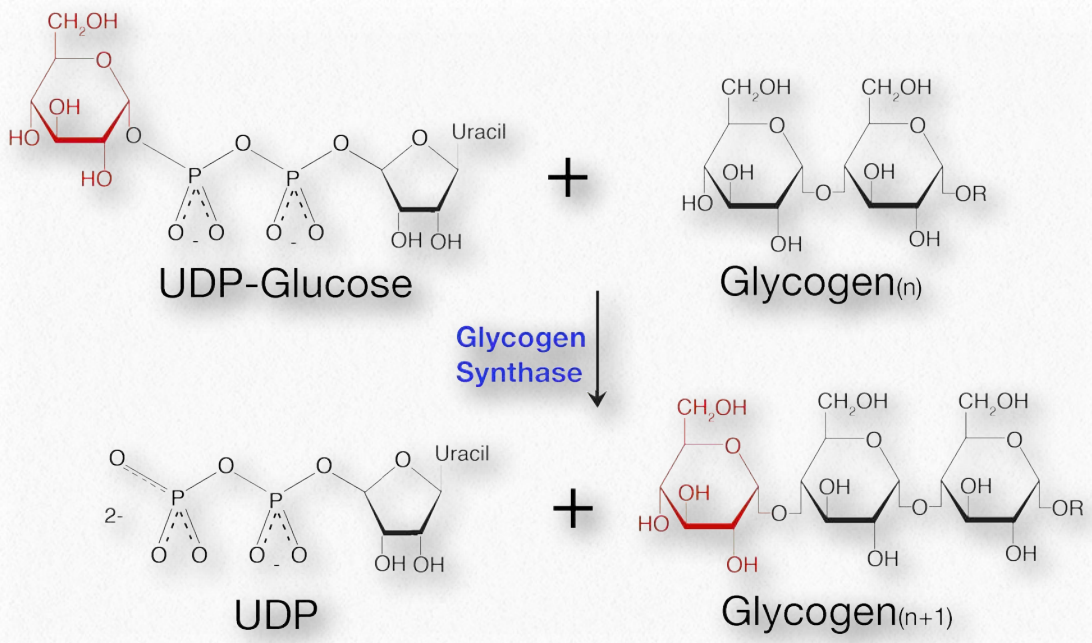

Figure 6.44 - Catalytic activity of glycogen synthase
Image by Penelope Irving

Synthesis of glycogen starts with G1P, which is converted to an 'activated' intermediate, UDP-glucose. This activated intermediate is what 'adds' the glucose to the growing glycogen chain in a reaction catalyzed by the enzyme known as glycogen synthase (Figure 6.44). Once the glucose is added to glycogen, the glycogen molecule may need to have branches inserted in it by the enzyme known as branching enzyme (Figure 6.45).

as cells reciprocally regulate glycolysis and gluconeogenesis to prevent a futile cycle between these pathways, so too do cells use reciprocal schemes to regulate glycogen breakdown and synthesis.

Steps

Let us first consider the steps in glycogen synthesis. 1) Glycogen synthesis from glucose involves phosphorylation to form G6P, and isomerization to form G1P (using phospho-

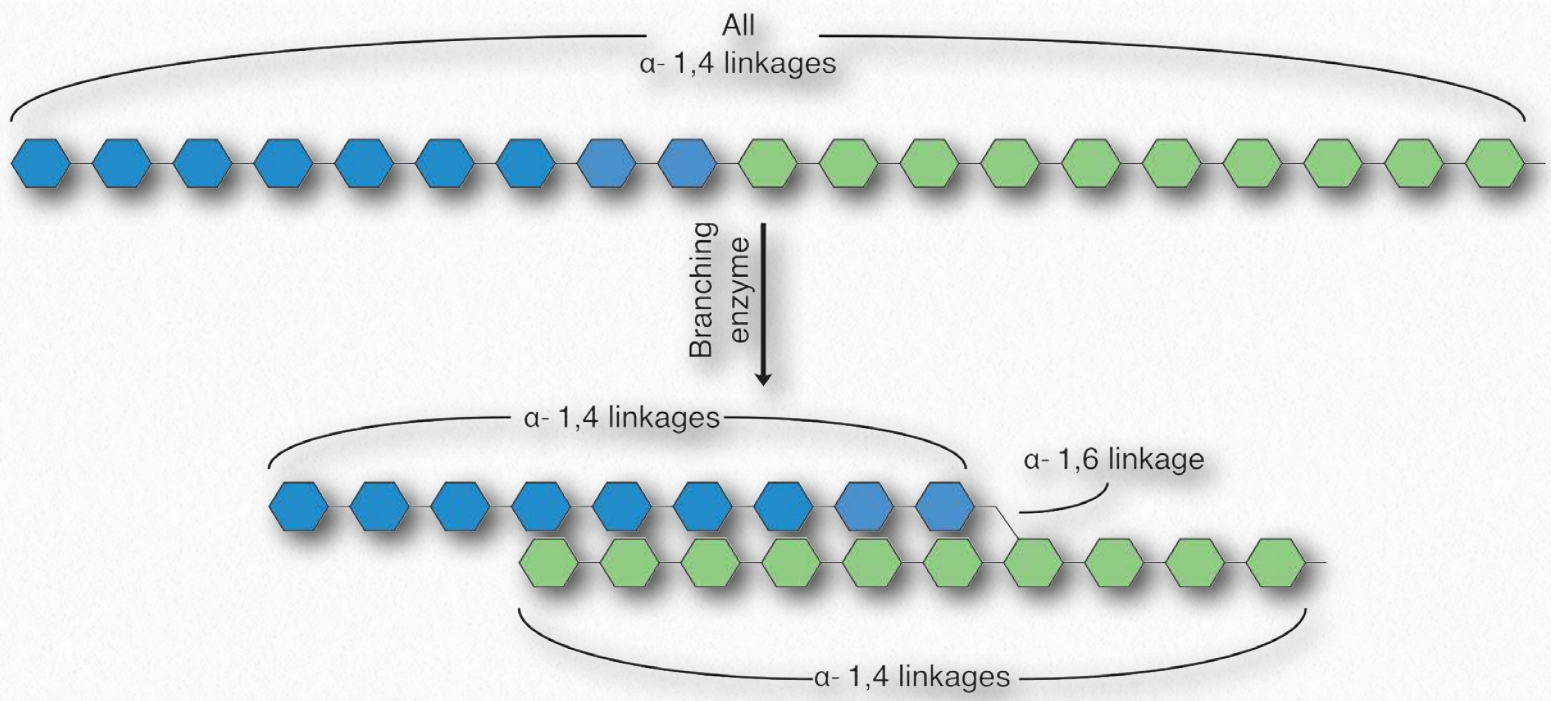

Figure 6.45 - Branch formation in glycogen by branching enzyme
Image by Penelope Irving

glucomutase, common to glycogen breakdown). G1P is reacted with UTP to form UDP-glucose in a reaction catalyzed by UDP-glucose pyrophosphorylase. Glycogen synthase catalyzes synthesis of glycogen by joining carbon #1 of the UDP-derived glucose onto the carbon #4 of the non-reducing end of a glycogen chain, to form the familiar α(1,4) glycogen links. Another product of the reaction is UDP.

YouTube Lectures by Kevin HERE & HERE

"Primer" requirements

It is also worth noting, in passing, that glycogen synthase will only add glucose units from UDP-Glucose onto a preexisting glycogen chain that has at least four glucose residues. Linkage of the first few glucose units to form the minimal "primer" needed for glycogen synthase recognition is catalyzed by a protein called glycogenin, which attaches to the first glucose and catalyzes linkage of the first eight glucoses by α(1,4) bonds. 3) The characteristic α(1,6) branches of glycogen are the products of the enzyme known as branching enzyme. Branching enzyme breaks α(1,4) chains and carries the broken chain to the carbon #6 and forms an α(1,6) linkage (Figure 6.45).

Regulation of glycogen synthesis

The regulation of glycogen biosynthesis is reciprocal to that of glycogen breakdown. It also has a cascading covalent modification system similar to the glycogen breakdown system described above. In fact, part of the system is identical to glycogen breakdown. Epinephrine or glucagon signaling stimulates adenylate cyclase to make cAMP, which activates PKA.

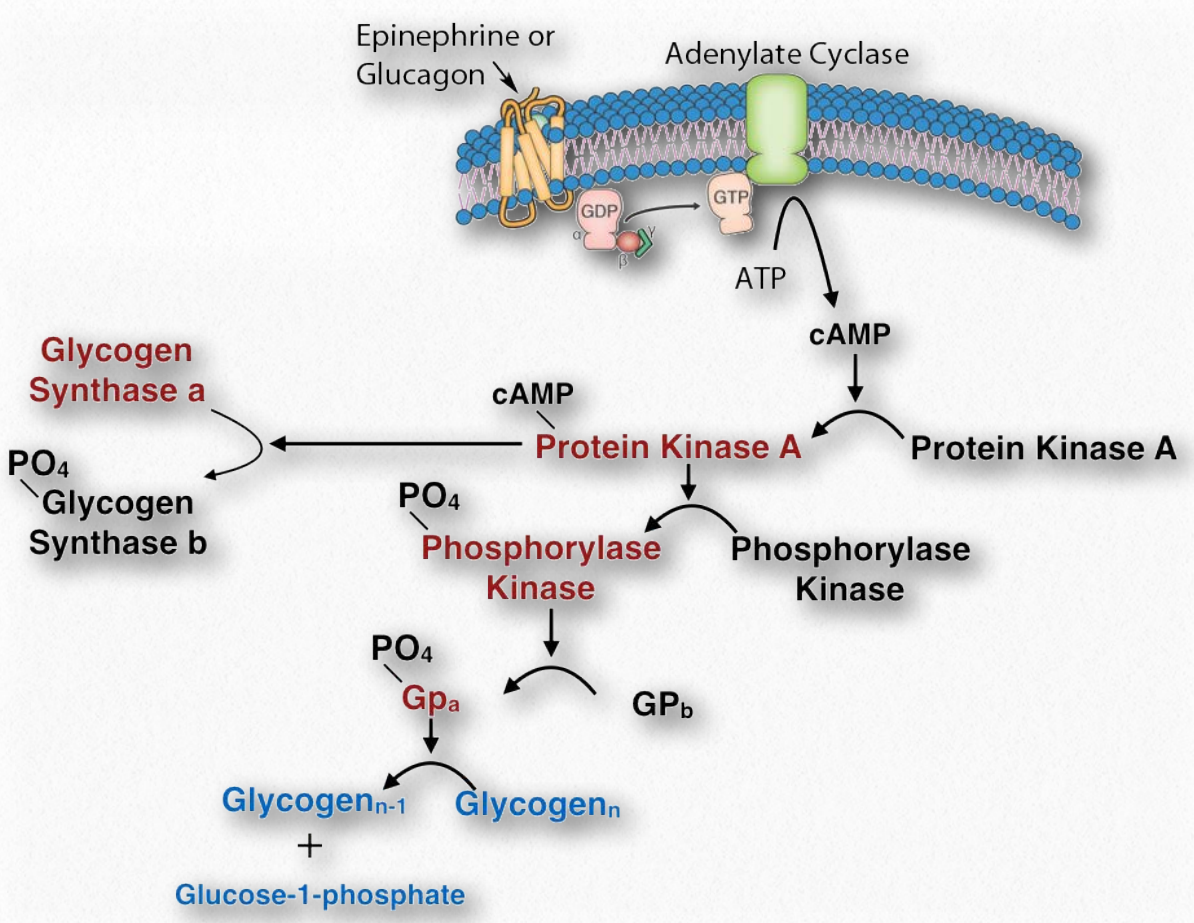

Figure 6.46 - Reciprocal regulation by the phosphorylation cascade - glycogen breakdown activated / glycogen synthesis inhibited

Image by Penelope Irving

Effect of phosphorylation

In glycogen synthesis, protein kinase A phosphorylates the active form of glycogen synthase (GS_a), and converts it into the usually inactive b form (called GS_b).

Note the conventions for glycogen synthase and glycogen phosphorylase. For both enzymes, the more active forms are called the 'a' forms (GP_a and GS_a) and the less active forms are called the 'b' forms (GP_b and GS_b). The *major* difference, however, is that GP_a has a phosphate, but GS_a does not and GP_b has no phosphate, but GS_b does.

Thus phosphorylation and dephosphorylation have *opposite effects* on the enzymes of glycogen metabolism (Figure 6.46). This is the hallmark of reciprocal regulation. It is of note that the less active glycogen synthase form, GS_b, can be activated by G6P. Recall that G6P had the exactly opposite effect on GP_b.

Glycogen synthase, glycogen phosphorylase (and phosphorylase kinase) can all be dephosphorylated by the same enzyme - phosphoprotein phosphatase - and it is activated when insulin binds to its receptor in the cell membrane.

Big picture

In the big picture, binding of epinephrine or glucagon to appropriate cell receptors stimulates a phosphorylation cascade which simultaneously activates breakdown of glycogen by glycogen phosphorylase and inhibits its synthesis of glycogen by glycogen synthase. Epinephrine, is also known as adrenalin, and the properties that adrenalin gives arise from a large temporary increase of blood glucose, which powers muscles.

Figure 6.47 - Cotton - the purest natural form of cellulose

Wikipedia

Interactive Learning Module HERE

On the other hand, insulin stimulates dephosphorylation by activating phosphoprotein phosphatase. Dephosphorylation reduces action of glycogen phosphorylase (less glycogen breakdown) and activates glycogen synthase (starts glycogen synthesis). Our bodies make glycogen when blood glucose levels rise. Since high blood glucose levels are harmful, insulin stimulates cells to take up glucose. In the liver and in muscle cells, the uptaken glucose is made into glycogen.

Cellulose synthesis

Cellulose is synthesized as a result of catalysis by cellulose synthase. Like glycogen synthesis it requires an activated intermediate to add glucose residues and there are two possible ones - GDP-glucose and UDP-glucose, depending on which cellulose synthase is involved. In plants, cellulose provides support to cell walls.

The reaction catalyzed is shown next where $Cellulose_n$ = a polymer of [(1→4)-β-D-glucosyl] n units long.

UDP-glucose + $Cellulose_n$

⇅

UDP + $Cellulose_{n+1}$

The GDP-glucose reaction is the same except with substitution of GDP-glucose for UDP-

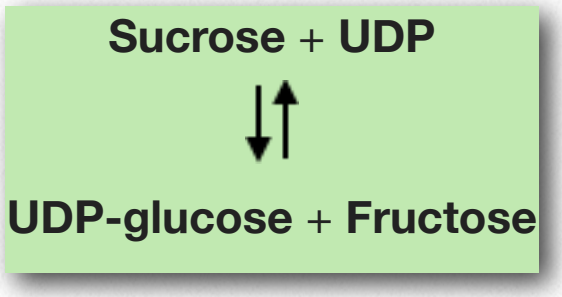
glucose. UDP-glucose for the reaction is obtained by catalysis of sucrose synthase.



The enzyme is named for the reverse reaction.

Pentose phosphate pathway

The pentose phosphate pathway (PPP - also called the hexose monophosphate shunt) is an oxidative pathway involving sugars that is sometimes described as a parallel pathway to glycolysis. It is, in fact, a pathway with multiple inputs and outputs (Figure 6.48). PPP is also a major source of NADPH for biosynthetic reactions and can provide ribose-5-phosphate for nucleotide synthesis.

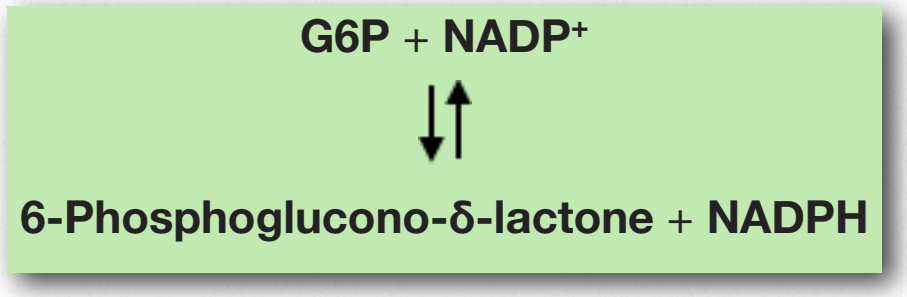
Though when drawn out, the pathway's "starting point" is often shown as glucose-6-phosphate (G6P), in fact there are multiple entry points including other glycolysis intermediates, such as fructose-6-phosphate (F6P) and glyceraldehyde-3-phosphate (GLYAL-3-P), as well as less common sugar compounds with 4,5, and 7 carbons.

YouTube Lectures by Kevin HERE & HERE

The multiple entry points and multiple outputs gives the cell tremendous flexibility to meet its needs by allowing it to use a variety of materials to make any of these products.

Oxidation #1

Beginning with G6P, PPP proceeds through its oxidative phase as follows:



The enzyme catalyzing the reaction is G6P dehydrogenase. It is the rate limiting step of the pathway and the enzyme is inhibited both by NADPH and acetyl-CoA. NADPH is important for anabolic pathways, such as fatty acid synthesis and also for maintaining glutathione in a reduced state. The latter is important in protection against damage from reactive oxygen species.

Deficiency of the G6P dehydrogenase enzyme is not rare, leading to acute hemolytic anemia, due to reduced NADPH concentration, and a reduced ability of the cell to disarm reactive oxygen species with glutathione. Reduced activity of the enzyme appears to have a protective effect against malarial infection, likely due to the increased fragility of the red blood cell membrane, which is then unable to sustain an infection by the parasite.

Hydrolysis

Reaction #2 is a hydrolysis and it is catalyzed by 6-phosphogluconolactonase. The reac-

tion converts the circular 6-phosphoglucono-δ-lactone into the linear 6-phosphogluconate (6-PG) in preparation for oxidation in the next step.

6-Phosphoglucono-δ-lactone + H_2O

⇅

6-phosphogluconate (6-PG) + H^+

Decarboxylation

Reaction #3 is the only decarboxylation in the PPP and the last oxidative step. It is catalyzed by 6-phosphogluconate dehydrogenase.

⇅

Ribulose-5-phosphate (Ru-5-P) + **NADPH** + **CO_2**

Mutations disabling the protein made from this gene negatively impact red blood cells. At this point, the oxidative phase of PPP is complete and the remaining reactions involve molecular rearrangements. Ru5P has two possible fates and these are each described below.

Isomerization

Reaction 4a: The enzyme catalyzing this reversible reaction is Ru5P isomerase (top of next column). It is important because this is the way cells make R-5-P for nucleotide synthesis. The R-5-P can also be used in other PPP reactions shown elsewhere.

TPP co-factor

Transketolase uses thiamine pyrophosphate (TPP) to catalyze reactions. TPP's thia-

zole ring's nitrogen and sulfur atoms on either side of a carbon, allow it to donate a proton and act as an acid, thus forming a carbanion, which gets stabilized by the adjacent tetravalent nitrogen (Figures 6.50 & 6.51)).

The stabilized carbanion plays important roles in the reaction mechanism of enzymes, such as transketolase that use TPP as a co-

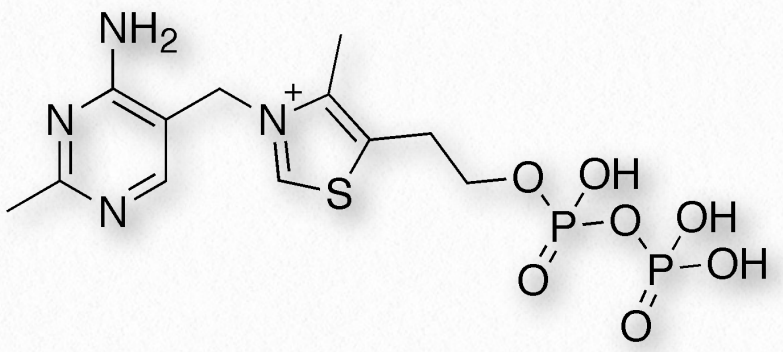

Figure 6.50 - Thiamine pyrophosphate

factor. Commonly, the carbanion acts as a nucleophile that attacks the carbonyl carbon of the substrate. Such is the case with transketolase. Attack by the carbanion breaks the carbonyl bond on the substrate and covalently links it to the ionized carbon of TPP, thus allowing it to "carry" the carbonyl group to the other substrate for attachment. In this way, two carbons are moved from Xu-5-P to E-4-P to make F6P (from E-4-P) and GLYAL-3-P (from Xu-5-P). Similarly, S-7-P and GLYAL-3-P are made from R-5-P and Xu-5-P, respectively.

Thiamines

Thiamines are a class of compounds involved in catalysis of important respiration-related

The Pentose Phosphate Pathway

by Kevin Ahern

I need erythrose phosphate
And don't know what to do
My cells are full of G-6-P
And NADP too

But I just hit upon a plan
As simple as can be
I'll run reactions through the path
That's known as PPP

In just two oxidations
There's ribulose-5P
Which morphs to other pentoses
Each one attached to P

The next step it is simple
Deserving of some praise
The pentose carbons mix and match
Thanks to transketolase

Glyceraldehyde's a product
Sedoheptulose is too
Each with a trailing phosphate
But we are not quite through

Now three plus seven is the same
As adding six and four
By swapping carbons back and forth
There's erythrose-P and more

At last I've got the thing I need
From carbons trading places
I'm happy that my cells are full
Of some transaldolases

reactions in the citric acid cycle, pyruvate metabolism, the pentose phosphate pathway, and the Calvin cycle. Thiamine was the first water-soluble vitamin (B_1) to be discovered via association with the peripheral nervous system disease known as Beriberi. Thiamine pyrophosphate (TPP) is an enzyme cofactor found in all living systems derived from thiamine by action of the enzyme thiamine diphosphokinase. TPP facilitates catalysis of several biochemical reactions essential for tissue respiration.

YouTube Lectures by Kevin HERE & HERE

Deficiency of the vitamin is rare today, though people suffering from Crohn's disease, anorexia, alcoholism or undergoing kidney dialysis may develop deficiencies. TPP is required for the oxidative decarboxylation of pyruvate to form acetyl-CoA and similar reactions. Transketolase, an important enzyme in the pentose phosphate pathway, also uses it as a coenzyme. Besides these reactions, TPP is also required for oxidative decarboxylation of α-keto acids like α-ketoglutarate and branched-chain α-keto acids arising from metabolism of valine, isoleucine, and leucine.

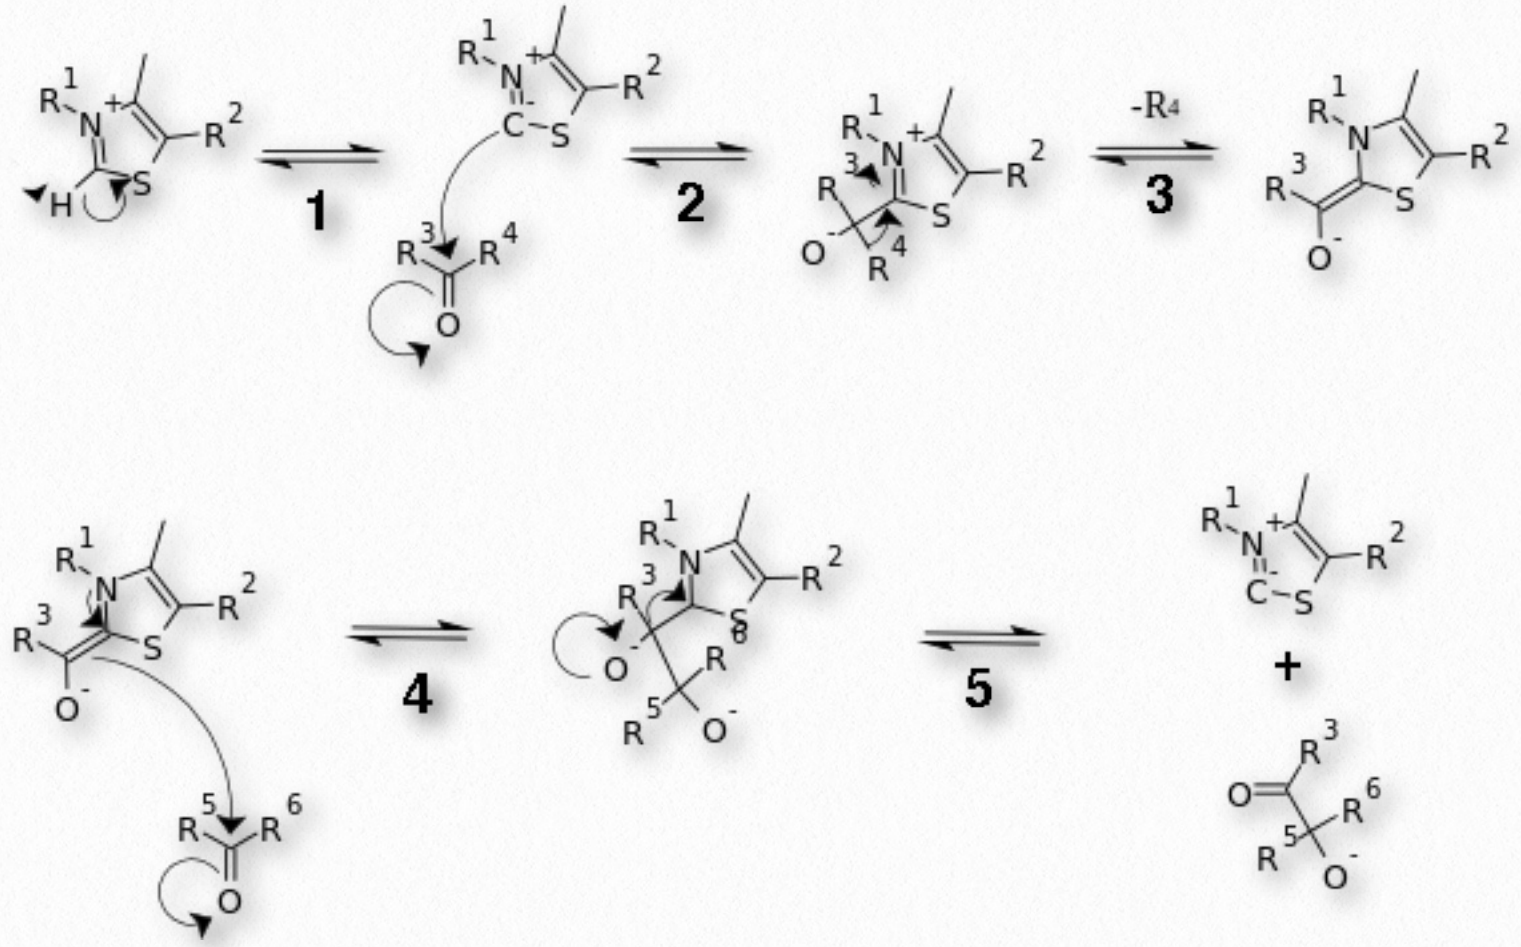

Figure 6.51 - Mechanism of action of thiamine pyrophosphate (TPP) - 1) Carbanion formation; 2) Nucleophilic attack; 3) Covalent attachment of carbonyl; 4) Transfer to second group; 5) Release of product and regeneration of TPP

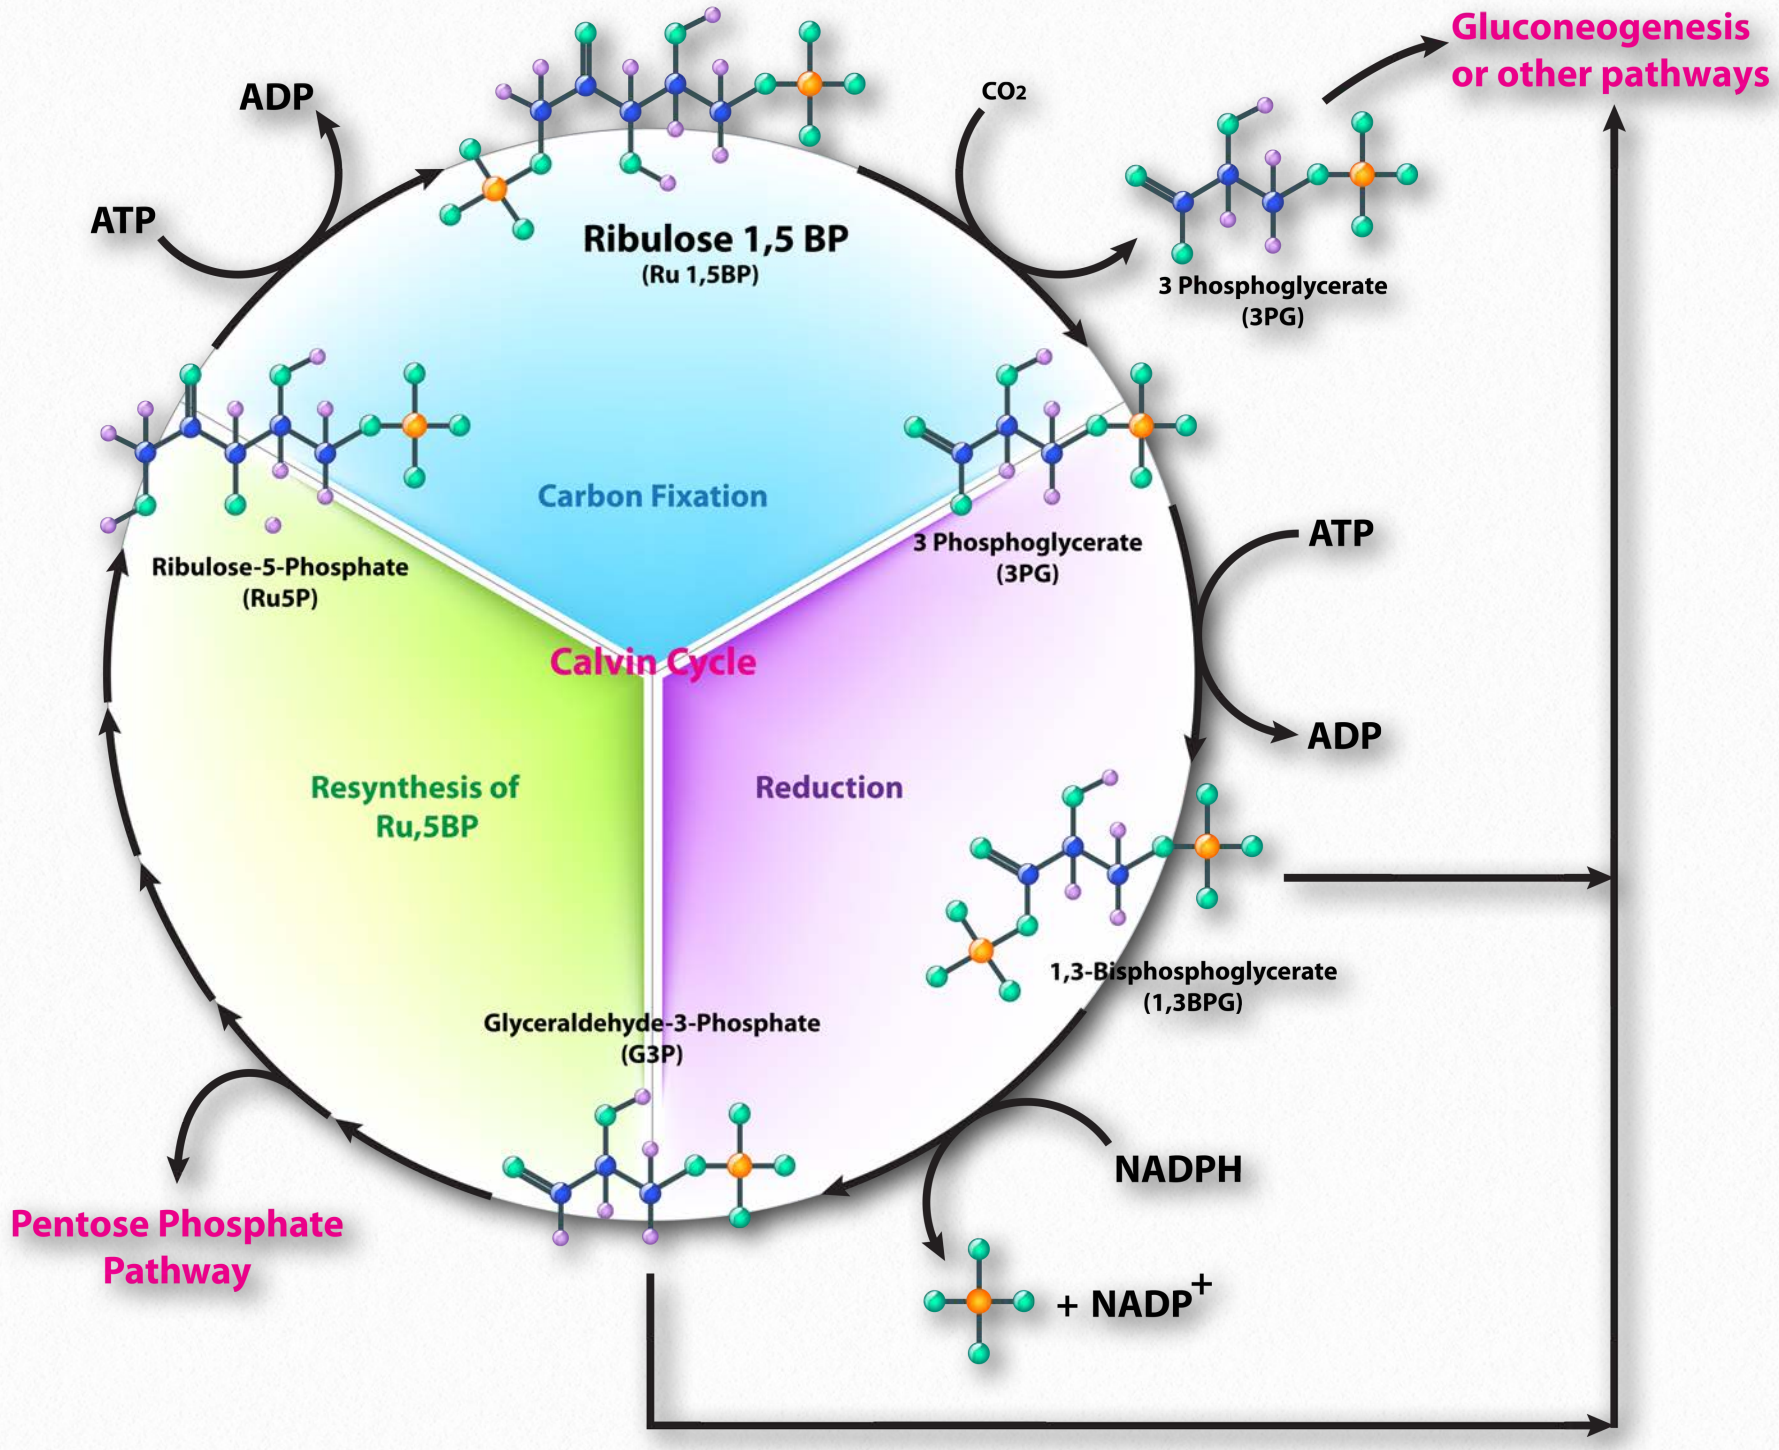

Figure 6.52 - The Calvin cycle - The resynthesis phase has multiple steps and is described below.

Image by Aleia Kim

TPP acts in the pyruvate dehydrogenase complex to assist in decarboxylation of pyruvate and "carrying" the activated acetaldehyde molecule to its attachment (and subsequent oxidation) to lipoamide. Central to TPP's function is the thiazolium ring, which stabilizes carbanion intermediates (through resonance) by acting as an electron sink (Figure 6.51). Such action facilitates breaking of carbon-carbon bonds such as occurs during decarboxylation of pyruvate to produce the activated acetaldehyde.

Thiamine deficiency

Thiamine is integral to respiration and is needed in every cell. Acute deficiency of thiamine leads to numerous problems - the best known condition is beriberi, whose symptoms include weight loss, weakness, swelling, neurological issues, and irregular heart rhythms.

Causes of deficiency include poor nutrition, significant intake of foods containing the enzyme known as thiaminase, foods with compounds that counter thiamine action (tea, coffee), and chronic diseases, including diabetes, gastrointestinal diseases, persistent vomiting. People with severe alcoholism often are deficient in thiamine.

Calvin cycle

The Calvin cycle (Figure 6.52) is a metabolic pathway occurring exclusively in photosynthetic organisms. Commonly referred to as the "Dark Cycle" or the Light-Independent Cycle, the Calvin cycle does not actually occur in the dark. The cell/chloroplast simply is not directly using light energy to drive it.

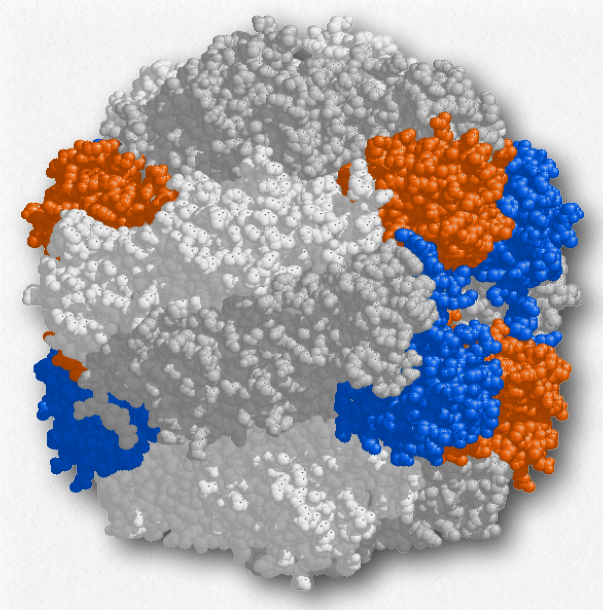

Figure 6.53 - Rubisco, the most abundant enzyme on Earth

Assimilation

It is in the Calvin cycle of photosynthesis that carbon dioxide is taken from the atmosphere and ultimately built into glucose (or other sugars). Reactions of the Calvin cycle take place in regions of the chloroplast known as the stroma, the fluid areas outside of the thylakoid membranes. The cycle can be broken into three phases

1) assimilation of CO_2

2) reduction reactions

3) regeneration of the starting material, ribulose 1,5 bisphosphate (Ru1,5BP).

Though reduction of carbon dioxide to glucose ultimately requires electrons from twelve molecules of NADPH (and 18 ATPs), it is confusing because one reduction occurs 12 times (1,3 BPG to GLYAL-3P) to input the overall reduction necessary to make one glucose.

Carbon dioxide

Another reason students find the pathway confusing is because the carbon dioxide molecules are absorbed one at a time into six different molecules of Ru1,5BP. At no point are the six carbons ever together in the same molecule to make a single glucose.

Instead, six molecules of Ru1,5BP (30 carbons) gain six more carbons via carbon dioxide and then split into 12 molecules of 3-phosphoglycerate (36 carbons). The gain of six carbons allows two three carbon molecules to be produced in excess for each turn of the cycle. These two molecules molecules are then converted into glucose using the enzymes of gluconeogenesis. The other ten molecules of 3-PG are used to regenerate the six molecules of Ru1,5BP.

Cyclic pathway

Like the citric acid cycle, the Calvin cycle doesn't really have a starting or ending point, but can we think of the first reaction as the fixation of carbon dioxide to Ru1,5BP. This reaction is catalyzed by the enzyme known as ribulose-1,5 bisphosphate carboxylase (RUBISCO - Figure 6.53). The resulting six carbon intermediate is unstable and is rapidly converted to two molecules of 3-phosphoglycerate.

As noted, if one starts with 6 molecules of Ru1,5BP and makes 12 molecules of 3-PG, the extra 6 carbons that are a part of the cycle can be shunted off as two three-carbon molecules of glyceraldehyde-3-phosphate (GLYAL3P) to gluconeogenesis, leaving behind 10 molecules to be reconverted into 6 mole-

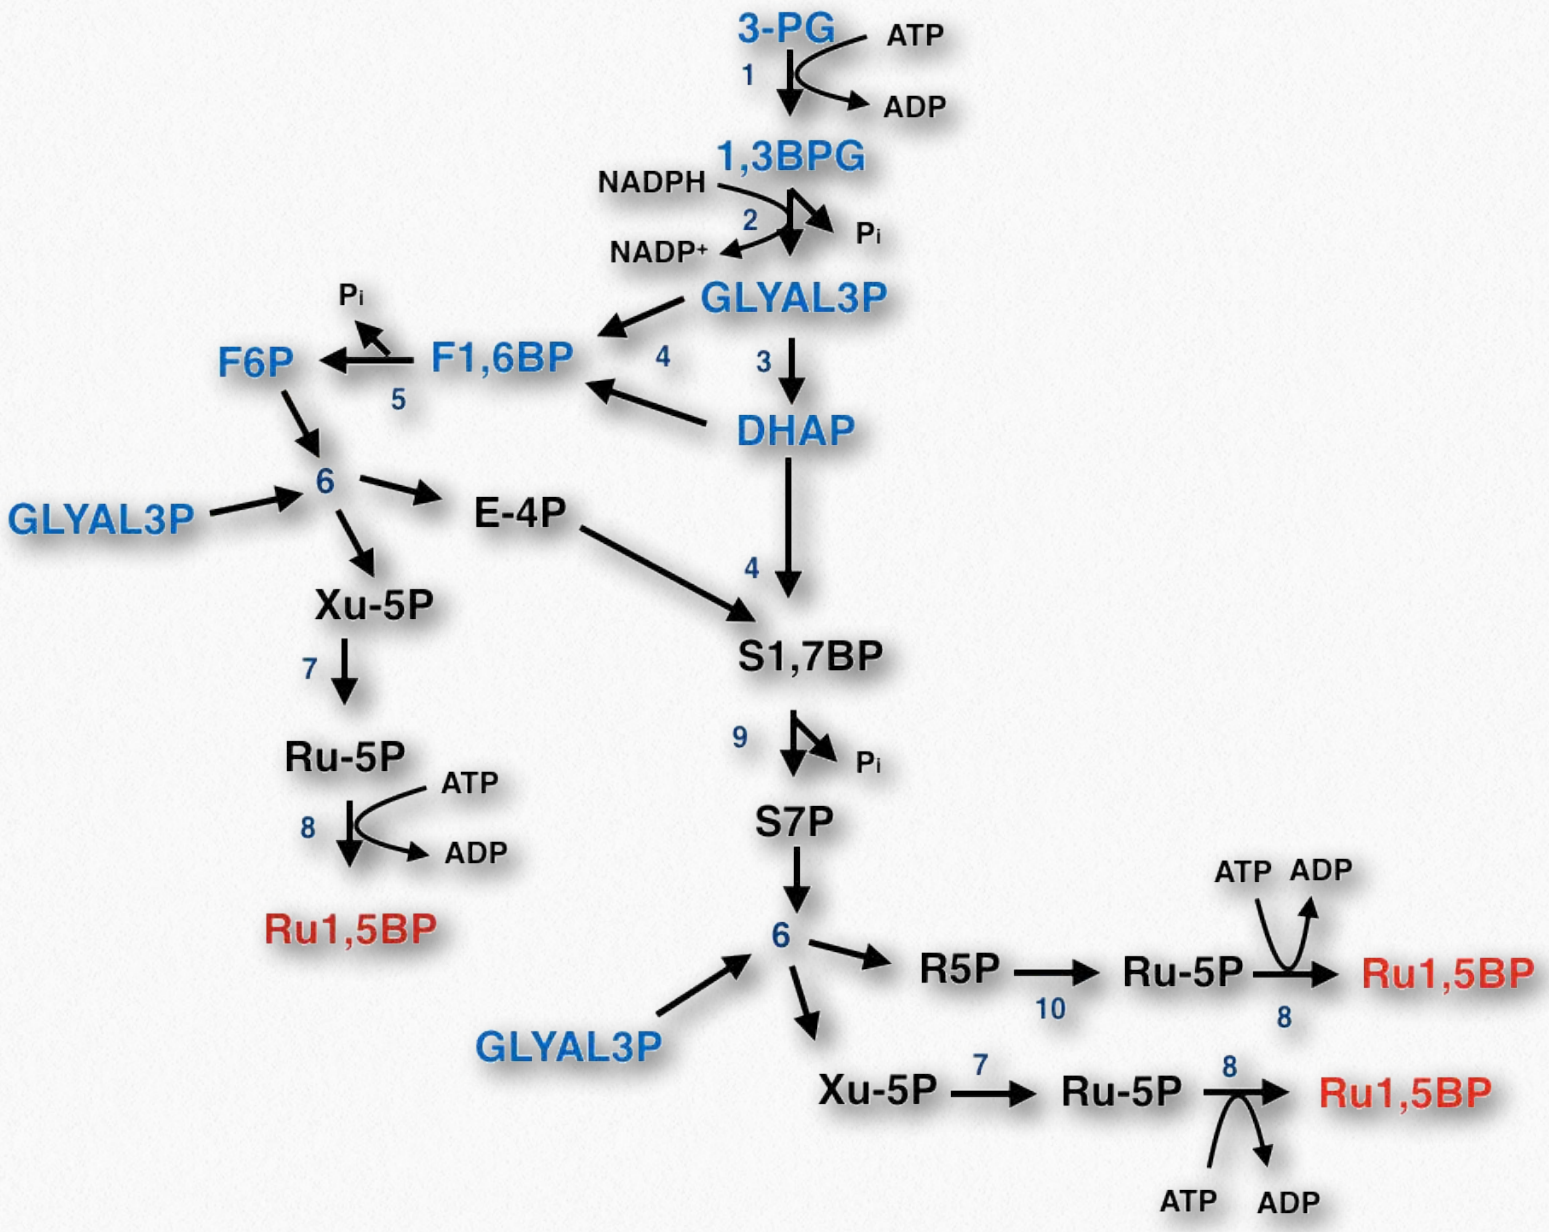

Figure 6.54 - Resynthesis phase of the Calvin cycle - All paths lead to regenerating Ru1,5BP, which is the aim of the resynthesis phase. Glycolysis/gluconeogenesis intermediates shown in blue. Enzyme numbers explained in text.

cules of Ru1,5BP. This occurs in what is called the resynthesis phase.

Resynthesis phase

The resynthesis phase (Figure 6.54) requires multiple steps, but only utilizes two enzymes unique to plants - sedoheptulose-1,7 bisphosphatase and phosphoribulokinase. RUBISCO is the third (and only other) enzyme of the pathway that is unique to plants.

All of the other enzymes of the pathway are common to plants and animals and include some found in the pentose phosphate pathway and gluconeogenesis. Enzymes shown as numbers in Figure 6.54 are as follows (enzymes unique to plants in green):

1 - Phosphoglycerate kinase
2 - G3PDH
3 - Triosephosphate Isomerase
4 - Aldolase
5 - Fructose 1,6 bisphosphatase
6 - Transketolase
7 - Phosphopentose Epimerase
8 - Phosphoribulokinase
9 - Sedoheptulose 1,7 bisphosphatase
10 - Phosphopentose Isomerase

Reactions

The resynthesis phase begins with conversion of the 3-PG molecules into GLYAL3P (there are actually 10 GLYAL3P molecules involved in resynthesis, as noted above, but we are omitting numbers to try to help students to see the bigger picture. Suffice it to say that there are sufficient quantities of all of the molecules to complete the reactions described). Some GLYAL3P is converted to DHAP by triose phosphate isomerase. Some DHAPs are converted (via gluconeogenesis) to F6P (one phosphate is lost for each F6P).

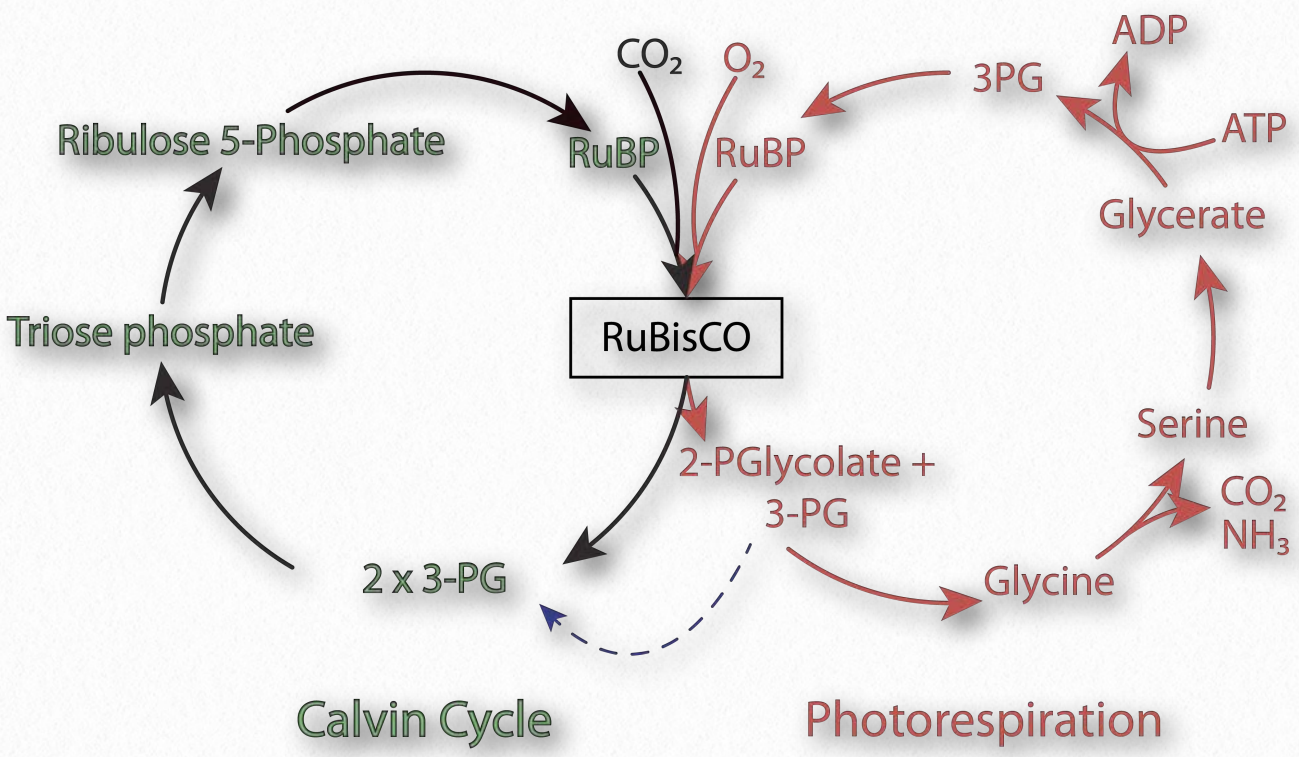

Figure 6.55 - Use of CO_2 (Calvin cycle) vs. O_2 (photorespiration) by RUBISCO.

Image by Pehr Jacobson

Two carbons from F6P are given to GLYAL3P to create E-4P and Xu-5P (reversal of PPP reaction). E-4P combines with DHAP to form sedoheptulose-1,7 bisphosphate (S1,7BP). The phosphate at position #1 is

cleaved by sedoheptulose-1,7 bisphosphatase to yield S-7-P. Transketolase (another PPP enzyme) catalyzes transfer to two carbons from S-7-P to GLYAL3P to yield Xu-5P and R5P.

YouTube Lectures by Kevin HERE & HERE

Phosphopentose isomerase catalyzes conversion of R5P to Ru5P and phosphopentose epimerase similarly converts Xu-5P to Ru5P. Finally, phosphoribulokinase transfers a phosphate to Ru5P (from ATP) to yield Ru1,5BP.

Photorespiration

In the Calvin cycle of photosynthesis, the enzyme ribulose-1,5-bisphosphate carboxylase (RUBISCO) catalyzes the addition of carbon dioxide to ribulose-1,5-bisphosphate (Ru1,5BP) to create two molecules of 3-phosphoglycerate. Molecular oxygen (O_2), however, competes with CO_2 for this enzyme, so about 25% of the time, the molecule that gets added is not CO_2, but rather O_2 (Figure 6.55). When this happens, the following reaction occurs

$$\text{Ru1,5BP} + O_2 \rightleftharpoons \text{Phosphoglycolate} + \text{3-phosphoglycerate} + 2H^+$$

This is the first step in the process known as photorespiration. The process of photorespiration is inefficient relative to the carboxylation of Ru1,5BP. Phosphoglycolate is converted to glyoxylate in the glyoxysome and then transamination of that yields glycine. Two glycines can combine in a complicated coupled set of reactions in the mitochondrion shown next.

$$2\ \text{Glycine} + NAD^+ + H_2O \rightleftharpoons \text{Serine} + CO_2 + NH_3 + NADH + H^+$$

Figure 6.56 - Maize - a C_4 plant

Deamination and reduction of serine yields pyruvate, which can be then be converted back to 3-phosphoglycerate. The end point of oxygenation of Ru1,5BP is the same as the carboxylation of Ru1,5BP reactions, but there are significant energy costs associated with it, making the process less efficient.

C_4 plants

The Calvin cycle is the means by which plants assimilate carbon dioxide from the atmosphere, ultimately into glucose. Plants use two general strategies for doing so. The first is employed by plants called C_3 plants (most plants) and it simply involves the pathway described above. They are called C_3 plants because the first stable intermediate after absorbing carbon dioxide contains three carbons - 3-phosphoglycerate. Another class of plants, called C_4 plants (Figure 6.56) employ a novel strategy for concentrating the

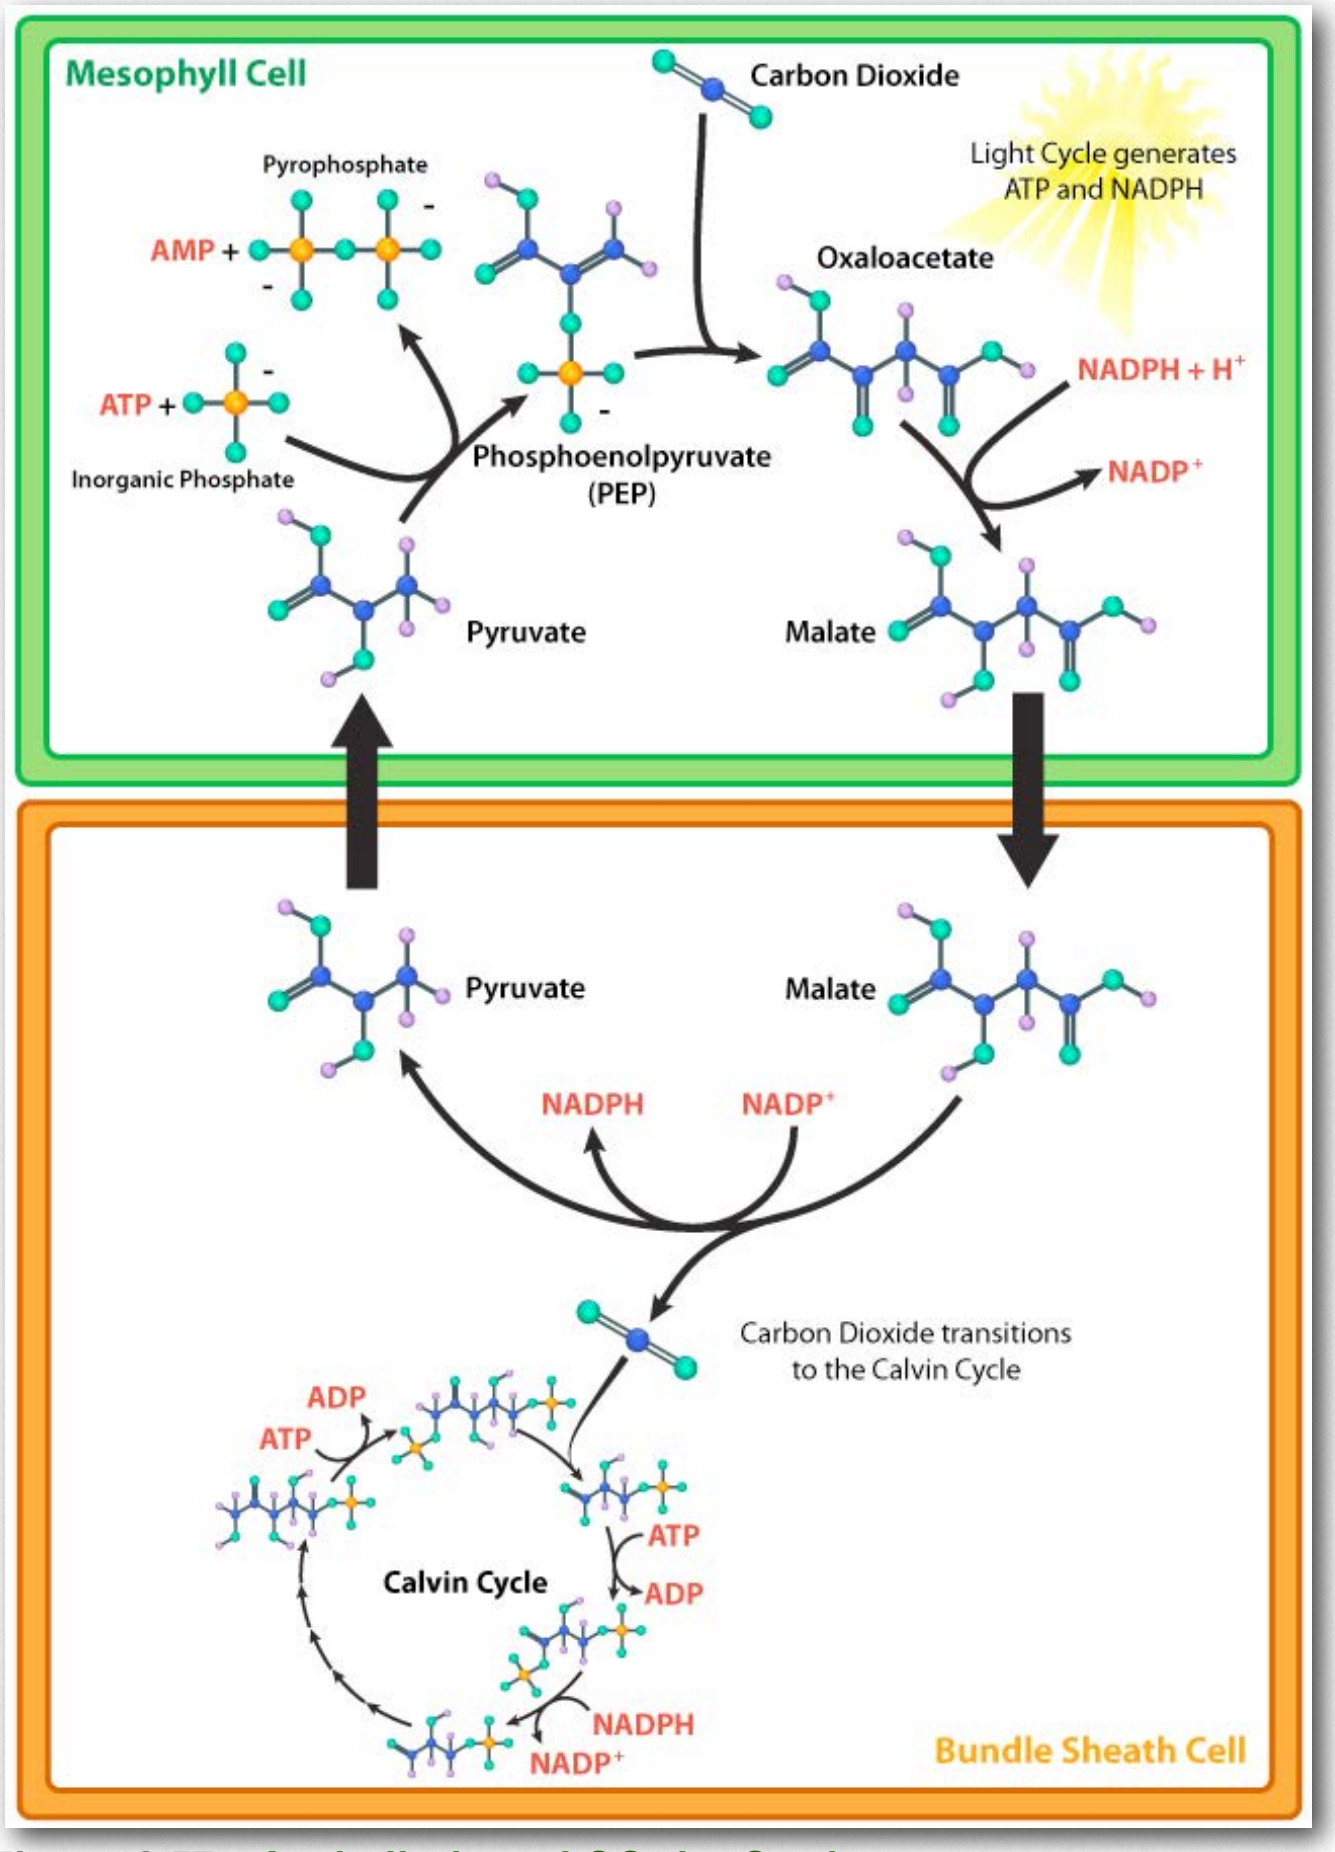

Figure 6.57 - Assimilation of CO_2 by C_4 plants

Image by Aleia Kim

CO_2 prior to assimilation. C_4 plants are generally found in hot, dry environments where conditions would otherwise favor the wasteful photorespiration reactions of RUBISCO and loss of water.

Capture by PEP

In C_4 plants, carbon dioxide is captured in special mesophyll cells first by phosphoenolpyruvate (PEP) to make oxaloacetate (contains four carbons and gives the C_4 plants their name - Figure 6.57). The oxaloacetate is converted to malate and transported into bundle sheath cells where the carbon dioxide is released and captured by Ru1,5BP, as in C_3 plants. The Calvin cycle proceeds from there. The advantage of the C_4 plant scheme is that it allows concentration of carbon dioxide while minimizing loss of water and photorespiration.

Peptidoglycan synthesis

Bacterial cell walls contain a layer of protection known as the peptidoglycan layer. Assembly of the layer begins in the cytoplasm. Steps in the process follow

1. Donation of an amine from glutamine to fructose-6-phosphate and isomerization to make glucosamine-6-phosphate.

2. Donation of an acetyl group from acetyl-CoA to make N-acetyl-glucosamine-6-phosphate

3. Isomerization of N-acetyl-glucosamine-6-phosphate makes N-acetyl-glucosamine-1-phosphate

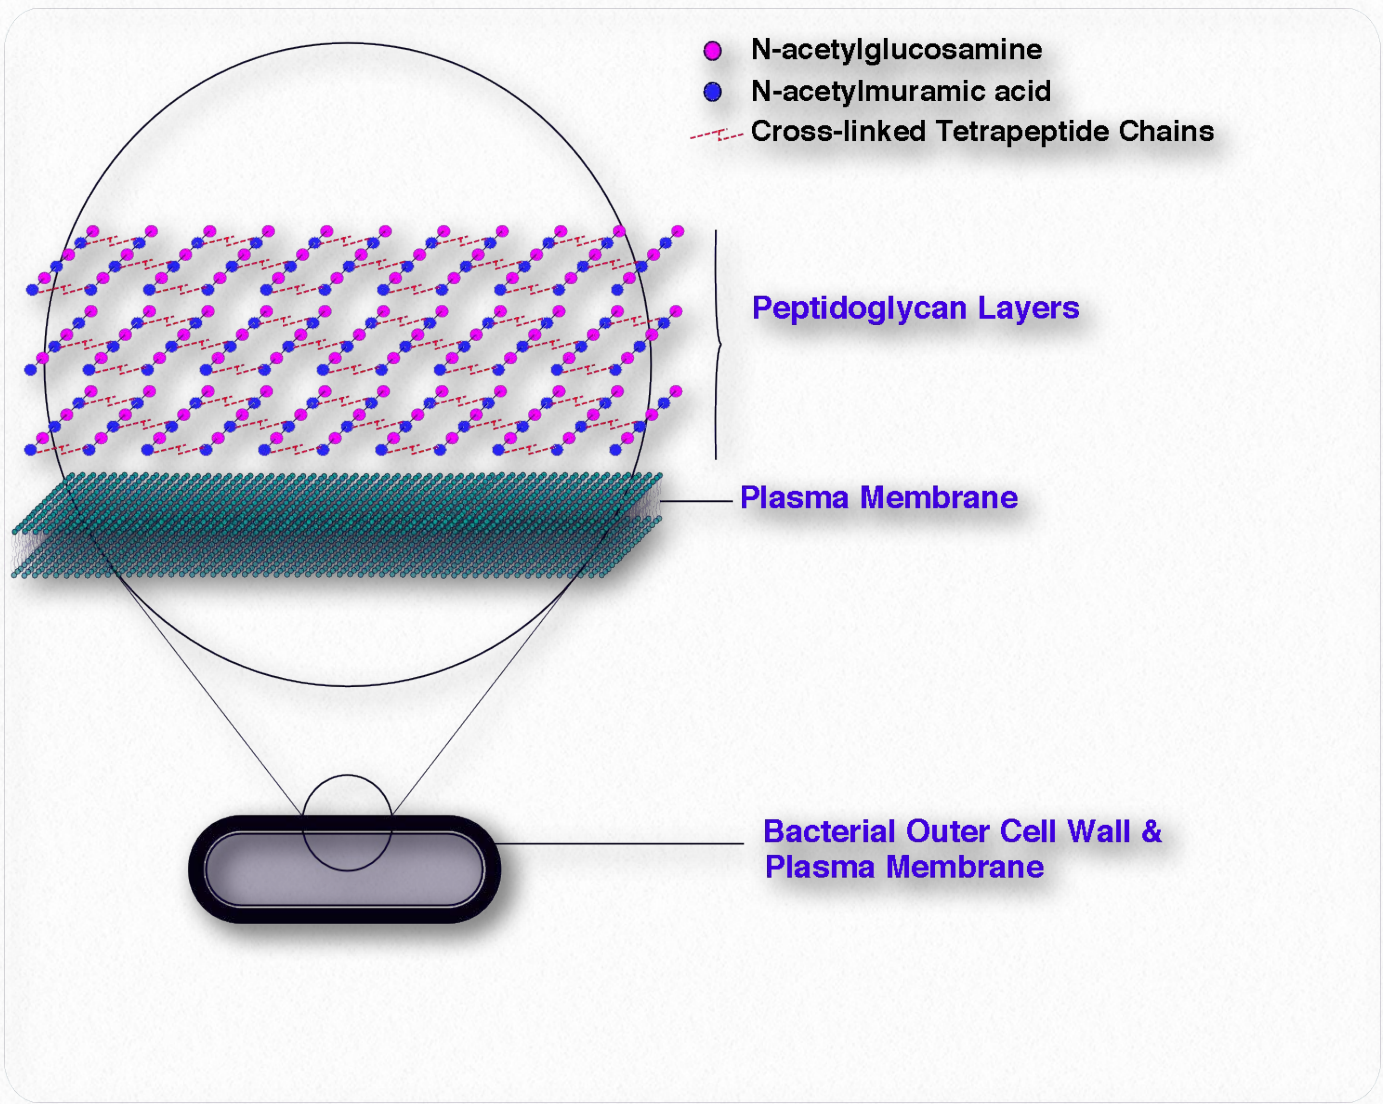

Figure 6.58 - Peptidoglycan layer in a bacterial outer cell wall
Wikipedia

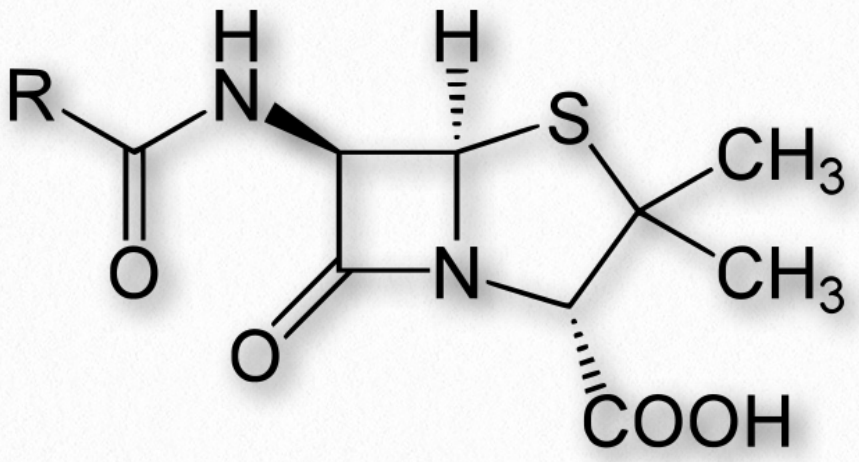

Figure 6.59 - Penicillin

4. UTP combines with N-acetyl-glucosamine-1-phosphate to make UDP-N-acetyl-glucosamine-1-phosphate

5. Addition of PEP and electrons from NADPH yields UDP-N-acetylmuramic acid

6. A pentapeptide or tetrapeptide chain is attached to the UDP-N-acetylmuramic acid. The sequence varies a bit between species, but commonly is L-Ala - D-Glu - L-Lys - D-Ala - D-Ala

7. Dolichol phosphate replaces UMP on the UDP-N-acetylmuramic acid-pentapeptide.

8. UDP-N-acetyl-glucosamine donates a glucose to the N-acetylmuramic acid part of the Dolichol-PP-N-acetylmuramic acid-pentapeptide

9. A pentapeptide chain of glycines (penta-glycine) is linked to lysine of the pentapeptide chain to create a Dolichol-PP-N-acetylmuramic acid-N-acetylglucosamine-decapeptide. The pentaglycine serves as cross links in the overall structure.

10. Dolichol-PP is removed to yield N-acetylmuramic acid-N-acetylglucosamine-decapeptide

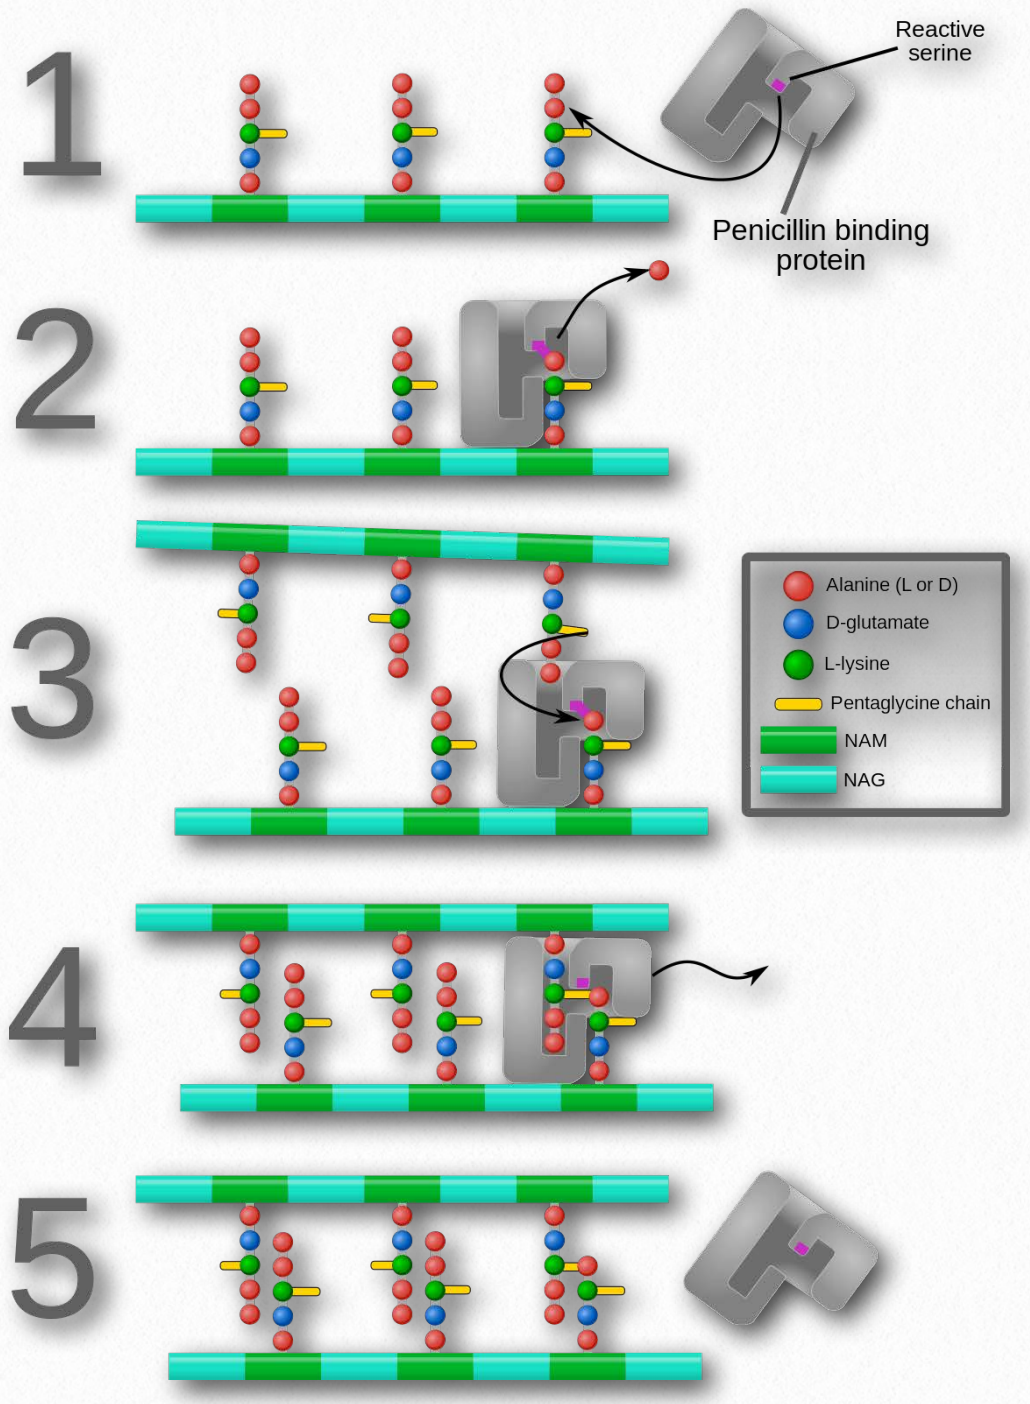

Figure 6.60 - Catalytic activity of DD-transpeptidase

Wikipedia

11. This last group is added to the growing peptidoglycan network by joining the pentaglycine of one chain to the tetrapeptide/pentapeptide of another.

YouTube Lectures by Kevin HERE & HERE

The enzyme catalyzing the addition of the N-acetylmuramic acid-N-acetylglucosamine-decapeptide to the network in the last step is DD-transpeptidase. This is the cellular enzyme targeted by penicillin and its derivatives. One reason penicillin is so effective is because synthesis of a peptidoglycan cell wall for a single bacterium requires millions of cycles of reactions above. Even slowing down the process can have a major effect on bacterial growth. On the flip side, resistance to penicillin and derivatives arises as a result of mutations in one enzyme - the transpeptidase.

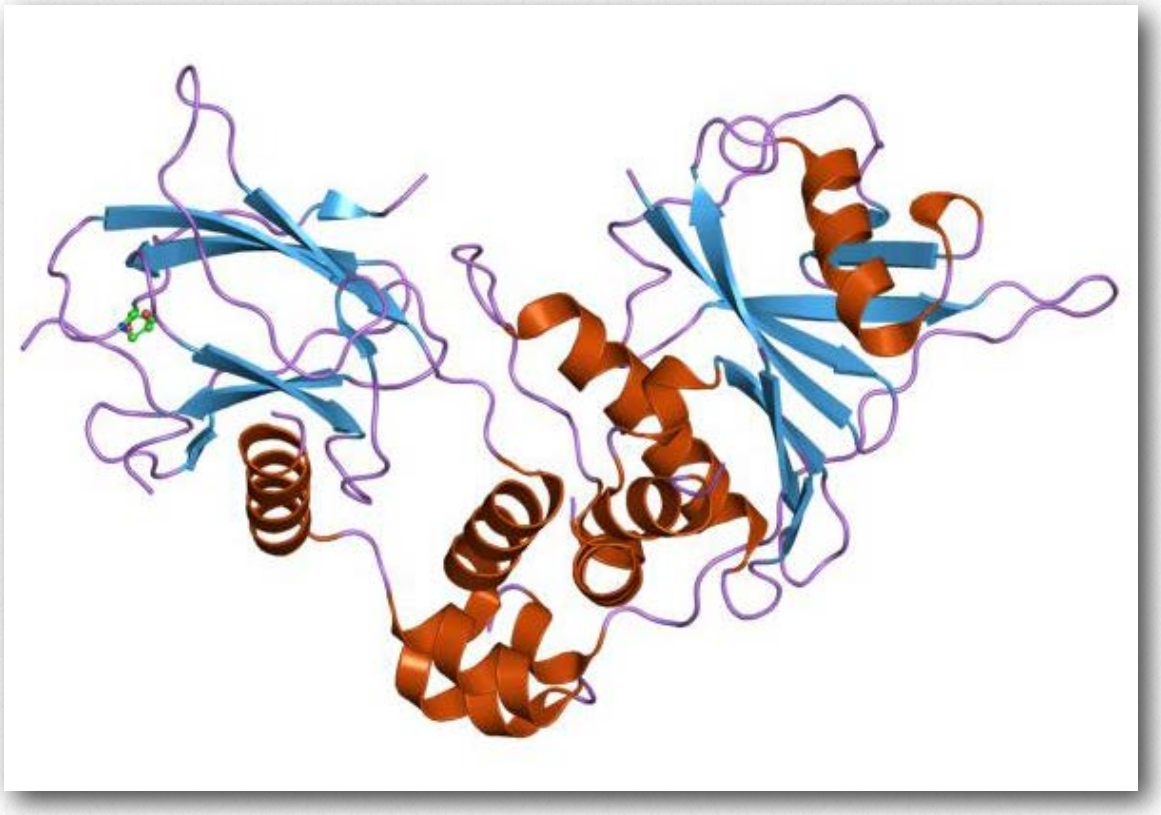

Figure 6.61 - Hypoxia inducible factor

Metabolons

At this point, it is appropriate to bring up the concept of metabolons. Metabolons are cellular complexes containing multiple enzymes of a metabolic pathway that appear to be arranged so that the product of one enzymatic reaction is passed directly as substrate to the enzyme that catalyzes the next reaction in the metabolic pathway. The structural complexes are temporary and are held together by non-covalent forces.

Metabolons appear to offer advantages of reducing the amount of water needed to hydrate enzymes. Activity of enzymes in the complex is increased. Most of the basic metabolic pathways are thought to use metabolons. They include glycolysis, the citric acid cycle, nucleotide metabolism, glycogen synthesis, steroid synthesis, DNA synthesis, RNA synthesis, the urea cycle, and the process of electron transport.

Hypoxia

Hypoxia occurs when the body or a region of it has an insufficient oxygen supply. Varia-

tions in arterial oxygen concentrations in normal physiology may lead to hypoxia, for example, during hypoventilation training or strenuous physical exercise. Generalized hypoxia may appear in healthy people when at high altitudes. Cancer cells, which may be undergoing faster respiration than surrounding tissues may also tend to be hypoxic. Hypoxia is an important consideration for sugar metabolism due to the ability of cells to change their sugar metabolism (fermentation) when these conditions exist.

The body's response to hypoxia is to produce Hypoxia-Inducible Factors (HIFs), which are transcription factors that induce expression of genes to help cells adapt to the hypoxic conditions. Many of the genes activated by HIFs are enzymes of glycolysis and GLUTs (glucose transport proteins). The combination of these gene products allows cells to 1) import more glucose and 2) metabolize it more rapidly when it arrives. This is to be expected because anaerobic sugar metabolism is only about 1/15th as efficient as aerobic metabolism. Consequently, it requires much more sugar metabolism to keep the cancer cells alive. A recently discovered protein called cytoglobin is believed to help assist in hypoxia by facilitating transfer of oxygen from arteries to the brain.

Covalent modification

HIFs are regulated partly by an interesting covalent modification. When oxygen concentration is high, the enzyme prolyl hydroxylase will hydroxylate proline residues in HIFs. This stimulates the protein degradation system (proteasome) to degrade them. When oxygen concentration is low, the hydroxylation occurs to a much lower extent (or does not occur at all), reducing/stopping degradation of HIFs and allowing them to activate genes. In this way, the concentration of HIFs is kept high under low oxygen concentration (to activate HIF genes) and low under high oxygen concentrations (to stop synthesis of HIF genes).

Gluconeogenesis

To the tune of "*Supercalifragelisticexpialidocious*"
Metabolic Melodies Website HERE

When cells have lots of ATP and NADH too
They strive to store this energy as sugar yes they do
Inside of mitochondria they start with pyruvate
(*slow*) Carboxylating it to make oxaloacetate

Oh gluconeogenesis is so exhilarating
Memorizing it can really be exasperating
Liver cells require it so there's no need for debating
Gluconeogenesis is so exhilarating

Oh, glucose, glucose come to be
Glucose, glucose come to be

Oxaloacetate has got to turn to PEP
Employing energy that comes from breaking GTP
From there it goes to make a couple phosphoglycerates
(*slow*) Exploiting ee-nolase and mutase' catalytic traits

Oh gluconeogenesis is liver's specialty
Producing sugar for the body most admirably
Six ATPs per glucose is the needed energy*
Gluconeogenesis is liver's specialty

Oh glucose, glucose joy to me
Glucose, glucose joy to me

Converting phosphoglycerate to 1,3BPG
Requires a phosphate that includes A-T-P energy
Reduction with electrons gives us all an N-A-D
(*slow*) And G3P's isomerized to make D-H-A-P

Oh gluconeogenesis is anabolic bliss
Reversing seven mechanisms of glycolysis
To do well on the final students have to learn all this
Gluconeogenesis is anabolic bliss

Oh, glucose, glucose factory
Glucose, glucose factory

The aldolase reaction puts together pieces so
A fructose molecule is made with two phosphates in tow
And one of these gets cleaved off by a fructose phosphatase
(*slow*) Unless F2,6BP's acting blocking path-a-ways

Oh gluconeogenesis a pathway to revere
That makes a ton of glucose when it kicks into high gear
The cell's a masterminding metabolic engineer
Gluconeogenesis a pathway to revere

Oh glucose, glucose jubilee
Glucose, glucose jubilee

From F6P to G6P, that is the final phase
The enzyme catalyzing it is an isomerase
Then G6P drops phosphate and a glucose it becomes
(*slow*) Inside the tiny endoplasmic-al reticulums

Oh gluconeogenesis is not so very hard
I know that on the final we will not be caught off guard
Cuz our professor lets us use a filled out index card
Gluconeogenesis is not so very hard

*Actually, you need two NADHs too, but that wouldn't fit the rhyme :-)

Recording by Tim Karplus
Lyrics by Kevin Ahern

The Sound of Glucose

To the tune of "*A Few of My Favorite Things*"

Metabolic Melodies Website HERE

Aldehyde sugars are always aldoses and
If there's a ketone we call them ketoses
Some will form structures in circular rings
Saccharides do some incredible things

Onto a glucose we add a 'P' to it
ATP energy ought to renew it
Quick rearranging creates F6P
Without requiring input energy

At a high rate
Add a phosphate
With PFK
F1,6BP is made up this way
So we can run and play

Aldolase breaks it and then it releases
DHAP and a few G-3-Pieces
These both turn in to 1,3 BPG
Adding electrons onto NAD

Phosphate plus ADP makes ATP
While giving cells what they need - en-er-gy
Making triphosphate's a situa-shun
Of substrate level phosphoryla-shun

3-B-P-G
2-B-P-G
Lose a water
PEP gets a high energy state
Just to make py-ru-vate

So all the glucose gets broken and bent
If there's no oxygen cells must ferment
Pyruvate / lactate our cells hit the wall
Some lucky yeast get to make ethanol

This is the end of your glucose's song
Unless you goof up and get it all wrong
Break it, don't make it to yield ATP
You'll save your cells from fu-til-i-ty

Lyrics by Kevin Ahern

In My Liver

To the tune of "*And I Love Her*"

Metabolic Melodies Website HERE

If I am missing meals
On busy days
That's when my body steals
Glucose away
From my liver

It starts with glucagon
When I'm weak kneed
The hormone acts to spawn
New energy
In my liver

Bridge
The signaling
Acts rapidly
c-A-M-P's
Fire up kinase

Phosphorylase then gets
Re-activated
So glycogen begets
Glucose phosphated
In my liver

Instrumental

Then in the last step here
A phosphatase
Makes phosphate disappear
With no delays
In my liver

Recording by David Simmons
Lyrics by Kevin Ahern

It Flows, Then My Glycogen Grows

To the tune of "*Love Grows Where My Rosemary Goes*"

Metabolic Melodies Website HERE

When I'm exercisin'
It is not surprisin'
That insulin is absentee
But when it flows
Then my glycogen grows
And nobody knows like me

During all the flexing
It may seem perplexing
The liver's working easily
Turning lactate
Into glucose is great
And it is first rate to me

There's something about an insulin high
That is hard to deny
And I shouldn't suppress, Yes!
It gets the sugar into the cells
More than anything else
Easing cellular stress

Epinephrine's crazy
Absent when I'm lazy
Made when I am scared you see
Then when it flows, all my glycogen goes
And G1P grows in me

My hormones they are treating my fine
Working all of the time
Don't know what I would do - ooh!
Activating protein kinase
So my phosphorylase
Does a glycogen chew

There is such a balance
Thanks to hormones' talents
Managing the energy
Making glucose from my head to my toes
So evenly flow in me

It keeps working every night and day
And nobody knows like me
I just love it but never think of it
And nobody knows like me

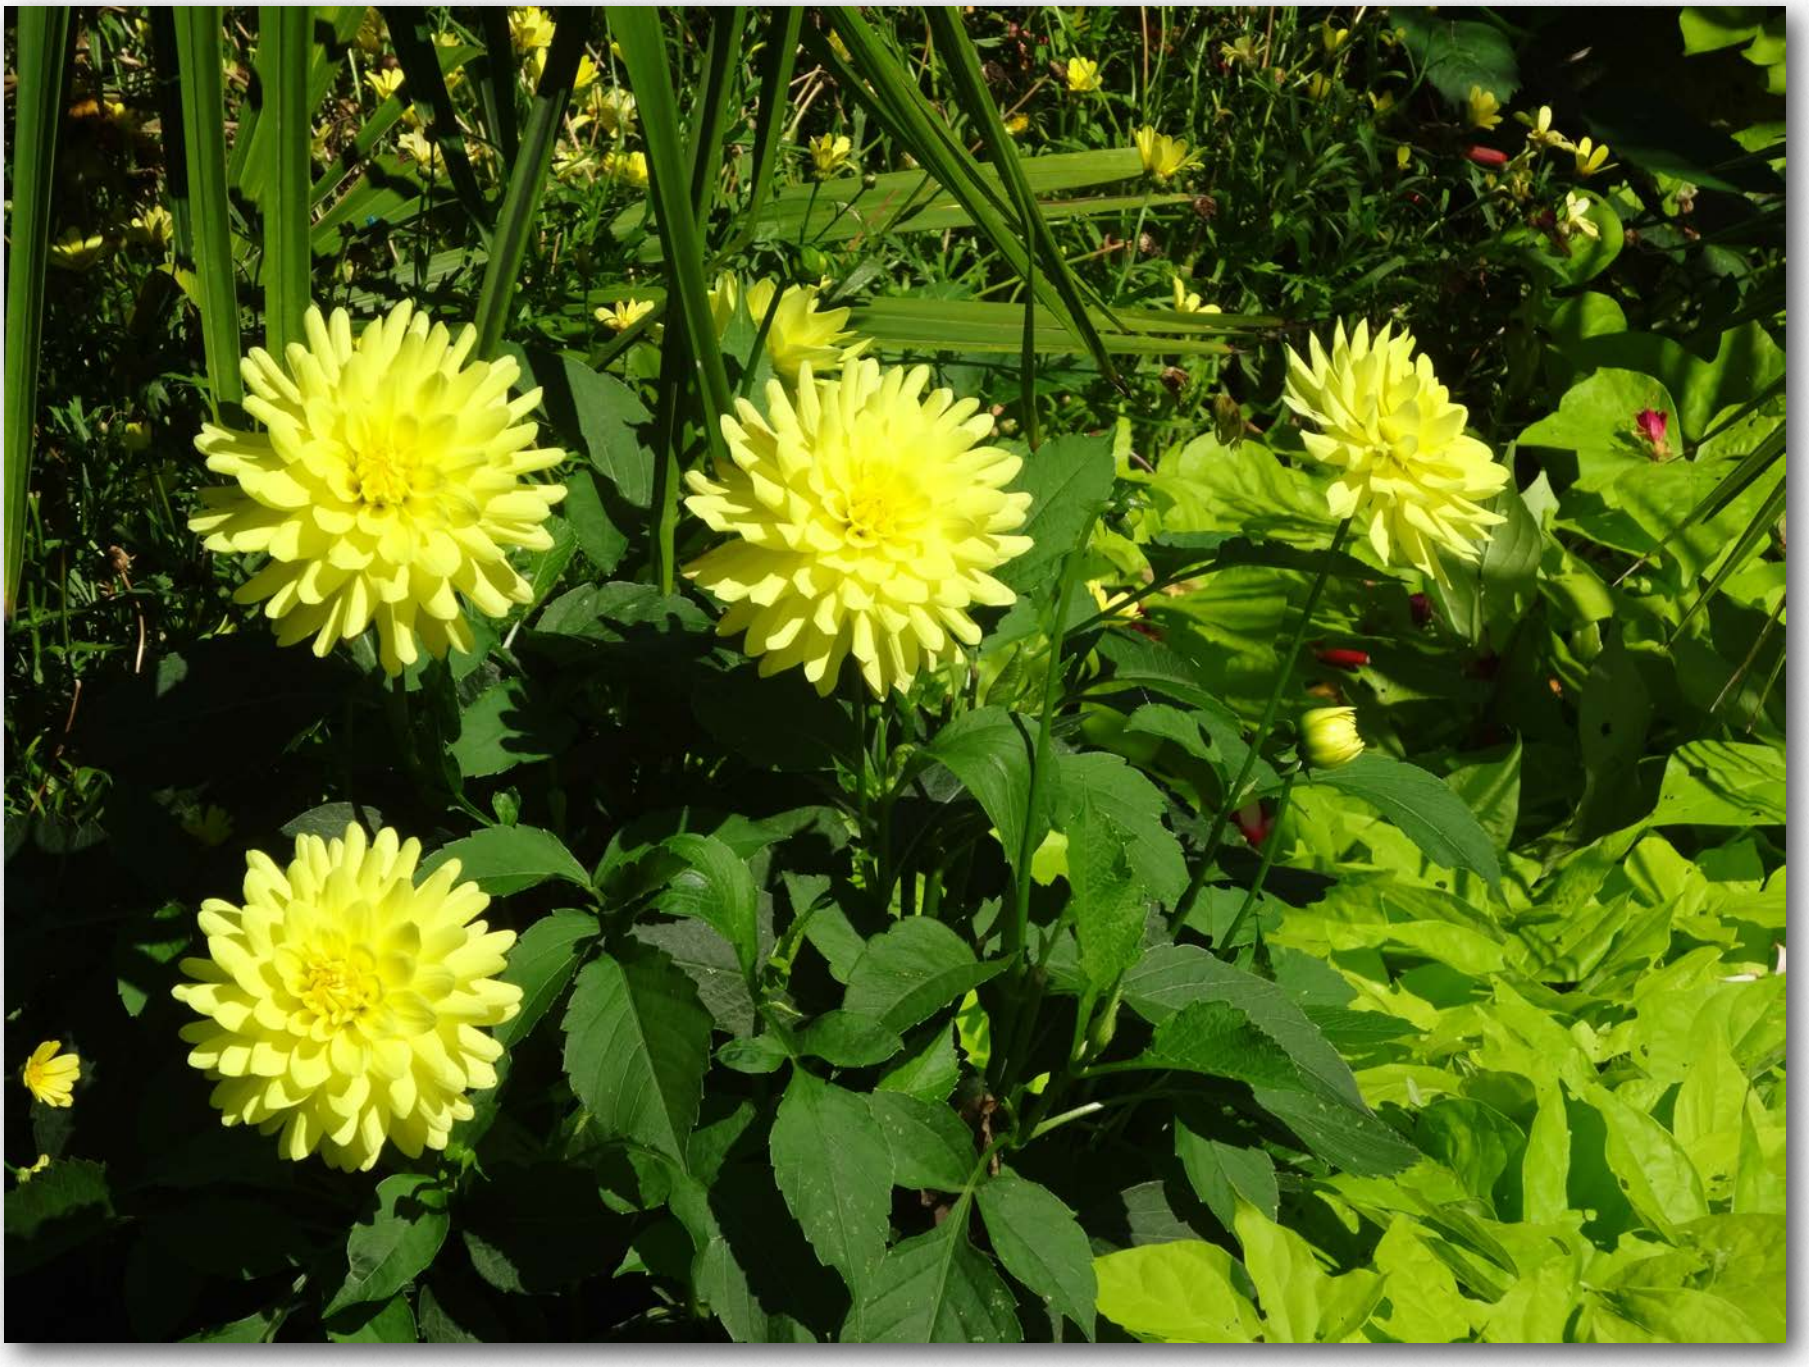
Metabolism: Citric Acid Cycle & Related Pathways



Citric acid cycle

The primary catabolic pathway in the body is the citric acid cycle because it is here that oxidation to carbon dioxide occurs for breakdown products of the cell's major building blocks - sugars, fatty acids, and amino acids. The pathway is cyclic (Figure 6.63) and thus, doesn't really have a starting or ending point. All of the reactions occur in mitochondria, though one enzyme is embedded in the organelle's inner membrane. As needs change, cells may use a subset of the reactions of the cycle to produce a desired molecule rather than to run the entire cycle (see HERE).

YouTube Lectures by Kevin HERE & HERE

Acetyl-CoA

The molecule "feeding" the citric acid cycle is acetyl-CoA and it can be obtained from pyruvate (from glycolysis), from fatty acid β-oxidation, from ketone bodies, and from amino acid metabolism. Molecules from other pathways feeding into the citric acid cycle for catabolism make the

citric acid cycle 'cataplerotic'. It is worth noting that acetyl-CoA has very different fates, depending on the cell's energy status/needs (see HERE). The description below describes oxidation (catabolism) in citric acid cycle.

Anabolically, acetyl-CoA is also very important for providing building blocks for synthesis of fatty acids, ketone bodies, amino acids and cholesterol. Other citric acid cycle intermediates are also important in amino acid metabolism (Figure 6.63), heme synthesis, electron shuttling, and shuttling of acetyl-CoA across the mitochondrial inner membrane. The ability of the citric acid cycle to supply intermediates to pathways gives rise to the term 'anaplerotic.' It means 'to fill up.' Before discussing the citric acid cycle, it is important to first describe one important enzyme complex that is a major source of acetyl-CoA for the cycle.

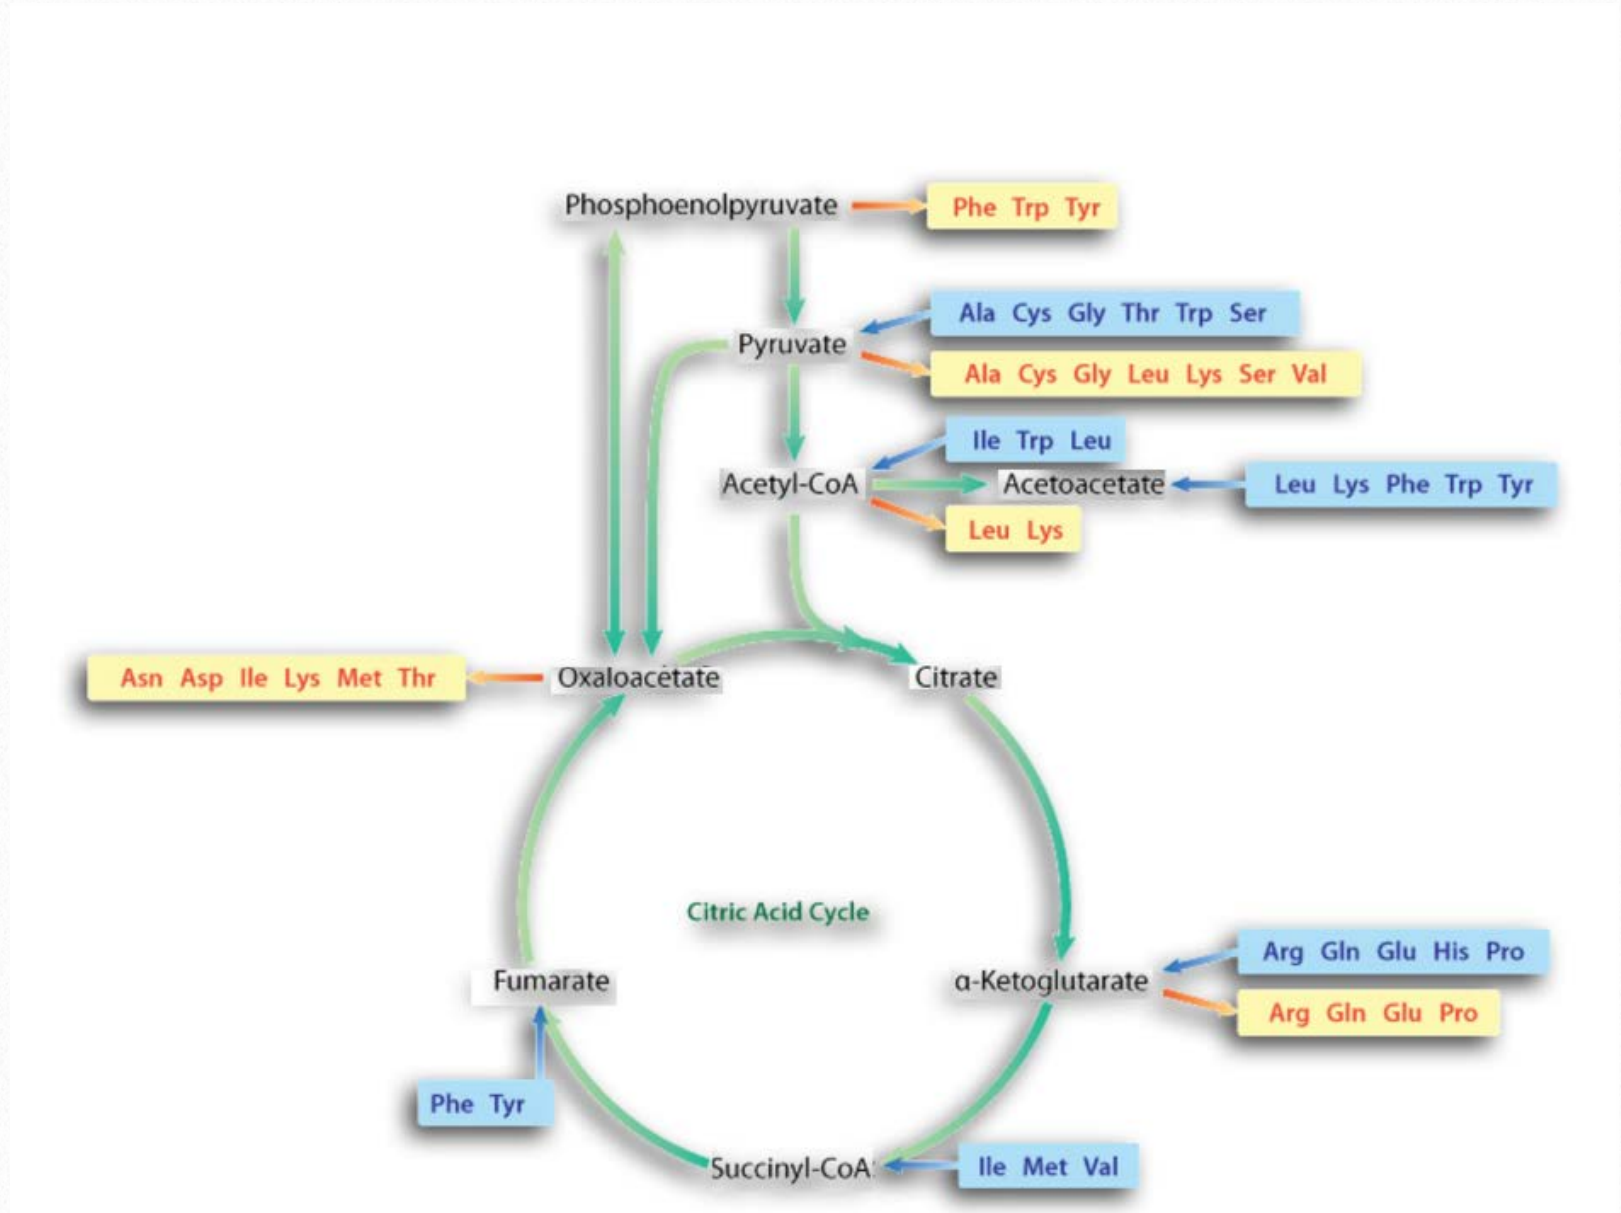


Figure 6.63 - Amino acid metabolism and the citric acid cycle. Amino acids boxed in yellow are made from the indicated intermediate. Amino acids in blue are made into the intermediate in catabolism.

Image by Aleia Kim

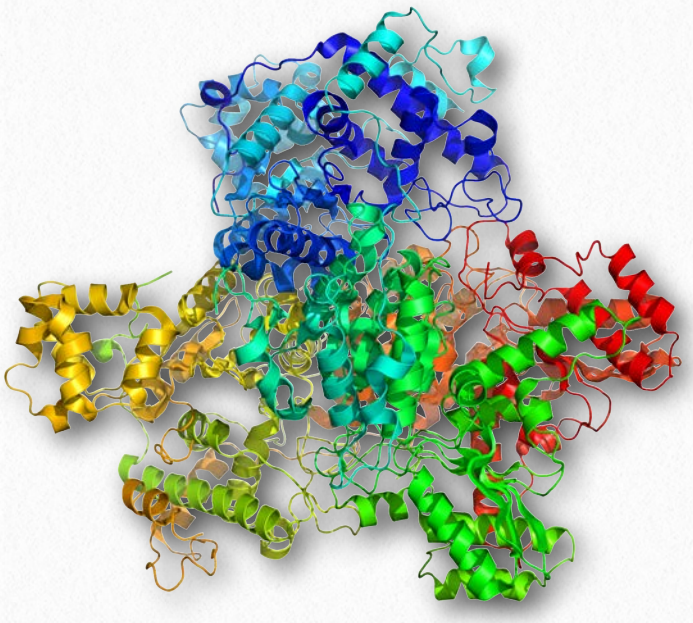

Figure 6.64 - E1 Subunit of Pyruvate Dehydrogenase

Wikipedia

Pyruvate decarboxylation

The pyruvate dehydrogenase enzyme is a complex of multiple copies of three subunits that catalyze the decarboxylation of pyruvate to form acetyl-CoA. The reaction mechanism requires use of five coenzymes. Pyruvate dehydrogenase is an enormous complex in mammals with a size five times greater than ribosomes.

Subunits

The three subunits are designated by E_1, E_2, and E_3. E_2 is also referred to as dihydrolipoamide acetyltransferase and E_3 is more precisely called dihydrolipoyl dehydroge-

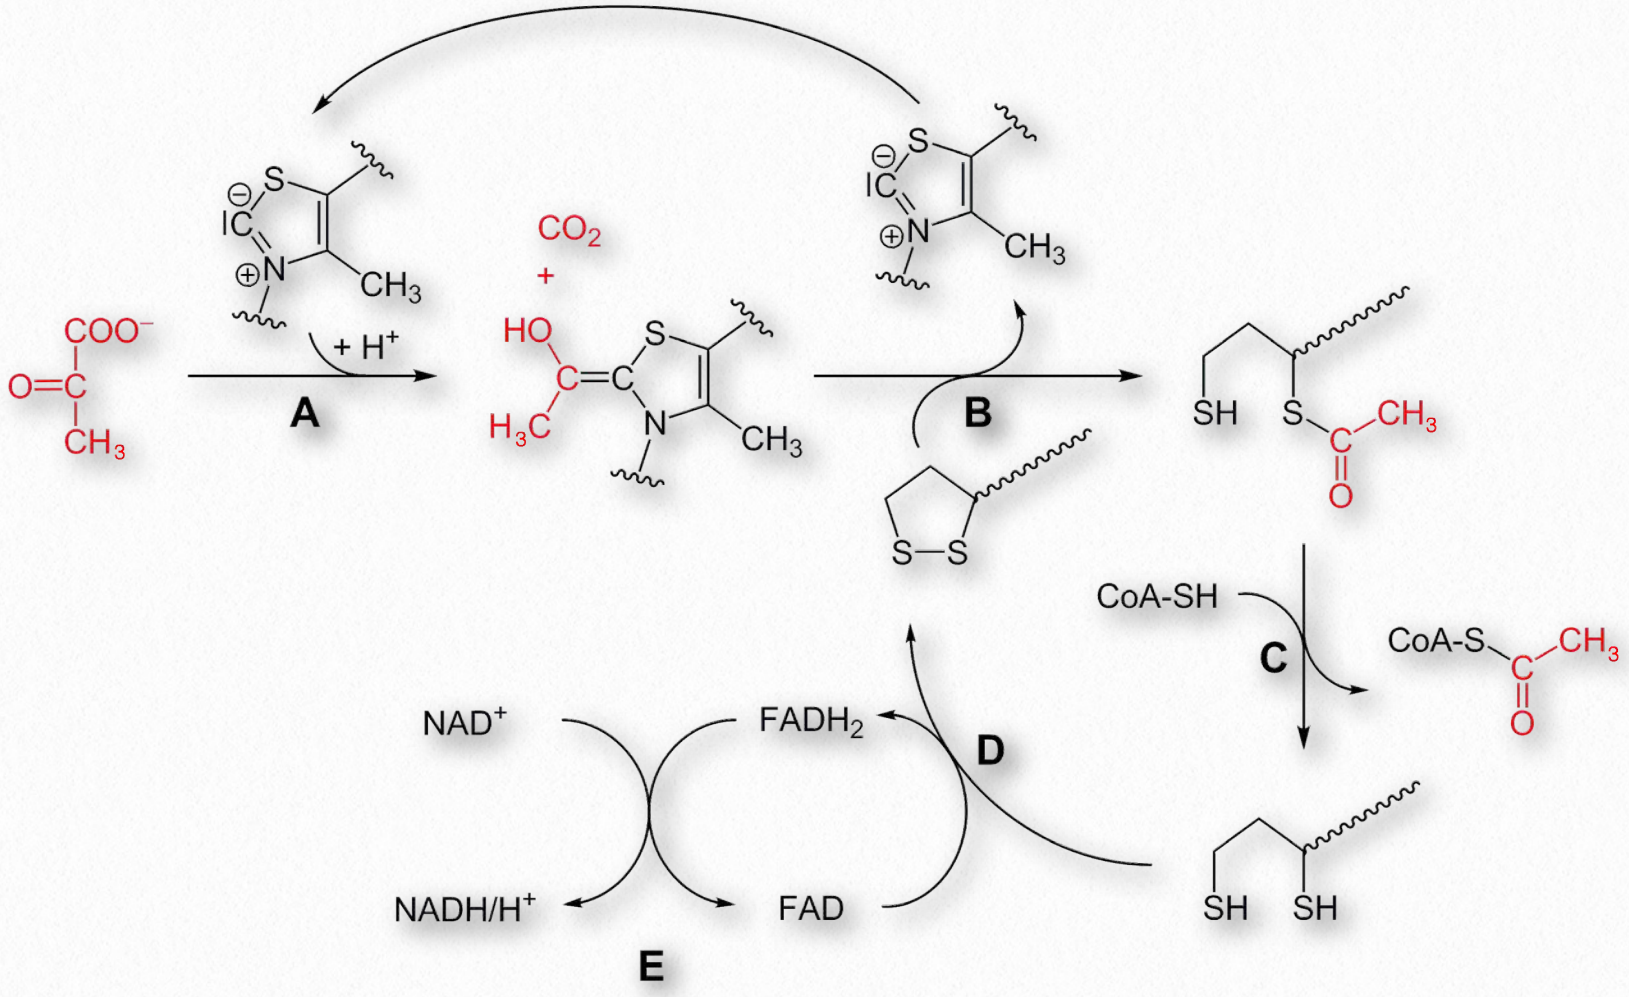

Figure 6.65 - Mechanism of action of pyruvate decarboxylation and oxidation by pyruvate dehydrogenase.

nase. Confusion arises with the name for E_1. Some call it pyruvate dehydrogenase and others give it the name pyruvate decarboxylase. We will use pyruvate decarboxylase solely to refer to E_1 and pyruvate dehydrogenase only to refer to the complex of E_1, E_2, and E_3.

The catalytic actions of pyruvate dehydrogenase can be broken down into three steps, each taking place on one of the subunits. The steps, sequentially occurring on E_1, E_2, and E_3, are 1) decarboxylation of pyruvate; 2) oxidation of the decarboxylated product; and 3) transfer of electrons to ultimately form NADH (Figure 6.65).

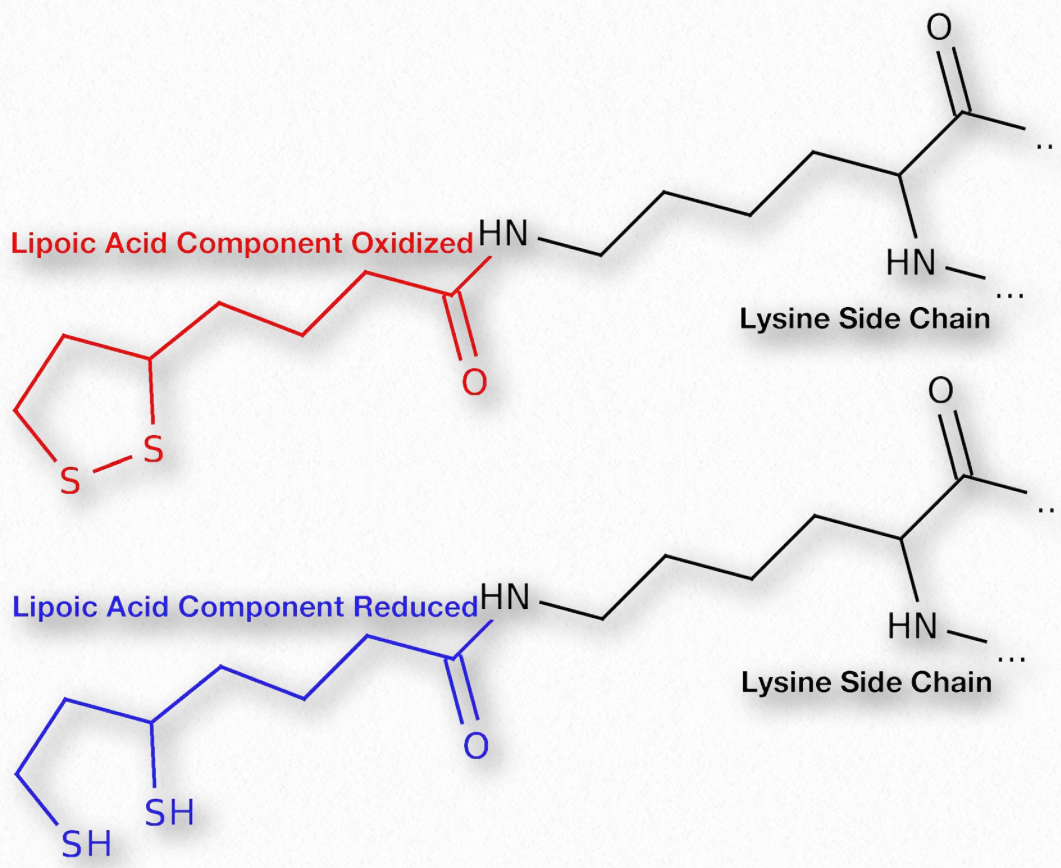

Figure 6.66 - Oxidized and reduced structures of lipoamide (lipoic acid linked to lysine)

Catalysis

The catalytic process begins after binding of the pyruvate substrate with activation of the thiamine pyrophosphate coenzyme through formation of an ylide intermediate. The nucleophilic carbanion of the ylide attacks the electrophilic ketone carbon on the pyruvate, releasing carbon dioxide and creating an enol that loses a proton on the carbon to become a 1,3 dipole that includes the positively charged nitrogen of the thiamine. The reaction (step A in Figure 6.65) is a non-oxidative decarboxylation. Oxidation of the two carbon hydroxyethyl unit occurs in the transfer to the lipoamide.

Reductive acetylation

Reductive acetylation occurs next (Step B) as the 2-carbon hydroxyethyl unit is transferred to lipoamide on E_2. (Lipoamide is the name for a molecule of lipoic acid covalently attached to a lysine side chain in the E_2 subunit). In prokaryotes in the absence of oxygen, the hydroxyethyl group is not passed to lipoamide, but instead is released as free acetaldehyde , which can accept electrons from NADH (catalyzed by alcohol dehydrogenase) and become ethanol in the process of fermentation. In the presence of oxygen in almost all aerobic organ-

isms, the process continues with transfer of the hydroxyethyl unit to E_2 and continuation of the cycle below.

YouTube Lectures by Kevin HERE & HERE

Oxidation step

Transfer of the hydroxyethyl group from E_1 to the lipoamide coenzyme in E_2 is an oxidation, with transfer of electrons from the hydroxyethyl group to lipoamide's disulfide (reducing it) and formation on the lipoamide of an acetyl-thioester (oxidizing it).

The acetyl group is then transferred from lipoamide to coenzyme A in E_2 (Step C in Figure 6.65), forming acetyl-CoA, which is released and leaving reduced sulfhydryls on the lipoamide. In order for the enzyme to return to its original state, the disulfide bond on lipoamide must be re-formed. This occurs with transfer of electrons from reduced lipoamide to an FAD covalently bound to E_3 (Step D). This reduces FAD to $FADH_2$.

Formation of NADH

In the last step in the process, electrons from $FADH_2$ are transferred to external NAD^+, forming NADH (Step E) and completing the overall cycle. Then enzyme can then begin another catalytic round by binding to a pyruvate.

Pyruvate dehydrogenase regulation

Pyruvate deyhdrogenase is regulated both allosterically and by covalent modification - phosphorylation / dephosphorylation.

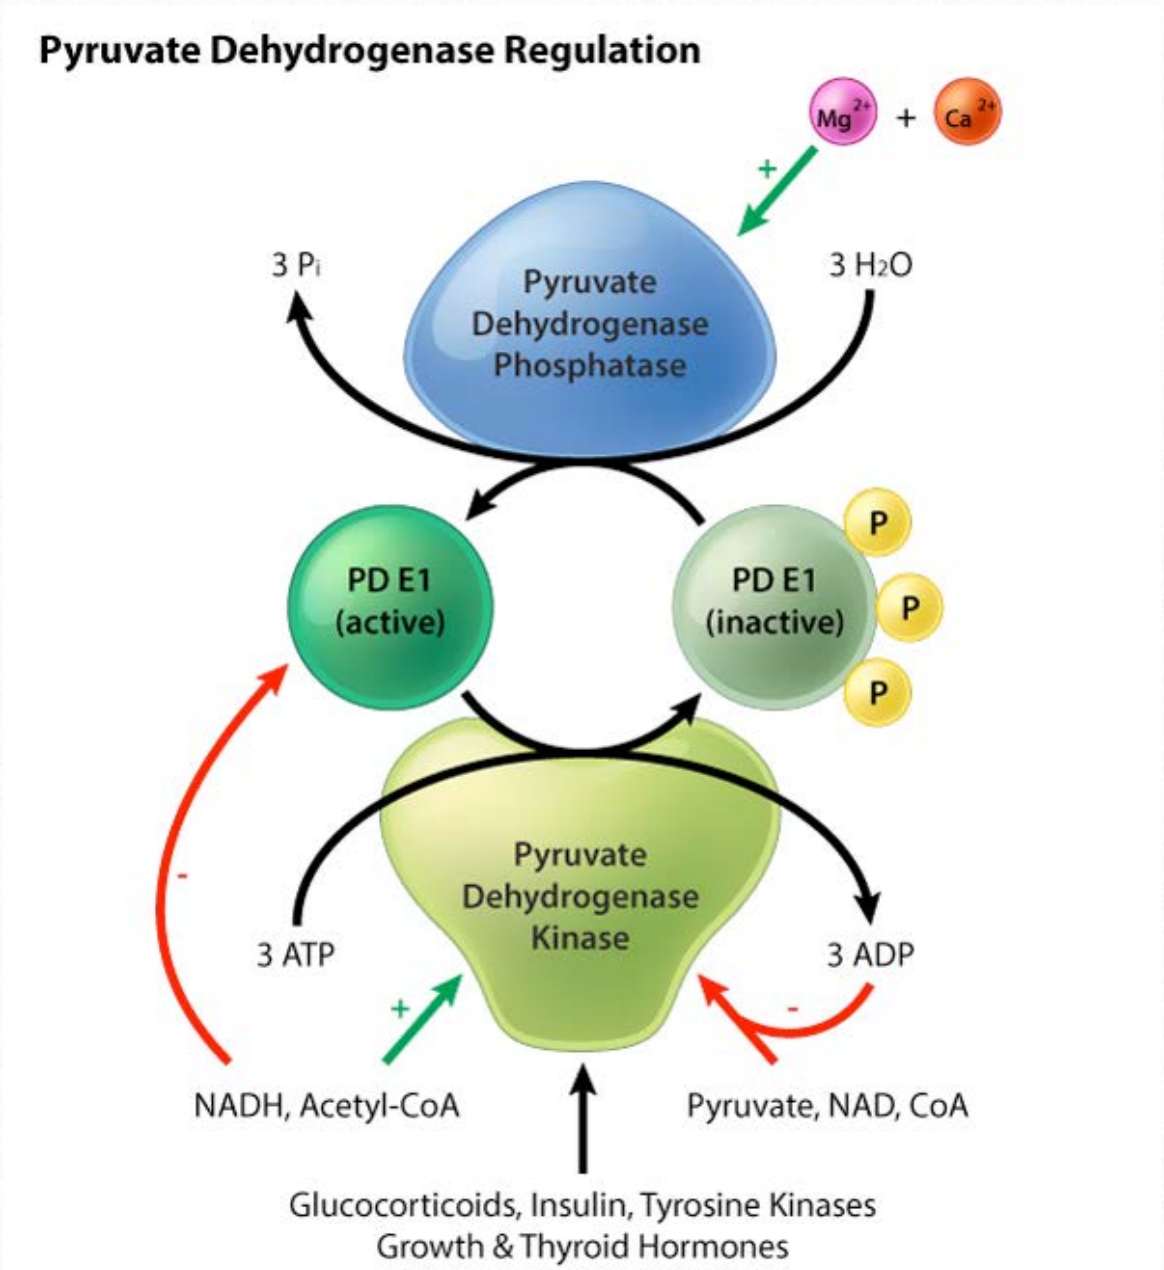

Figure 6.67 - Regulation scheme for pyruvate dehydrogenase (PD)

Image by Aleia Kim

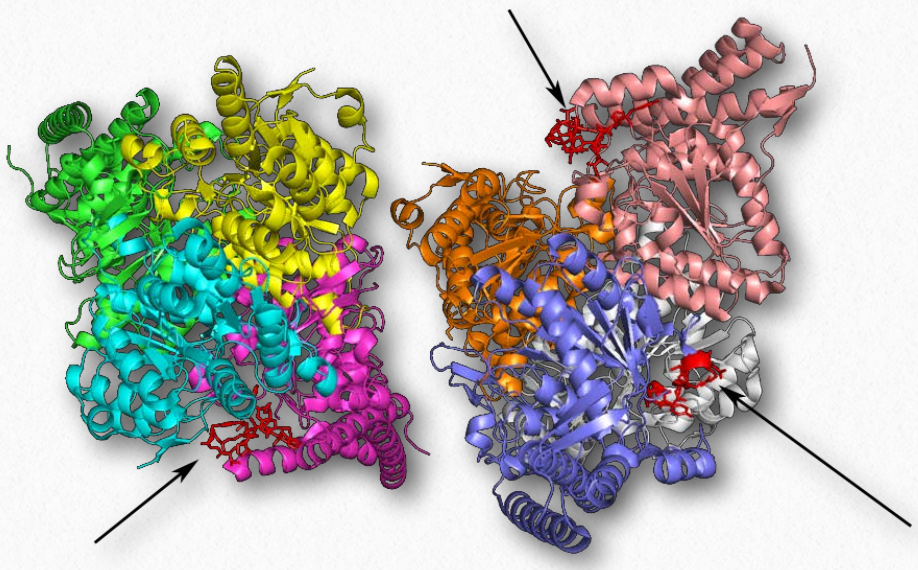

Figure 6.68 - Pyruvate dehydrogenase complex with three phosphorylation sites in red marked by arrows.

Wikipedia

tion. Regulation of pyruvate dehydrogenase, whether by allosteric or covalent mechanisms has the same strategy. Indicators of high energy shut down the enzyme, whereas indicators of low energy stimulate it. For allosteric regulation, the high energy indicators affecting the enzyme are ATP, acetyl-CoA, NADH, and fatty acids, which inhibit it. AMP, Coenzyme A, NAD^+, and calcium, on the other hand, stimulate it (Figure 6.67).

Covalent modification

Covalent modification regulation of pyruvate dehydrogenase is a bit more complicated. It occurs as a result of phosphorylation by pyruvate dehydrogenase kinase (PDK - Figure 6.67) or dephosphorylation by pyruvate dehydrogenase phosphatase (PDP).

PDK puts phosphate on any one of three serine residues on the E_1 subunit, which causes pyruvate kinase to not be able to perform its first step of catalysis - the decarboxylation of pyruvate. PDP can remove those phosphates. PDK is allosterically activated in the mitochondrial matrix when NADH and acetyl-CoA concentrations rise.

Product inhibition

Thus, the products of the pyruvate dehydrogenase reaction inhibit the production of more products by favoring its phosphorylation by PDK. Pyruvate, a substrate of pyruvate dehydrogenase, inhibits PDK, so increasing concentrations of substrate activate pyruvate dehydrogenase by reducing its phosphorylation by PDK. As concentrations of NADH and acetyl-CoA fall, PDP associates with pyruvate kinase and removes the phosphate on the serine on the E_1 subunit.

Low concentrations of NADH and acetyl-CoA are necessary for PDP to remain on the enzyme. When those concentrations rise, PDP dissociates and PDK gains access to the serine for phosphorylation. Insulin and calcium can also activate the PDP. This is very impor-

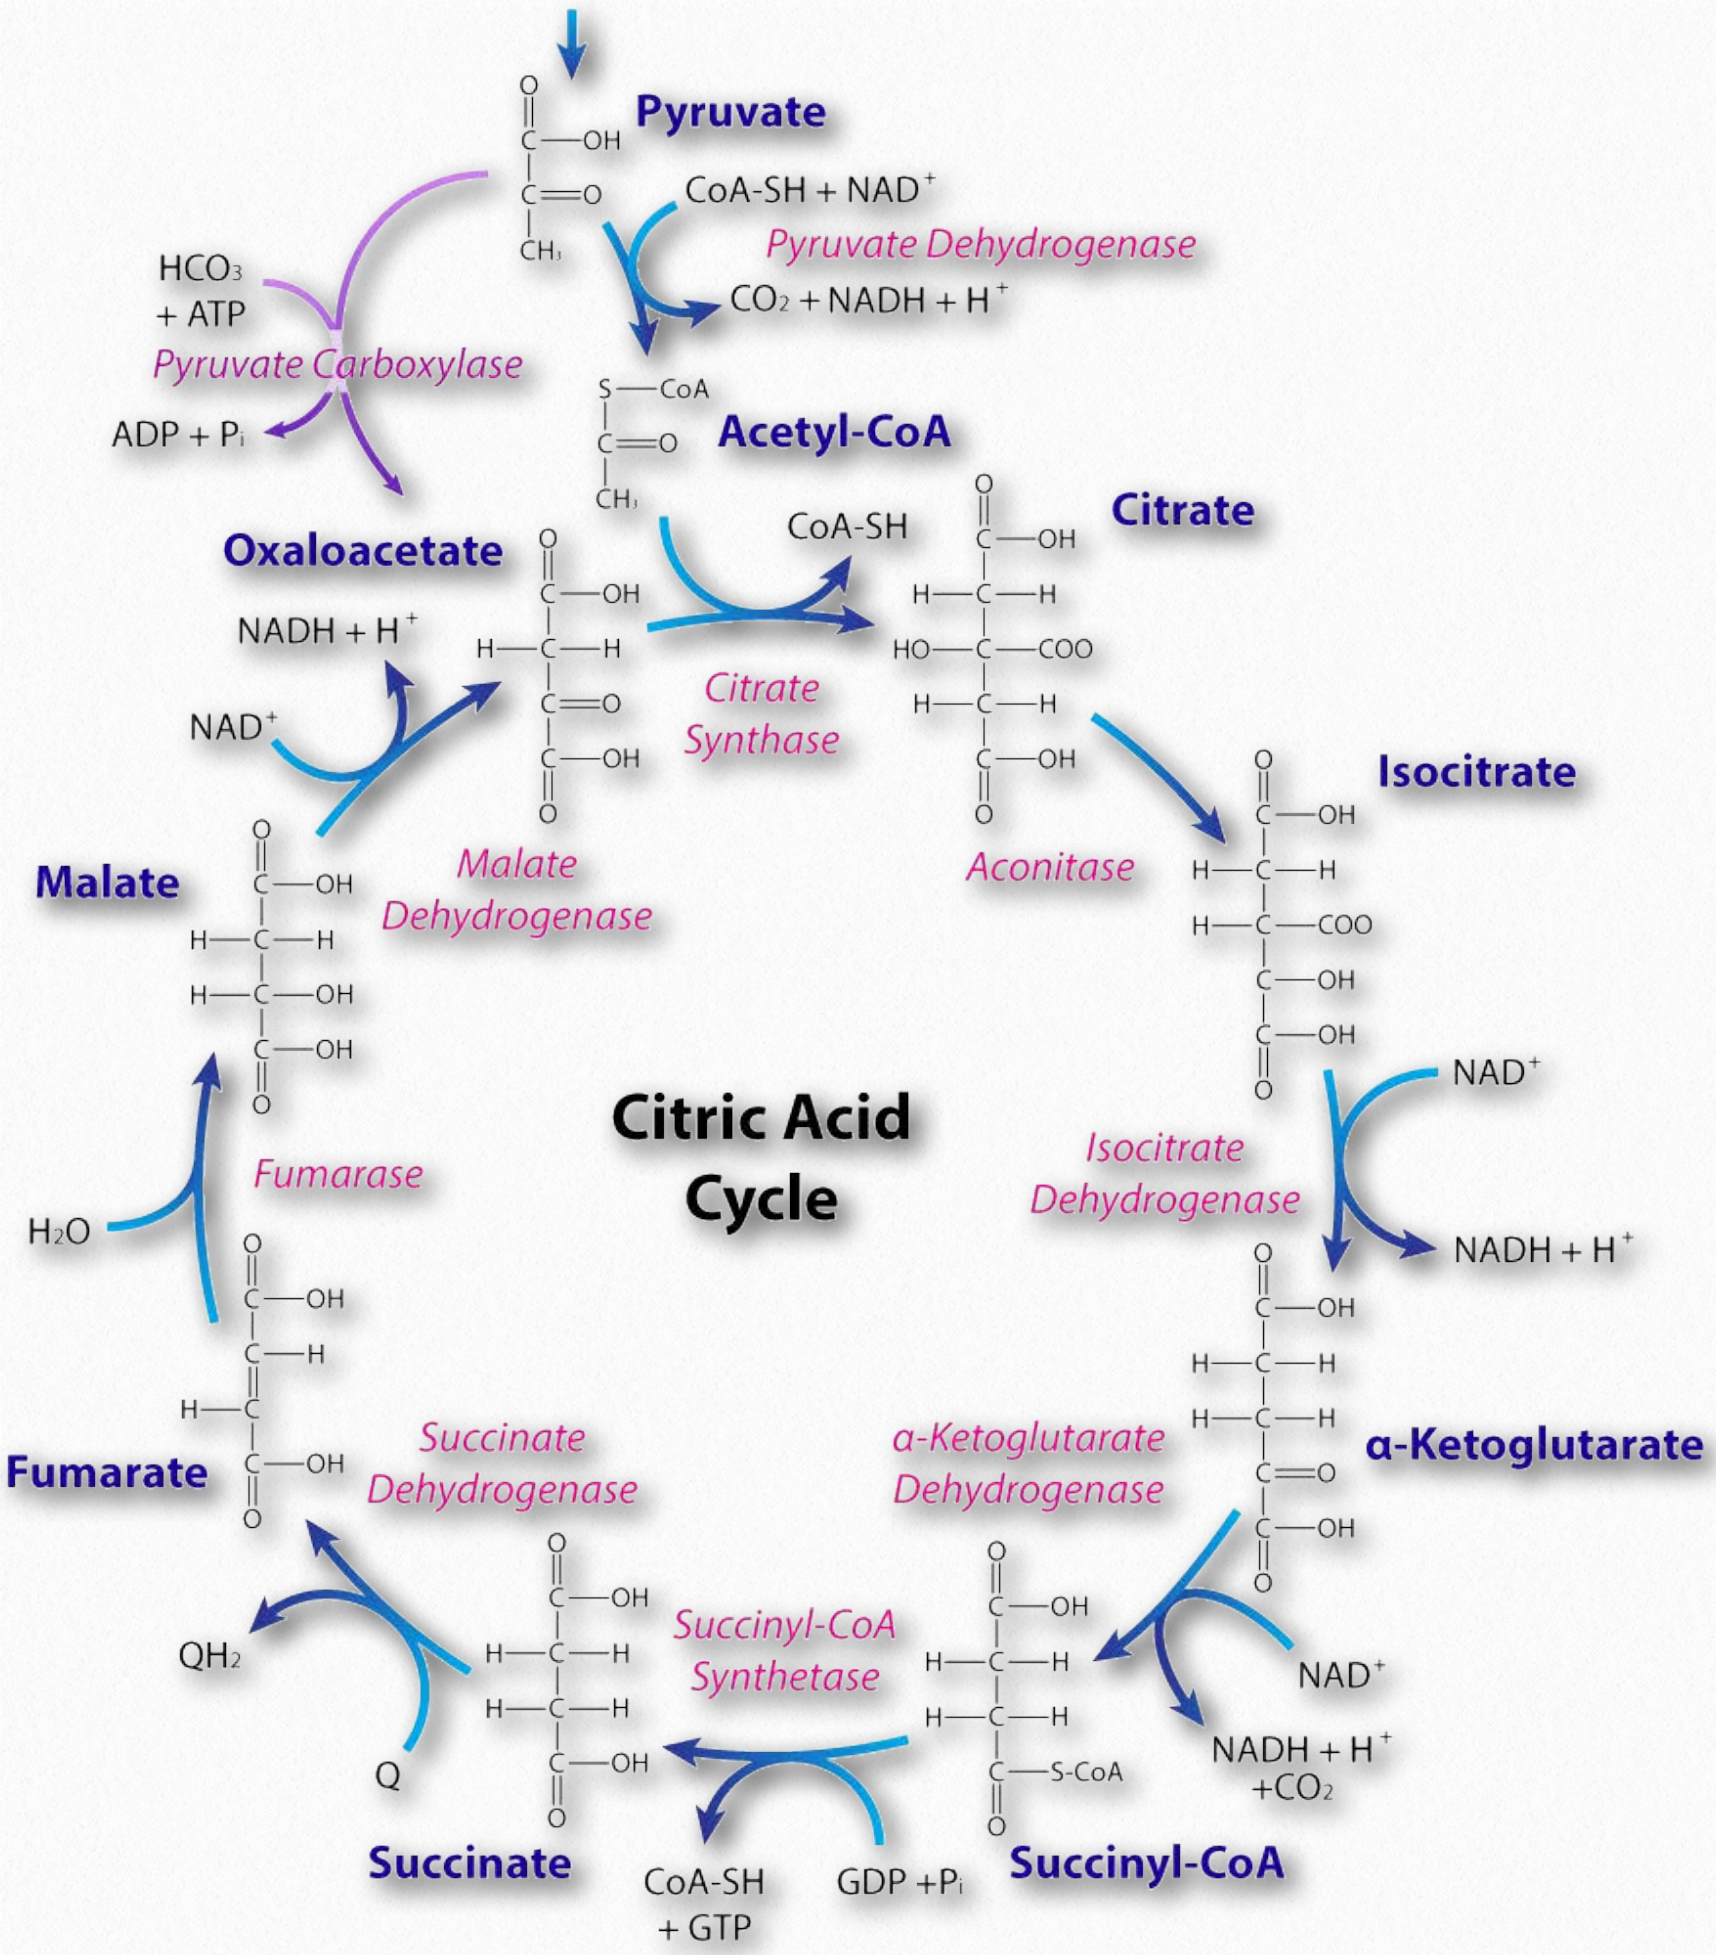

Figure 6.69 - The citric acid cycle

image by Aleia Kim

tant in muscle tissue, since calcium is a signal for muscular contraction, which requires energy.

Insulin also also activates pyruvate kinase and the glycolysis pathway to use internalized glucose. It should be noted that the cAMP phosphorylation cascade from the β-adrenergic receptor has no effect on pyruvate kinase, though the insulin cascade does, in fact, affect PDP and pyruvate kinase.

Citric acid cycle reactions

Focusing on the pathway itself (Figure 6.69), the usual point to start discussion is addition of acetyl-CoA to oxaloacetate (OAA) to form citrate.

Acetyl-CoA for the pathway can come from a variety of sources. The reaction joining it to OAA is catalyzed by citrate synthase and the $\Delta G^{\circ\prime}$ is fairly negative. This, in turn, helps to "pull" the malate dehydrogenase reaction preceding it in the cycle.

Acetyl-CoA + Oxaloacetate

⇅

Citrate + CoA-SH

In the next reaction, citrate is isomerized to isocitrate by action of the enzyme called aconitase.

Citrate

⇅

Isocitrate

Isocitrate is a branch point in plants and bacteria for the glyoxylate cycle (see HERE). Oxidative decarboxylation of isocitrate by

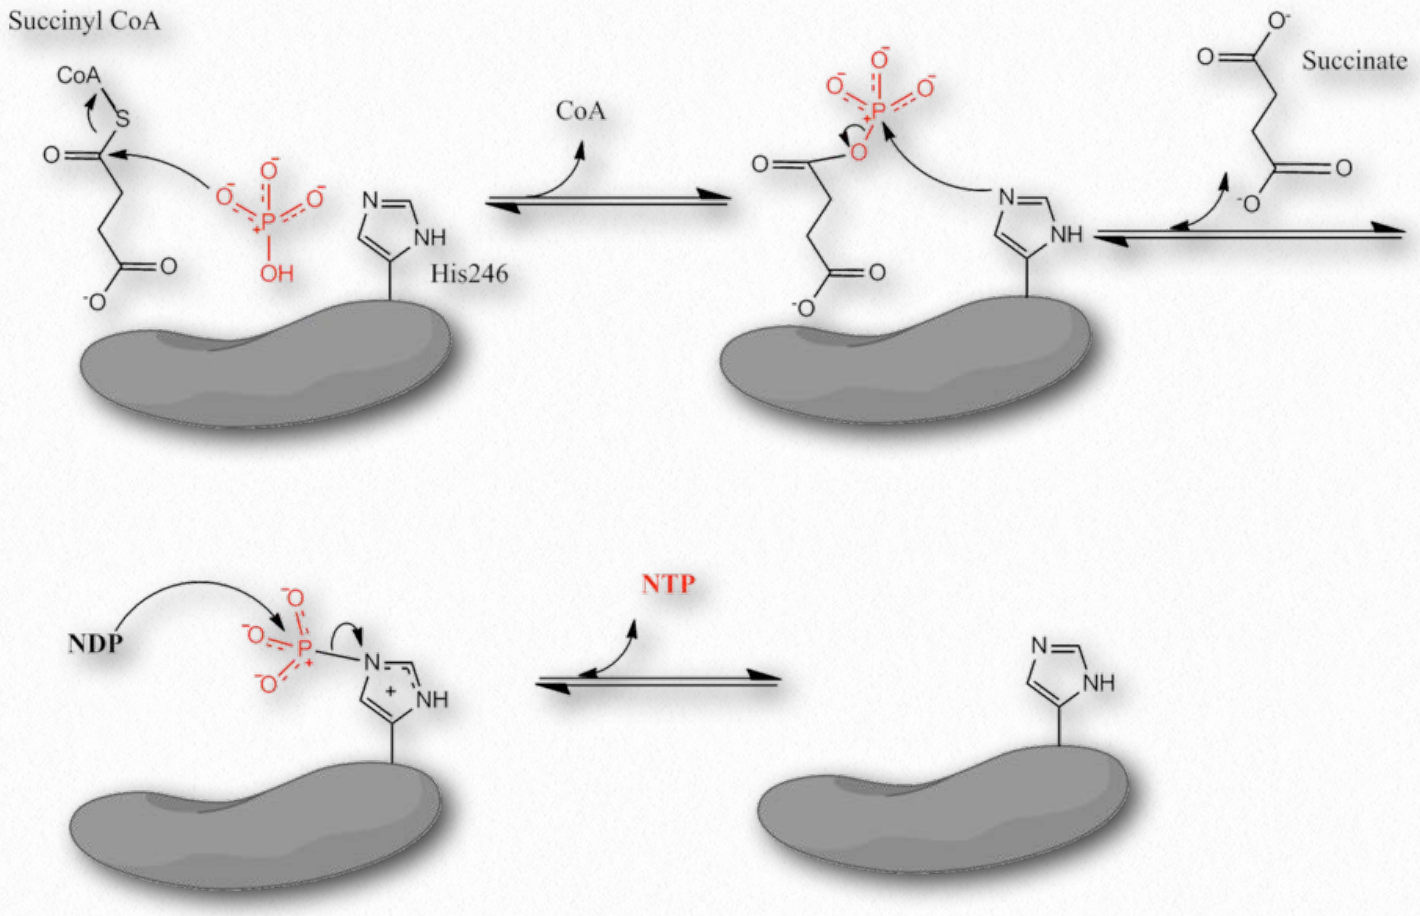

Figure 6.70 - Succinyl-CoA synthetase mechanism

isocitrate dehydrogenase produces the first NADH and yields α-ketoglutarate.

Isocitrate + NAD^+

⇅

α-ketoglutarate + NADH + CO_2

This five carbon intermediate is a branch point for synthesis of the amino acid glutamate. In addition, glutamate can also be made easily into this intermediate in the reverse reaction. Decarboxylation of α-ketoglutarate produces succinyl-CoA and is catalyzed by α-ketoglutarate dehydrogenase.

α-ketoglutarate + NAD^+ + CoA-SH

⇅

Succinyl-CoA + NADH + CO_2

The enzyme α-ketoglutarate dehydrogenase is structurally very similar to pyruvate dehydrogenase and employs the same five coenzymes – NAD^+, FAD, CoA-SH, thiamine pyrophosphate, and lipoamide.

Regeneration of oxaloacetate

The remainder of the citric acid cycle involves conversion of the four carbon succinyl-CoA into oxaloacetate. Succinyl-CoA is a branch point for the synthesis of heme (see HERE). Succinyl-CoA is converted to succinate in a reaction catalyzed by succinyl-CoA synthetase (named for the reverse reaction) and a GTP is produced, as well – the only substrate level phosphorylation in the cycle.

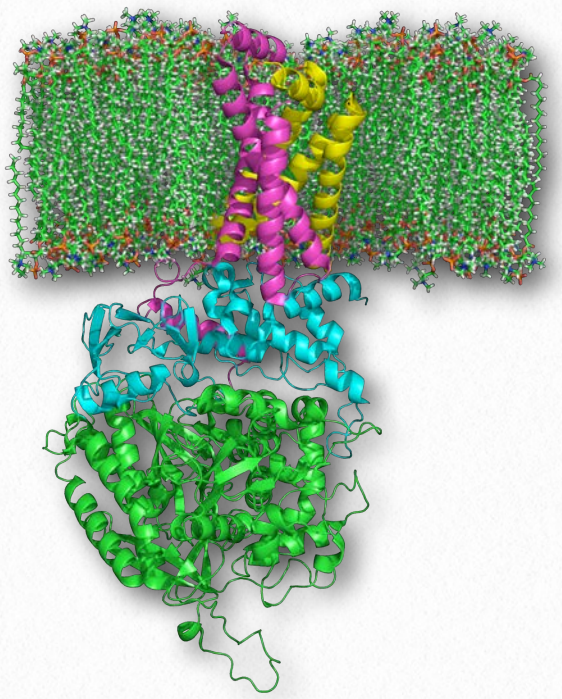

Figure 6.71 - Succinate dehydrogenase embedded in the mitochondrial inner membrane (top)
Wikipedia

Succinyl-CoA + GDP + P_i

⇅

Succinate + GTP + CoA-SH

The energy for the synthesis of the GTP comes from hydrolysis of the high energy thioester bond between succinate and the CoA-SH. Evidence for the high energy of a thioester bond is also evident in the citrate synthase reaction, which is also very energetically favorable. Succinate is also produced by metabolism of odd-chain fatty acids (see HERE).

Succinate Oxidation

Oxidation of succinate occurs in the next step, catalyzed by succinate dehydrogenase.

Succinate + FAD

⇅

Fumarate + $FADH_2$

This interesting enzyme both catalyzes this reaction and participates in the electron transport system, funneling electrons from the $FADH_2$ it gains in the reaction to coenzyme Q. The product of the reaction, fumarate, gains a water across its *trans* double bond in the next reaction, catalyzed by fumarase to form malate.

Fumarate + H_2O

⇅

L-Malate

Fumarate is also a byproduct of nucleotide metabolism and of the urea cycle. Malate is important also for transporting electrons across membranes in the malate-aspartate shuttle (see HERE) and in ferrying carbon dioxide from mesophyll cells to bundle sheath cells in C_4 plants (see HERE).

YouTube Lectures by Kevin HERE & HERE

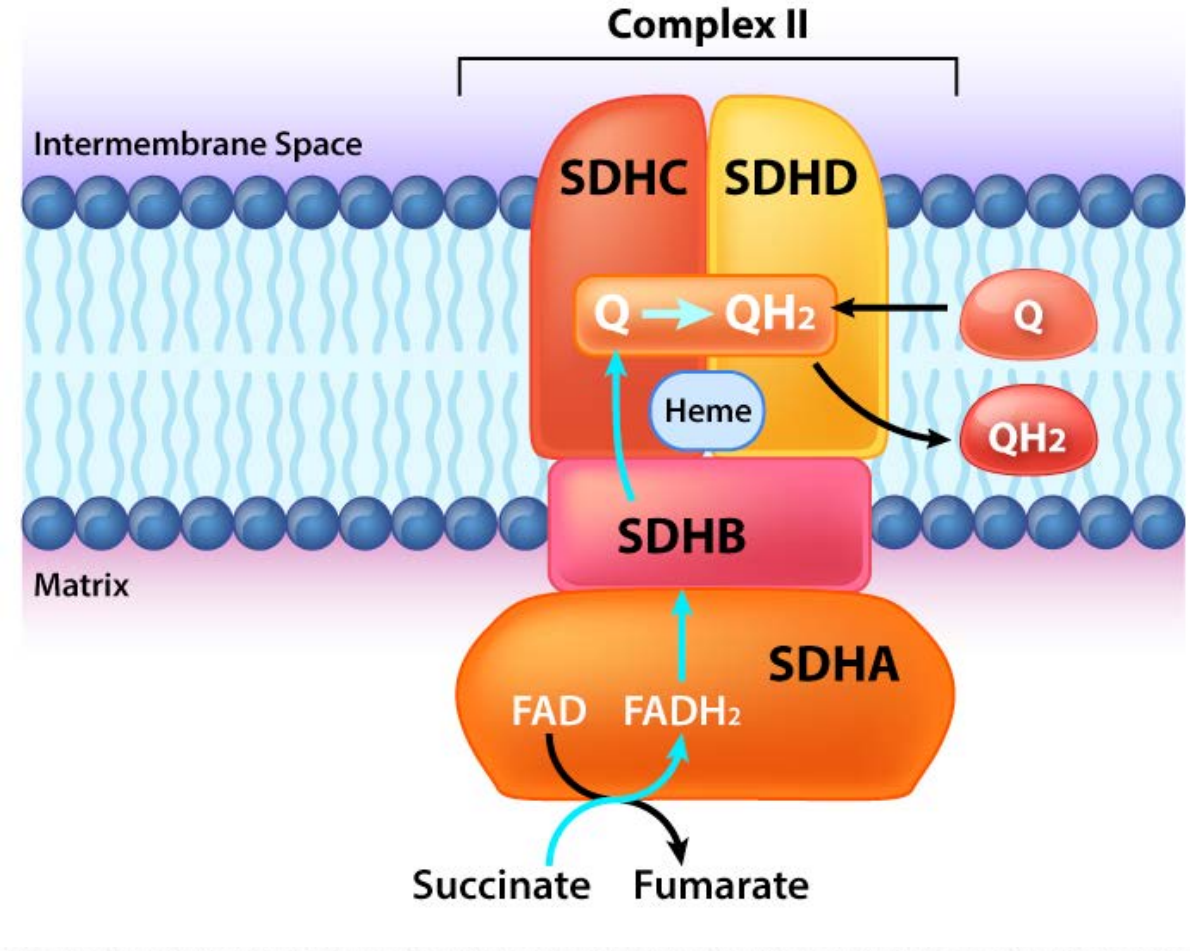

Figure 6.72 - Succinate dehydrogenase reaction

Image by Aleia Kim

Rare oxidation

Conversion of malate to oxaloacetate by malate dehydrogenase is a rare biological oxidation that has a $\Delta G°'$ with a positive value (29.7 kJ/mol).

L-Malate + NAD^+

⇅

Oxaloacetate + NADH

The reaction is 'pulled' by the energetically favorable conversion of oxaloacetate to citrate in the citrate

synthase reaction described above. Oxaloacetate intersects other important pathways, including amino acid metabolism (readily converted to aspartic acid), transamination (nitrogen movement) and gluconeogenesis.

It is worth noting that reversal of the citric acid cycle theoretically provides a mechanism for assimilating CO_2. In fact, this reversal has been noted in both anaerobic and microaerobic bacteria, where it is called the Arnon-Buchanan cycle (Figure 6.73).

Regulation of the citric acid cycle

Allosteric regulation of the citric acid cycle is pretty straightforward. The molecules involved are all substrates/products of the pathway or molecules involved in energy transfer. Substrates/products that regulate or affect the pathway include acetyl-CoA and succinyl-CoA .

Inhibitors and activators

High energy molecular indicators, such as ATP and NADH will tend to inhibit the cycle and low energy indicators (NAD^+, AMP, and ADP) will tend to activate the cycle. Pyruvate dehydrogenase, which catalyzes formation of acetyl-CoA for entry into the cycle is allosterically inhibited by its product (acetyl-CoA), as well as by NADH and ATP.

Regulated enzymes

Regulated enzymes in the cycle include citrate synthase (inhibited by NADH, ATP, and succinyl-CoA), isocitrate dehydrogenase (inhibited by ATP, activated by ADP and

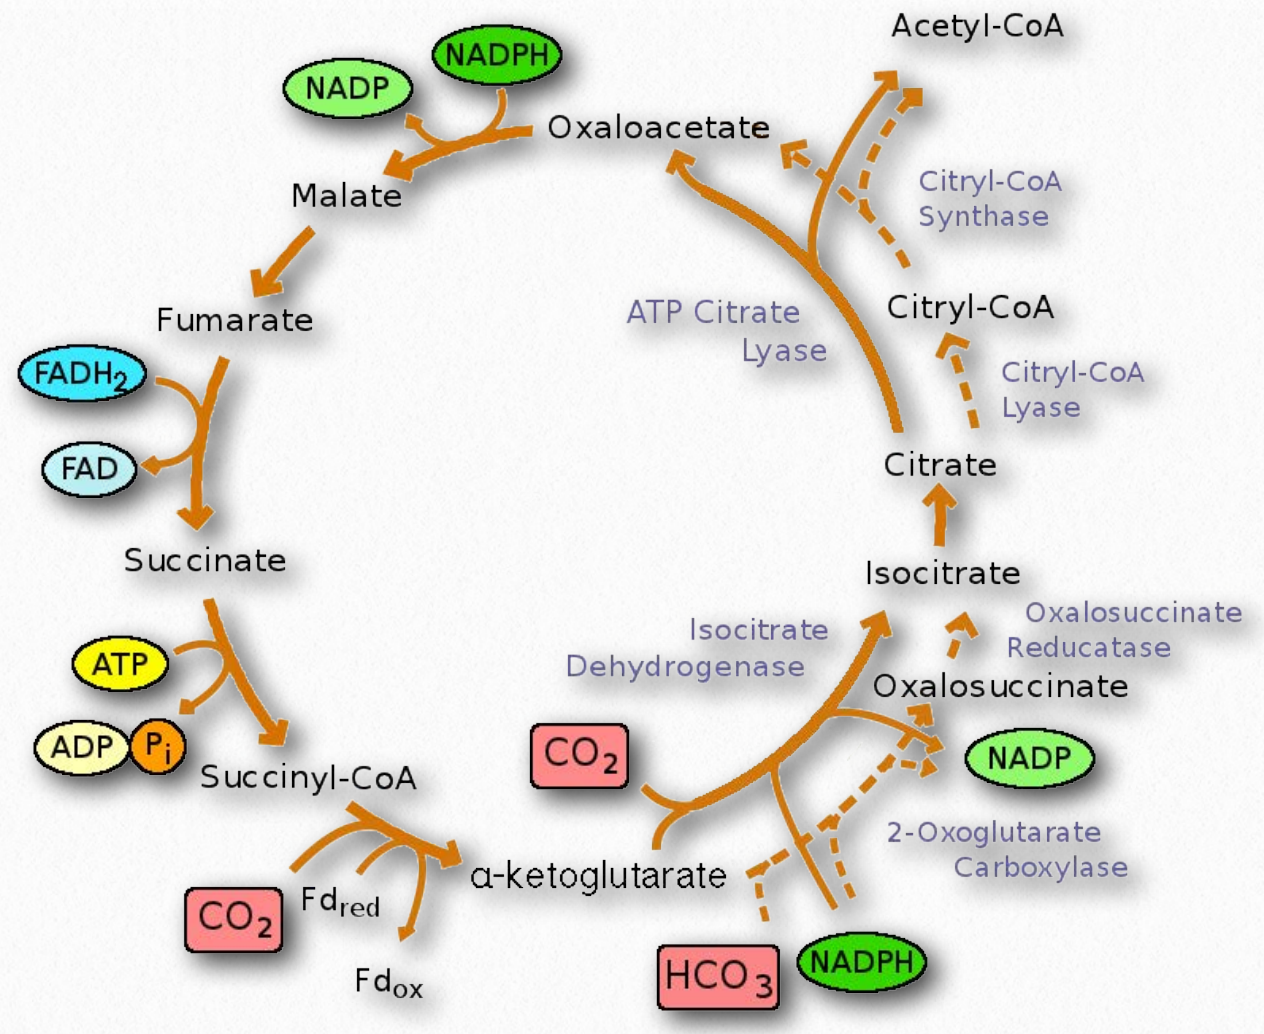

Figure 6.73 - Arnon-Buchanon cycle. Alternative enzymes shown on right in lavender. Fd = ferredoxin

Wikipedia

NAD^+), and α-ketoglutarate dehydrogenase (inhibited by NADH and succinyl-CoA and activated by AMP).

Anaplerotic/ cataplerotic pathway

The citric acid cycle is an important catabolic pathway oxidizing acetyl-CoA into CO_2 and generating ATP, but it is also an important source of molecules needed by cells and a mechanism for extracting energy from amino acids in protein breakdown and other breakdown products. This ability of the citric acid cycle to supply molecules as needed and to absorb metabolic by-products gives great flexibility to cells. When citric acid cycle intermediates are taken from the pathway to make other molecules, the term used to describe this is cataplerotic, whereas when molecules are added to the pathway, the process is described as anaplerotic.

Kevin Ahern

Cataplerotic molecules

The citric acid cycle's primary cataplerotic molecules include **α**-ketoglutarate, succinyl-CoA, and oxaloacetate. Transamination of α-ketoglutarate and oxaloacetate produces the amino acids glutamate and aspartic acid, respectively. Oxaloacetate is important for the production of glucose in gluconeogenesis.

Glutamate plays a very important role in the movement of nitrogen through cells via glutamine and other molecules and is also needed for purine synthesis. Aspartate is a precursor of other amino acids and for production of pyrimidine nucleotides. Succinyl-CoA is necessary for the synthesis of porphyrins, such as the heme groups in hemoglobin, myoglobin and cytochromes.

Citrate is an important source of acetyl-CoA for making fatty acids. When the citrate concentration is high (as when the citric acid cycle is moving slowly or is stopped), it gets shuttled across the mitochondrial

membrane into the cytoplasm and broken down by the enzyme citrate lyase to oxaloacetate and acetyl-CoA. The latter is a precursor for fatty acid synthesis in the cytoplasm.

Anaplerotic molecules

Anaplerotic molecules replenishing citric acid cycle intermediates include acetyl-CoA (made in many pathways, including fatty acid oxidation, pyruvate decarboxylation, amino acid catabolism, and breakdown of ketone bodies), α-ketoglutarate (from amino acid metabolism), succinyl-CoA (from propionic acid metabolism), fumarate (from the urea cycle and purine metabolism), malate (carboxylation of PEP in plants), and oxaloacetate (many sources, including amino acid catabolism and pyruvate carboxylase action on pyruvate in gluconeogenesis)

Glyoxylate cycle

A pathway related to the citric acid cycle found only in plants and bacteria is the glyoxylate cycle (Figures 6.74 & 6.75). The glyoxylate cycle, which bypasses the decarboxylation reactions while using most of the non-decarboxylation reactions of the citric acid cycle, does not operate in animals, because they lack two enzymes necessary for it – isocitrate

I'm thinking I could lose some weight
If I could make glyoxylate

Expends it glycolytically

lyase and malate synthase. The cycle occurs in specialized plant peroxisomes called glyoxysomes. Isocitrate lyase catalyzes the conversion of isocitrate into succinate and

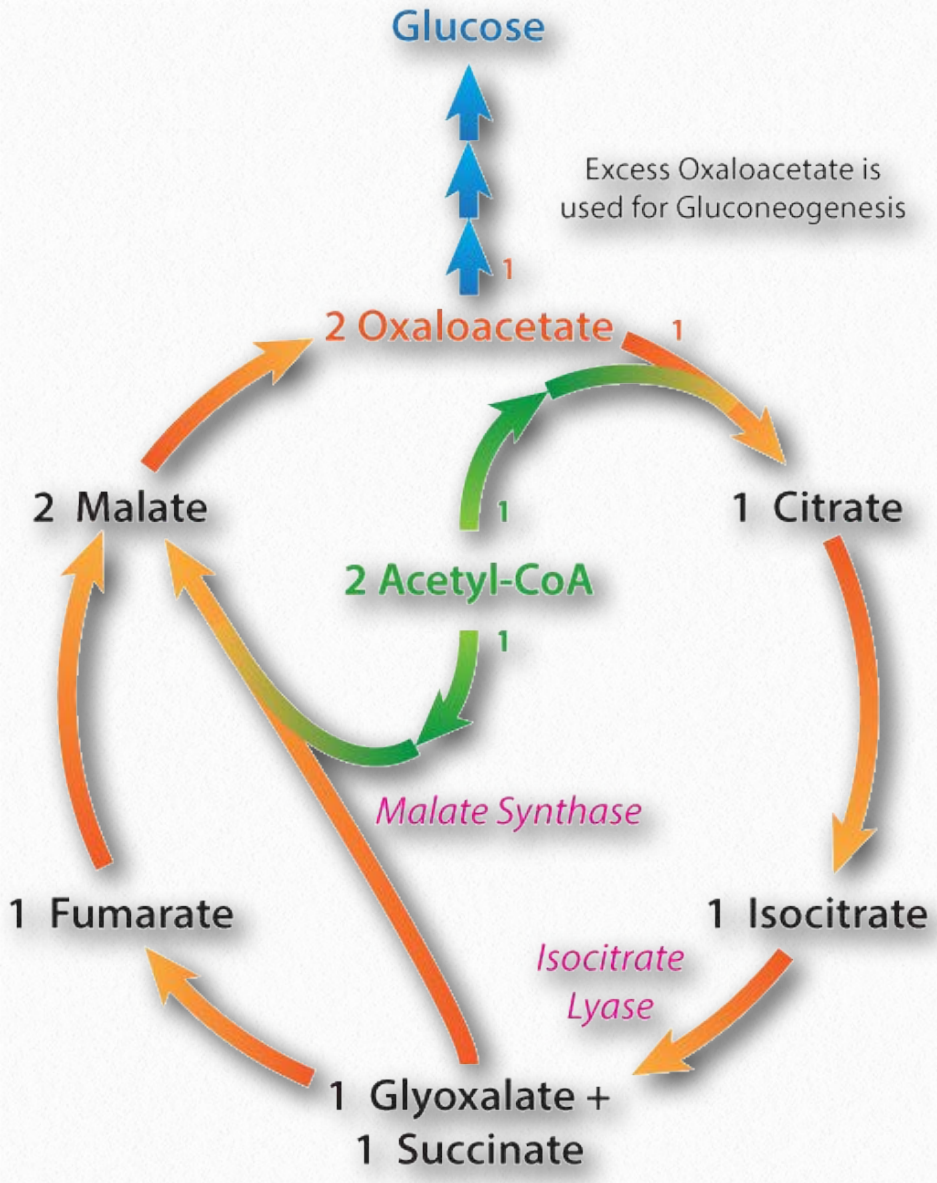

Figure 6.74 - Overview of the glyoxylate cycle
Image by Aleia Kim

glyoxylate. Because of this, all six carbons of the citric acid cycle survive each turn of the cycle and do not end up as carbon dioxide.

YouTube Lectures by Kevin HERE & HERE

Succinate continues through the remaining reactions to produce oxaloacetate. Glyoxylate combines with another acetyl-CoA

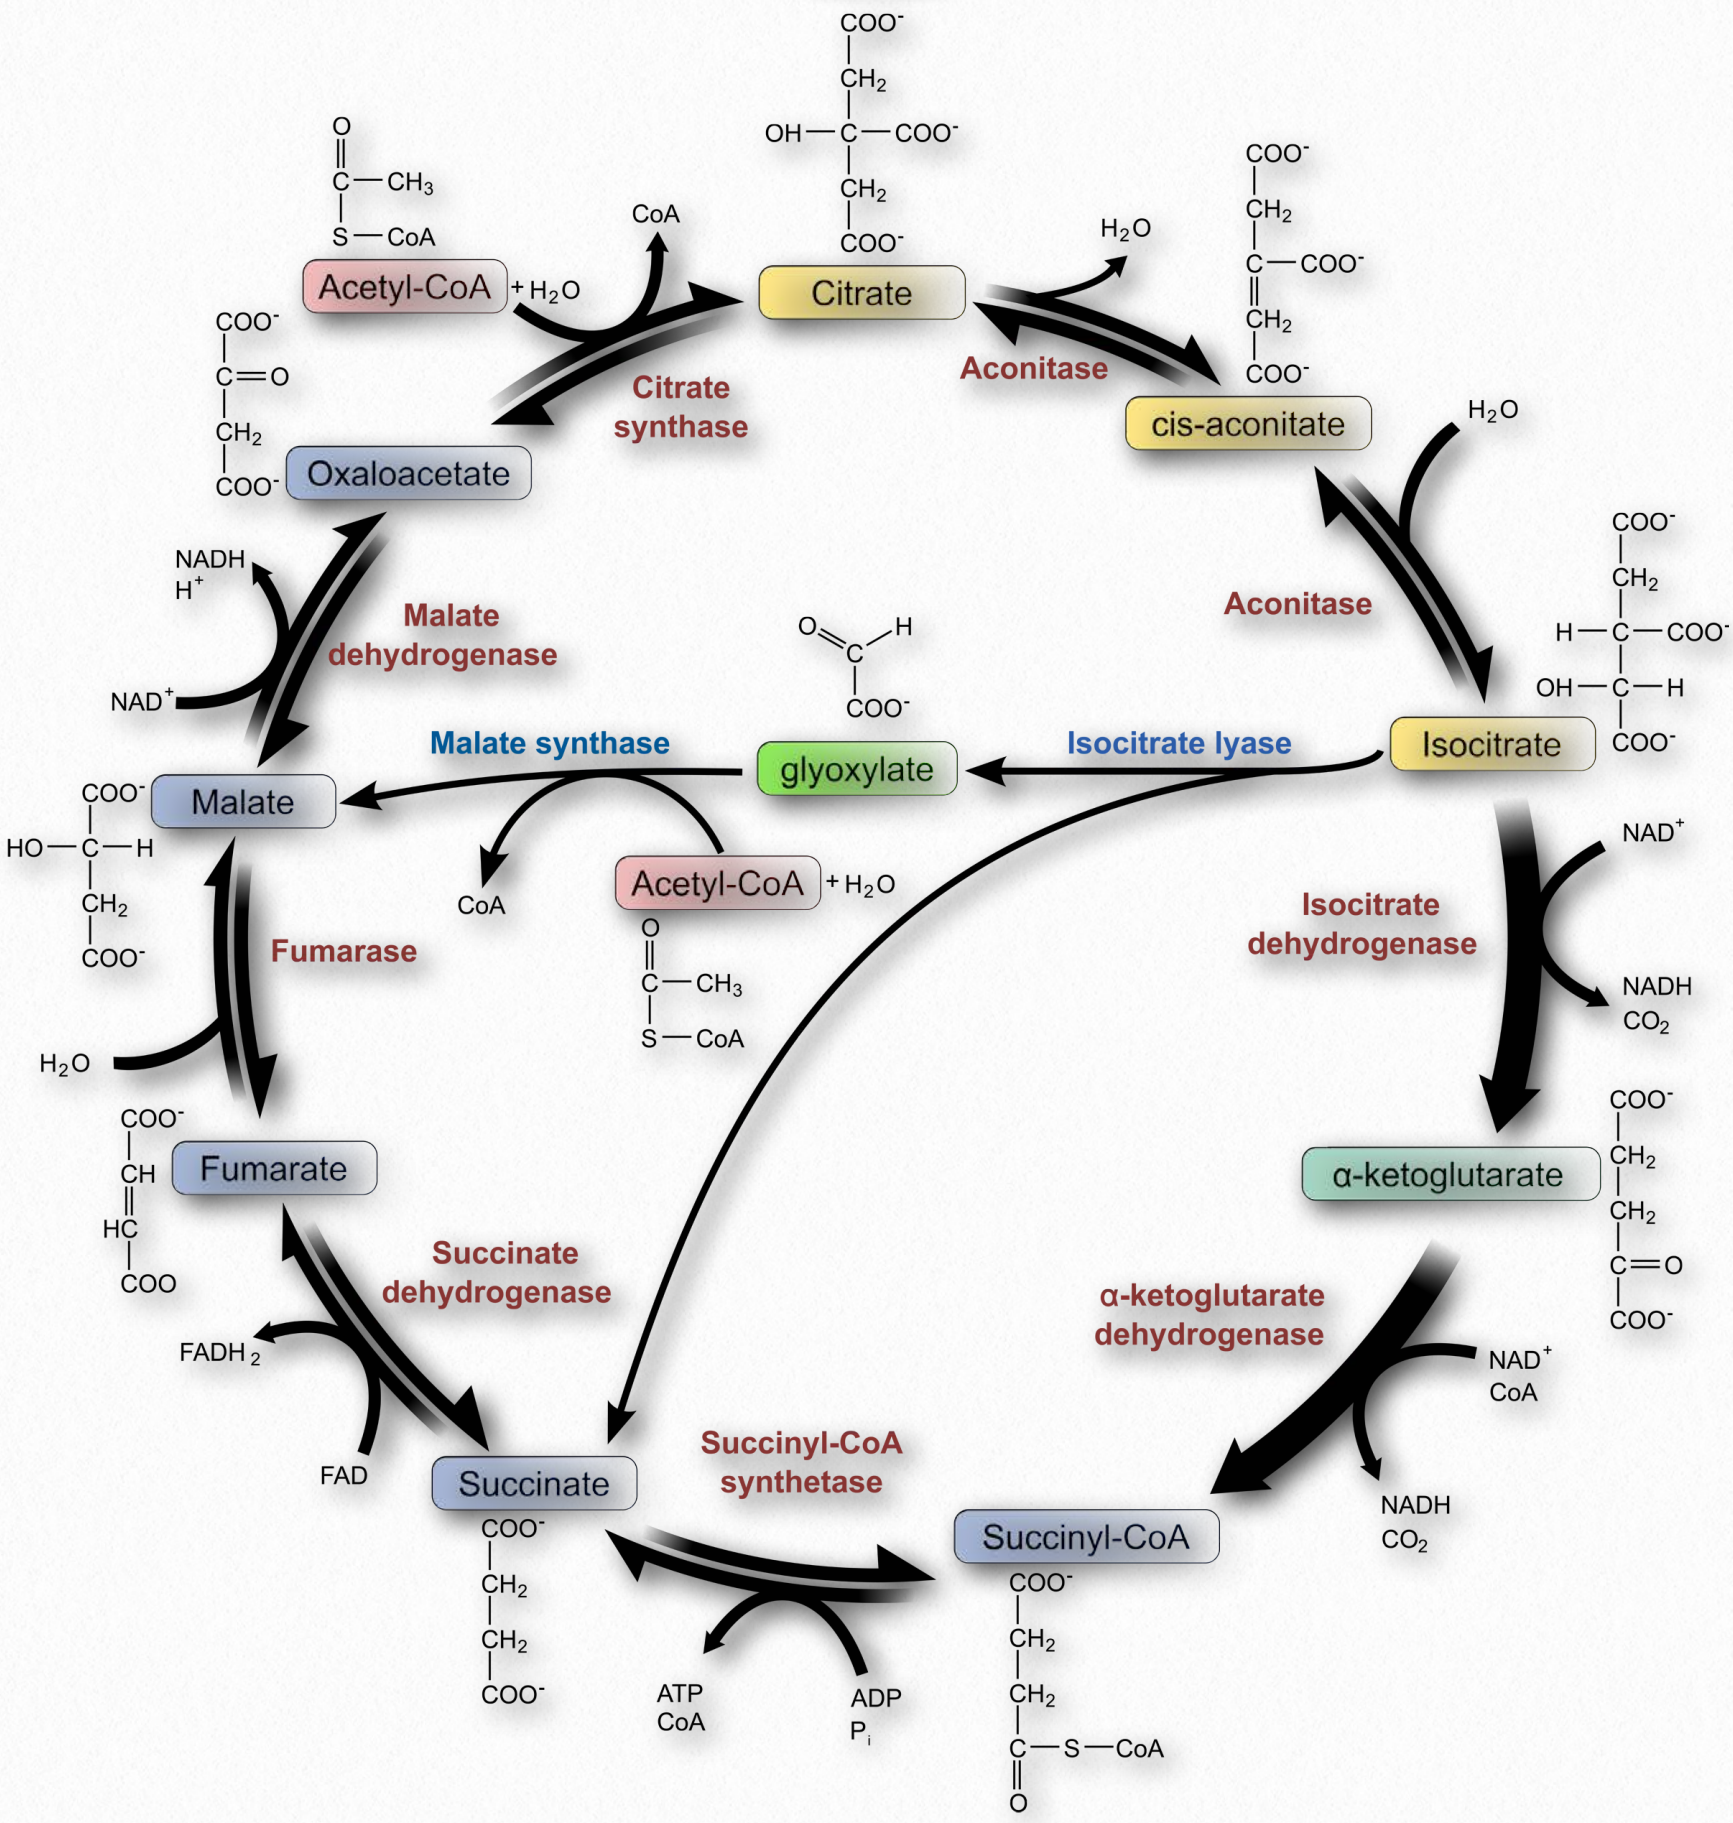

Figure 6.75 - Reactions of the glyoxylate cycle

Wikipedia

Figure 6.76 - A gingko seed embryo
Wikipedia

(one acetyl-CoA was used to start the cycle) to create malate (catalyzed by malate synthase). Malate can, in turn, be oxidized to oxaloacetate.

It is at this point that the glyoxylate pathway's contrast with the citric acid cycle is apparent. After one turn of the citric acid cycle, a single oxaloacetate is produced and it balances the single one used in the first reaction of the cycle. Thus, in the citric acid cycle, there is no net production of oxaloacetate in each turn of the cycle.

Net oxaloacetate production

On the other hand, thanks to assimilation of carbons from two acetyl-CoA molecules, each turn of the glyoxylate cycle results in two oxaloacetates being produced, after starting with one. The extra oxaloacetate of the glyoxylate cycle can be used to make other molecules, including glucose in gluconeogenesis. This is particularly important for plant seed germination (Figure 6.76), since the seedling is not exposed to sunlight. With the glyoxylate cycle, seeds can make glucose from stored lipids.

Because animals do not run the glyoxylate cycle, they cannot produce glucose from acetyl-CoA in net amounts, but plants and bacteria can. As a result, plants and bacteria can turn acetyl-CoA from fat into glucose, while animals can't. Bypassing the oxidative decarboxylations (and substrate level phosphorylation) has energy costs, but, there are also benefits. Each turn of the glyoxylate cycle produces one $FADH_2$ and one NADH instead of the three NADHs, one $FADH_2$, and one GTP made in each turn of the citric acid cycle.

Carbohydrate needs

Organisms that make cell walls, such as plants, fungi, and bacteria, need large quantities of carbohydrates as they grow to support the biosynthesis of the complex structural polysaccharides of the walls. These include cellulose, glucans, and chitin. Notably, each of the organisms can operate the glyoxylate cycle using acetyl-CoA from β-oxidation.

Coordination of the glyoxylate cycle and the citric acid cycle

The citric acid cycle is a major catabolic pathway producing a considerable amount of

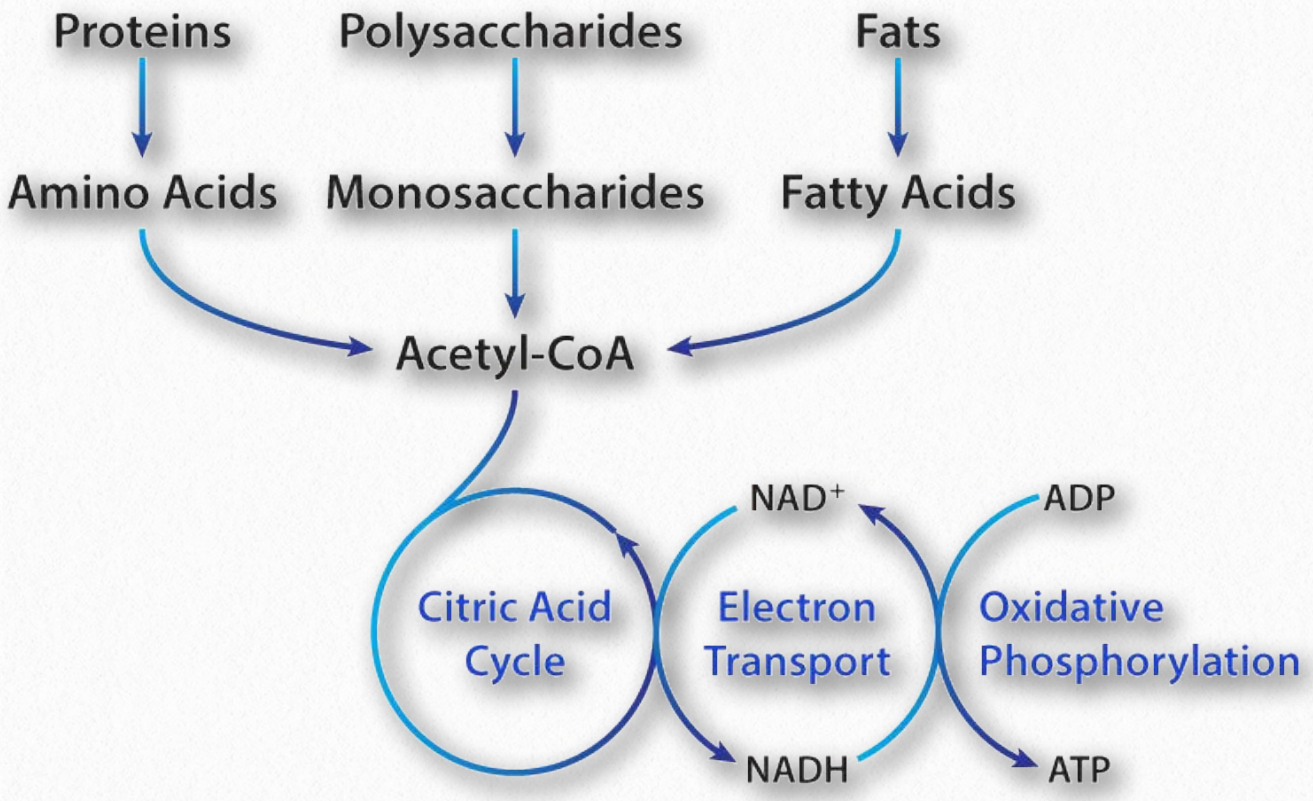

Figure 6.77 - Acetyl-CoA metabolism

Image by Aleia Kim

energy for cells, whereas the glyoxylate cycle's main function is anabolic - to allow production of glucose from fatty acids in plants and bacteria. The two pathways are physically separated from each other (glyoxylate cycle in glyoxysomes / citric acid cycle in mitochondria), but nonetheless a coordinated regulation of them is important.

The enzyme that appears to provide controls for the cycle is isocitrate dehydrogenase. In plants and bacteria, the enzyme can be inactivated by phosphorylation by a kinase found only in those cells. Inactivation causes isocitrate to accumulate in the mitochondrion and when this happens, it gets shunted to the glyoxysomes, favoring the glyoxylate cycle.

Removal of the phosphate from isocitrate dehydrogenase is catalyzed by an isocitrate dehydrognease-specific phosphoprotein phosphatase and restores activity to the enzyme.

When this happens, isocitrate oxidation resumes in the mitochondrion along with the rest of the citric acid cycle reactions.

In bacteria, where the enzymes for both cycles are present together in the cytoplasm, accumulation of citric acid cycle intermediates and glycolysis intermediates will tend to favor the citric acid cycle by activating the phosphatase, whereas high energy conditions will tend to favor the glyoxylate cycle by inhibiting it.

Acetyl-CoA metabolism

Acetyl-CoA is one of the most "connected" metabolites in biochemistry, appearing in fatty acid oxidation/synthesis, pyruvate oxidation, the citric acid cycle, amino acid anabolism/catabolism, ketone body metabolism, steroid/bile acid synthesis, and (by extension from fatty acid metabolism) prostaglandin synthesis . Most of these pathways

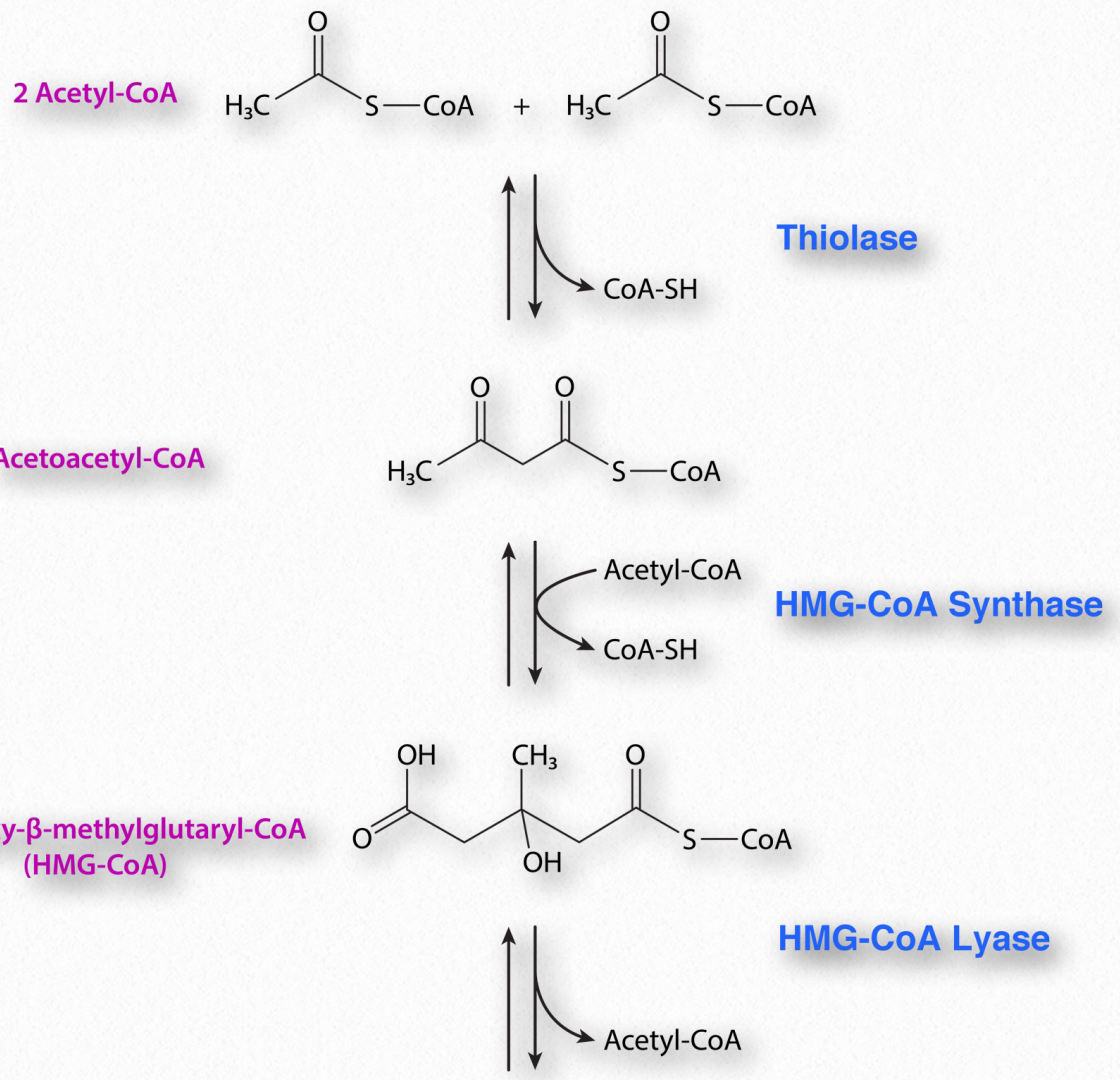

Figure 6.78 Ketone body metabolism

Image by Pehr Jacobson

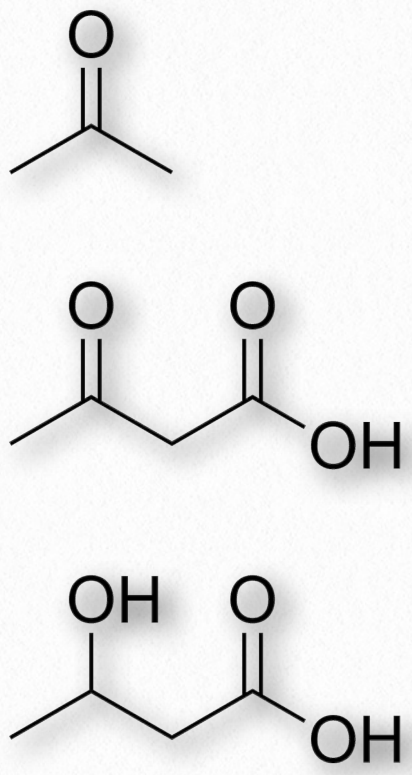

Figure 6.79 - Three ketone bodies - acetone (top), acetoacetic acid (middle), and β-hydroxybutyrate (bottom)

will be dealt with separately. Here we will cover ketone body metabolism.

Ketone body metabolism

Ketone bodies are molecules made when the blood levels of glucose fall very low. Ketone bodies can be converted to acetyl-CoA by reversing the reaction of the pathway that makes them (Figure 6.78). Acetyl CoA, of course, can be used for ATP synthesis via the citric acid cycle. People who are very hypoglycemic (including some diabetics) will produce ketone bodies (Figure 6.79) and these are often first detected by the smell of acetone on their breath.

Overlapping pathways

The pathways for ketone body synthesis and cholesterol biosynthesis (Figure 6.80

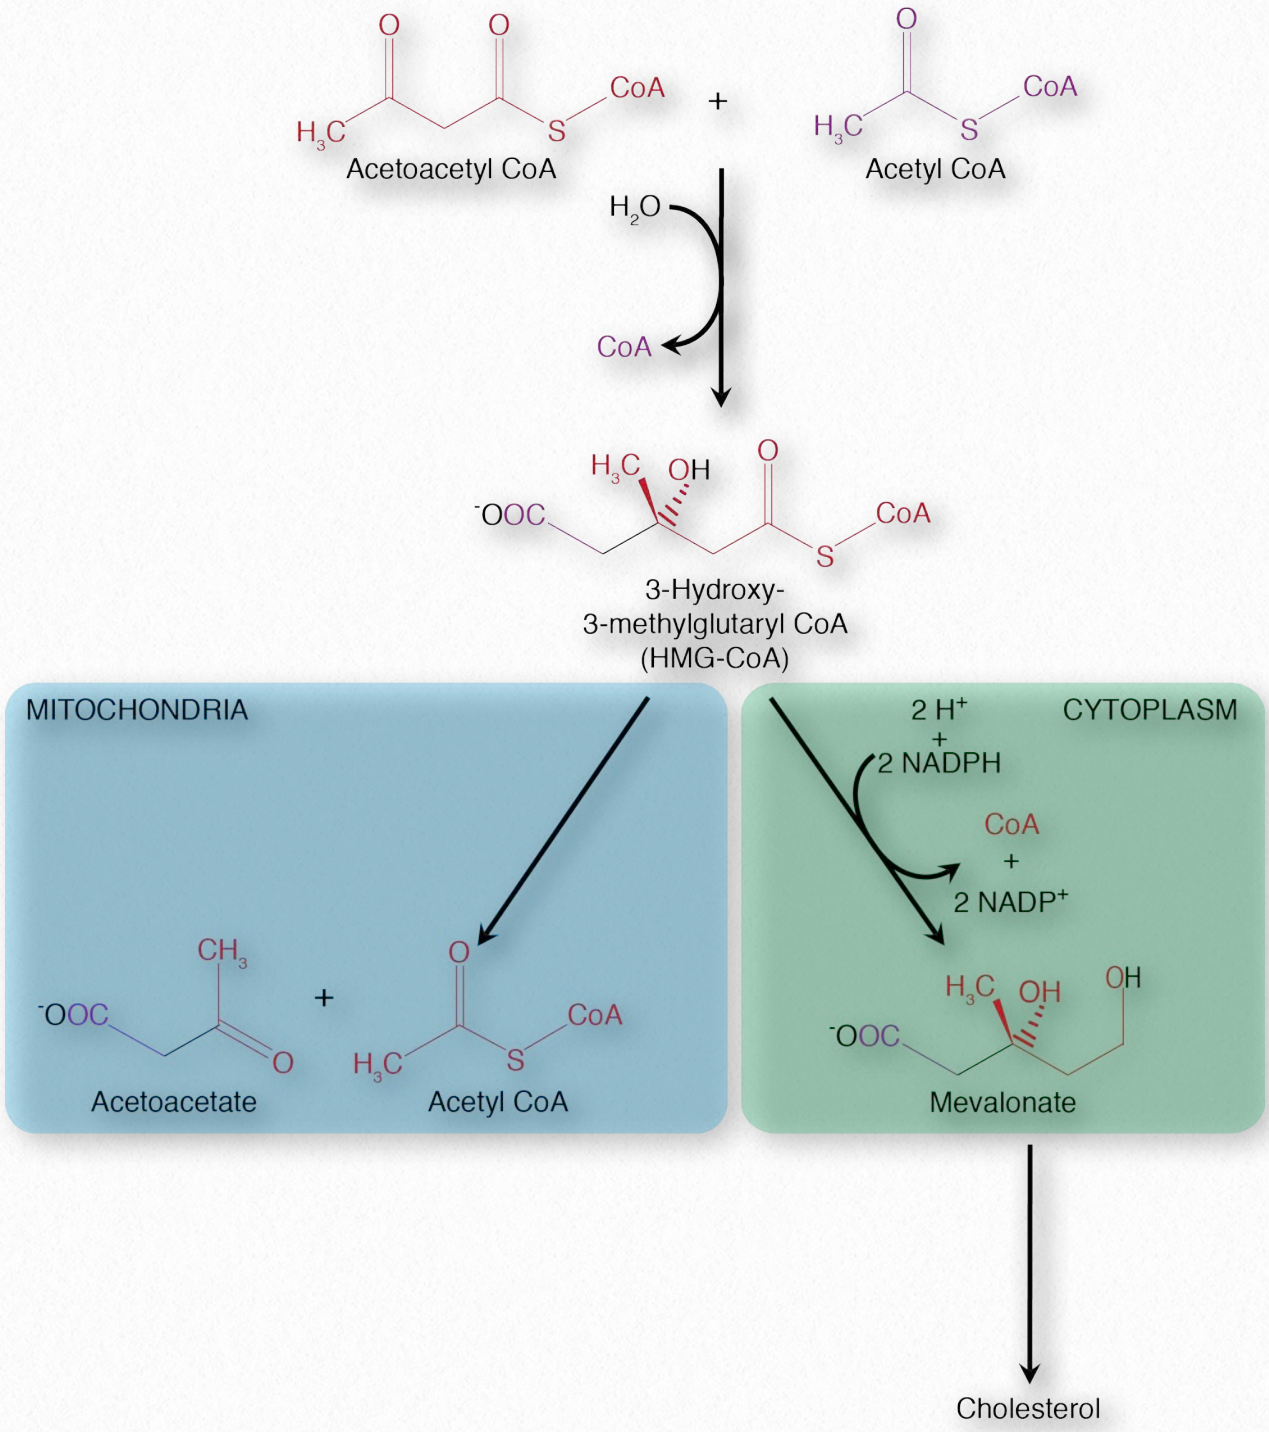

Figure 6.80 - Diverging biosynthetic pathways for ketone bodies (left) and cholesterol biosynthesis (right)

Image by Penelope Irving

and see HERE) overlap at the beginning. Each of these starts by combining two acetyl-CoAs together to make acetoacetyl-CoA. Not coincidentally, that is the next to last product of β-oxidation of fatty acids with even numbers of carbons (see HERE for fatty acid oxidation). In fact, the enzyme that catalyzes the joining is the same as the one that catalyzes its breakage in fatty acid oxidation – thiolase. Thus, these pathways start by reversing the last step of the last round of fatty acid oxidation.

YouTube Lectures by Kevin HERE & HERE

HMG-CoA formation

Both pathways also include addition of two more carbons to acetoacetyl-CoA from a third acetyl-CoA to form hydroxy-methyl-glutaryl-CoA, or HMG-CoA, as it is more commonly known. It is at this point that the two pathways diverge. HMG-CoA is a branch point between the two pathway and can either go on to become cholesterol or ketone bodies. In the latter pathway, HMG-CoA is broken down into acetyl-CoA and acetoacetate.

Acetoacetate is itself a ketone body and can

be reduced to form another one, D-β-hydroxybutyrate (not actually a ketone, though). Alternatively, acetoacetate can be converted into acetone. This latter reaction can occur either spontaneously or via catalysis by acetoacetate decarboxylase. Acetone can be converted into pyruvate and pyruvate can be made into glucose.

D-β-hydroxybutyrate travels readily in the blood and crosses the blood-brain barrier. It can be oxidized back to acetoacetate, converted to acetoacetyl-CoA, and then broken down to two molecules of acetyl-CoA for oxidation in the citric acid cycle.

Ketosis

When a body is producing ketone bodies for its energy, this state in the body is known as ketosis. Formation of ketone bodies in the liver is critical. Normally glucose is the body's primary energy source. It comes from the diet, from the breakdown of storage carbohydrates, such as glycogen, or from glucose synthesis (gluconeogenesis). Since the primary stores of glycogen are in muscles and liver and since gluconeogenesis occurs only in liver, kidney, and gametes, when the supply of glucose is interrupted for any reason, the liver must supply an alternate energy source.

From fatty acid breakdown

In contrast to glucose, ketone bodies can be made in animals from the breakdown of fat/fatty acids. Most cells of the body can use ketone bodies as energy sources. Ketosis may arise from fasting, a very low carbohydrate diet or, in some cases, diabetes.

Acidosis

The term acidosis refers to conditions in the body where the pH of arterial blood drops be-

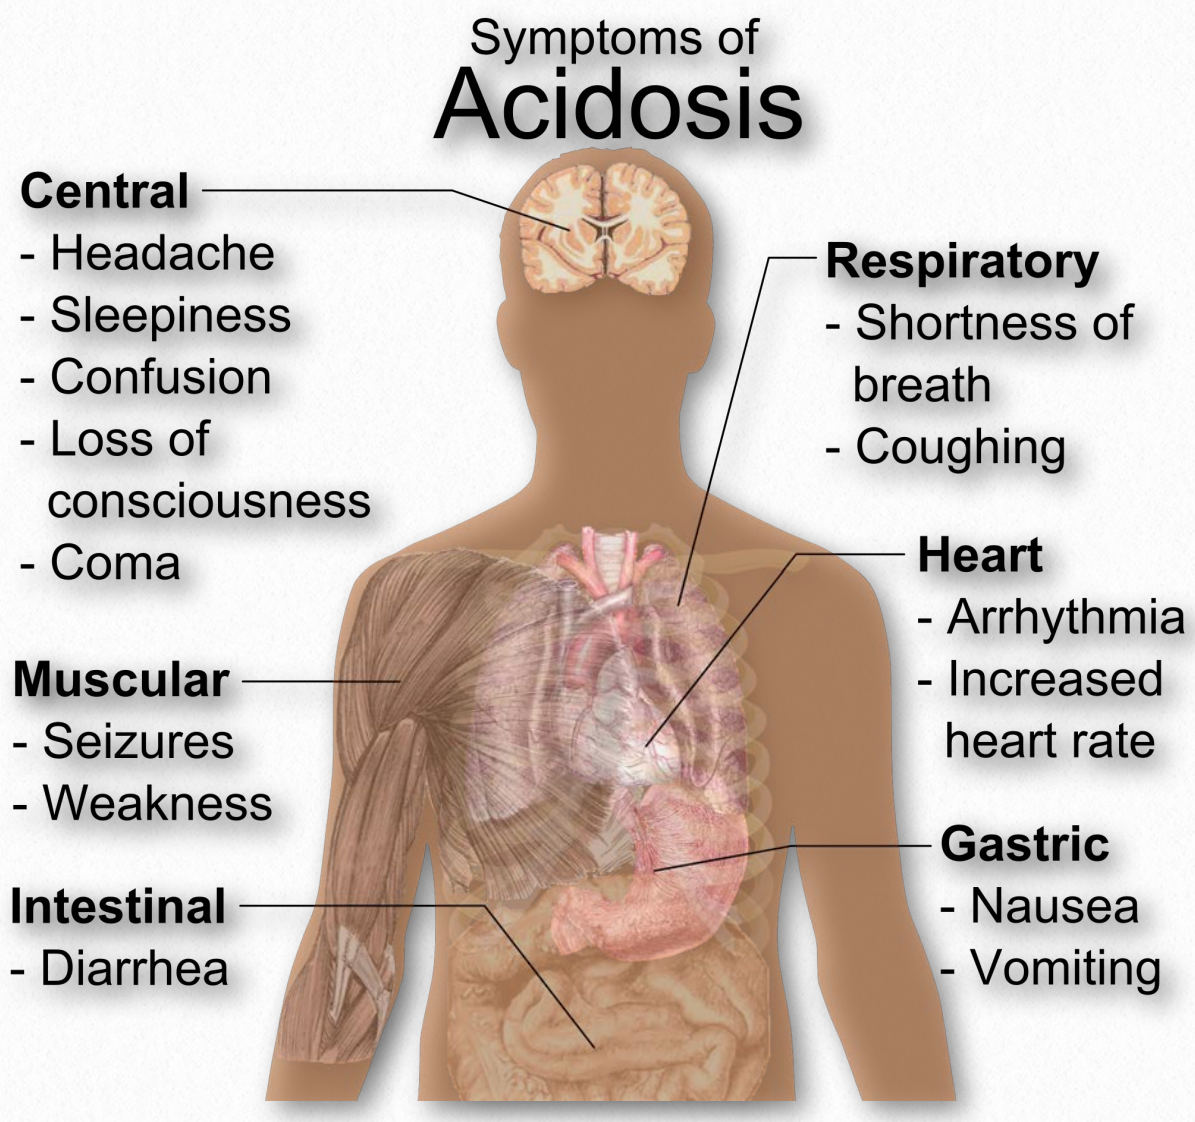

Figure 6.81 - Symptoms of acidosis

low 7.35. It is the opposite of the condition of alkalosis, where the pH of the arterial blood rises above 7.45. Normally, the pH of the blood stays in this narrow pH range. pH values of the blood lower than 6.8 or higher than 7.8 can cause irreversible damage and may be fatal. Acidosis may have roots in metabolism (metabolic acidosis) or in respiration (respiratory acidosis).

There are several causes of acidosis. In metabolic acidosis, production of excess lactic acid or failure of the kidneys to excrete acid can cause blood pH to drop. Lactic acid is produced in the body when oxygen is limiting, so anything that interferes with oxygen delivery may create conditions favoring production of excess lactic acid. These may include restrictions in the movement of blood to target tissues, resulting in hypoxia (low oxygen conditions) or decreases in blood volume. Issues with blood movement can result from heart problems, low blood pressure, or hemorrhaging.

Strenuous exercise can also result in production of lactic acid due to the inability of the blood supply to deliver oxygen as fast as tissues require it (hypovolemic shock). At the end of the exercise, though, the oxygen supply via the blood system quickly catches up.

Respiratory acidosis arises from accumulation of carbon dioxide in the blood. Causes include hypoventilation, pulmonary problems, emphysema, asthma, and severe pneumonia.

The Citric Acid Cycle

To the tune of "*When Irish Eyes Are Smiling*"

Metabolic Melodies Website HERE

(This song uses only the chorus of the original song)

The citric acid cycle
Is a source of energy
It gets electrons moving
While reducing NAD

It starts with citric acid
Turning to aconitate
Which becomes an isocitrate
On the way to glutarate

The loss of one more carbon
Gives succinyl-CoA
And then succinic acid
When the CoA goes away

A further oxidation
Gives one *trans* fumarate
Which gains a water on the
Next step to make malate

One simple oxidation
Makes O-A-A you see
Which combined with Ac-Co-A
Returns us cyclically

Recording by David Simmons
Lyrics by Kevin Ahern

The Mellow Woes of Testing

To the tune of "*Yellow Rose of Texas*"

Metabolic Melodies Website HERE

The term is almost at an end
Ten weeks since it began
I worried how my grade was cuz
I did not have a plan

The first exam went not so well
I got a sixty three
'Twas just about the average score
In biochemistry

I buckled down the second time
Did not sow my wild oats
I downloaded the videos
And took a ton of notes

I learned about free energy
And Delta Gee Naught Prime
My score increased by seven points
A C-plus grade was mine

I sang the songs, I memorized
I played the mp_3s
I learned the citrate cycle
And I counted ATPs

I had electron transport down
And all of complex vee
I gasped when I saw my exam
It was a ninety three

So heading to the final stretch
I crammed my memory
And came to class on sunny days
For quizzing comedy

I packed a card with info and
My brain almost burned out
'Twas much to my delight I
Got the 'A' I'd dreamed about

So here's the moral of the song
It doesn't pay to stew
If scores are not quite what you want
And you don't have a clue

The answers get into your head
When you know what to do
Watch videos, read highlights and

Recording by David Simmons
Lyrics by Kevin Ahern

Metabolism: Fats and Fatty Acids

In the modern Western world, which is fat and getting fatter, there is a tremendous amount of interest in the metabolism of fat and fatty acids. Fat is the most important energy storage form of animals, storing considerably more energy per carbon than carbohydrates, but its insolubility in water requires the body to package it specially for transport. Surprisingly, fat/fatty acid metabolism is not nearly as tightly regulated as that of carbohydrates. Neither are the metabolic pathways of breakdown and synthesis particularly complicated, either.

YouTube Lectures by Kevin
HERE & HERE

Movement of dietary fat

Before we discuss the breakdown and synthesis of fat, let us first discuss the movement of dietary fat and oil (triglycerides - Figure 6.82) in the body. Upon consumption of triglycerides in the diet, they first are solubilized in the digestive system by the churning action of the stomach and the emulsifying properties of the bile acids.

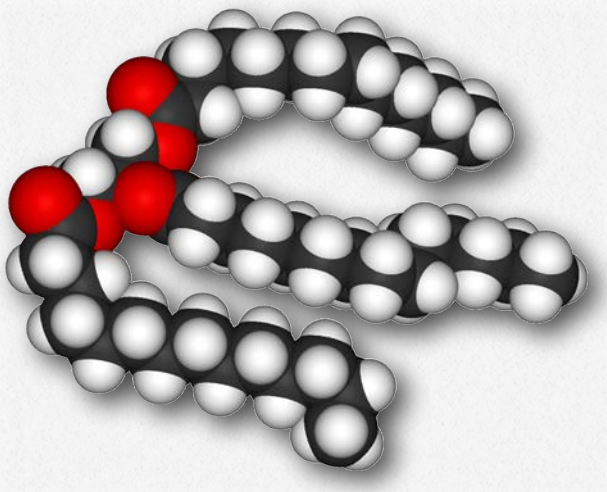

Figure 6.82 - Trimyristin - A triacylglyceride

Upon passing into the lumen of the intestine, the triglycerides are acted on first by enzymes known as lipases that use water twice on each triglyceride to release two fatty acids, leaving behind a monoacylglyceride. As shown in Figure 6.83, the fatty acids and the monoacylglyceride are moved across the intestinal wall into the lymph system where they are reassembled back into a triglyceride. In the lymph system triglycerides and other insoluble lipids are packaged into lipoprotein complexes called chylomicrons that enter the blood stream and travel to target cells. The journey of lipids in the body after leaving the digestive system is long and is discussed in more depth HERE.

In the body, fat is stored in specialized cells known as adipocytes. When these cells receive appropriate signals, they begin the breakdown of fat into glycerol and fatty acids.

Breakdown of fat

Breakdown of fat in adipocytes requires catalytic action of three enzymes. The first

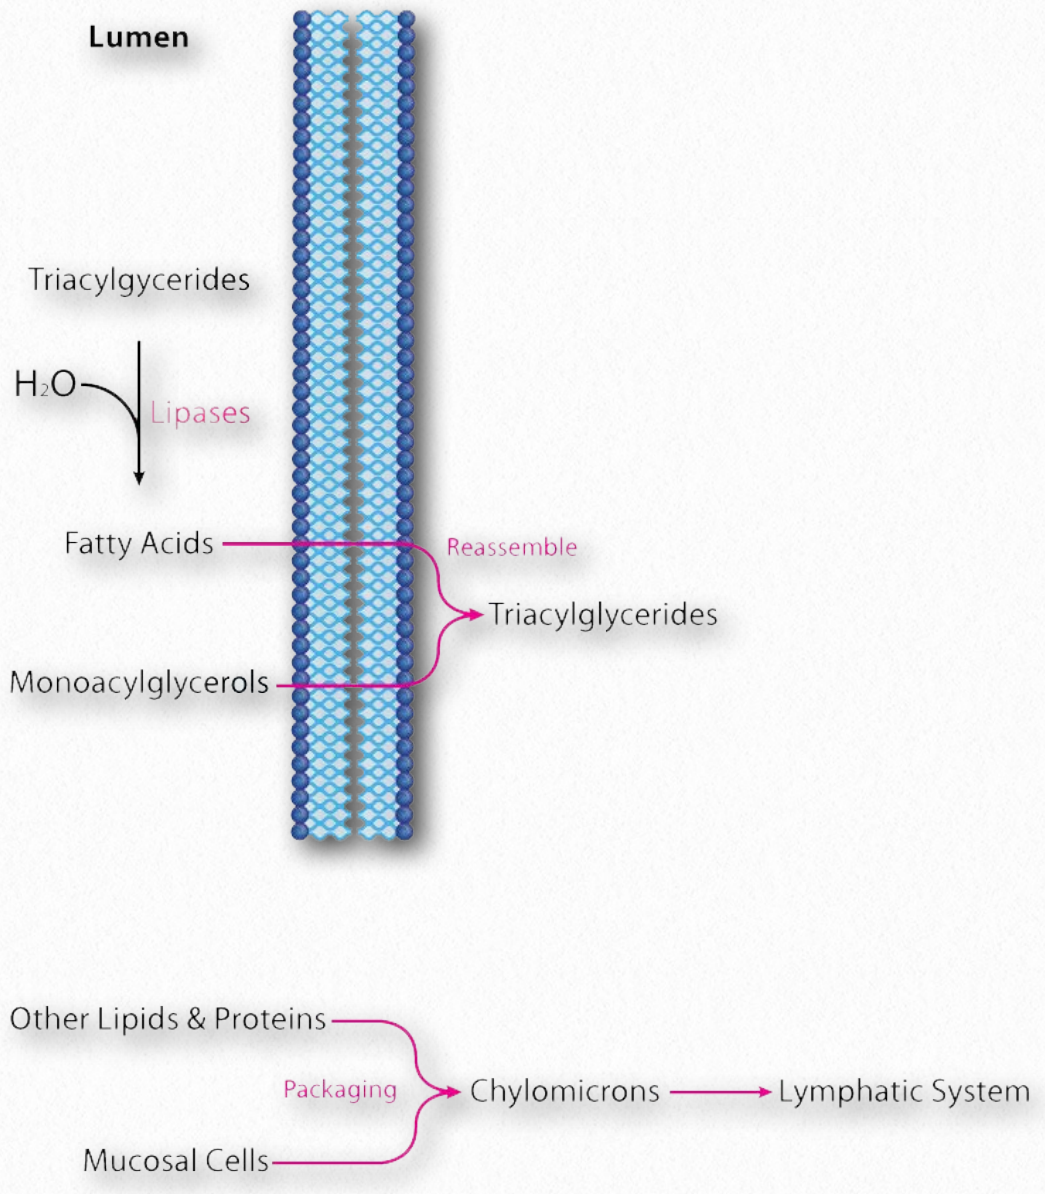

Figure 6.83 - Movement of dietary triglycerides

Image by Aleia Kim

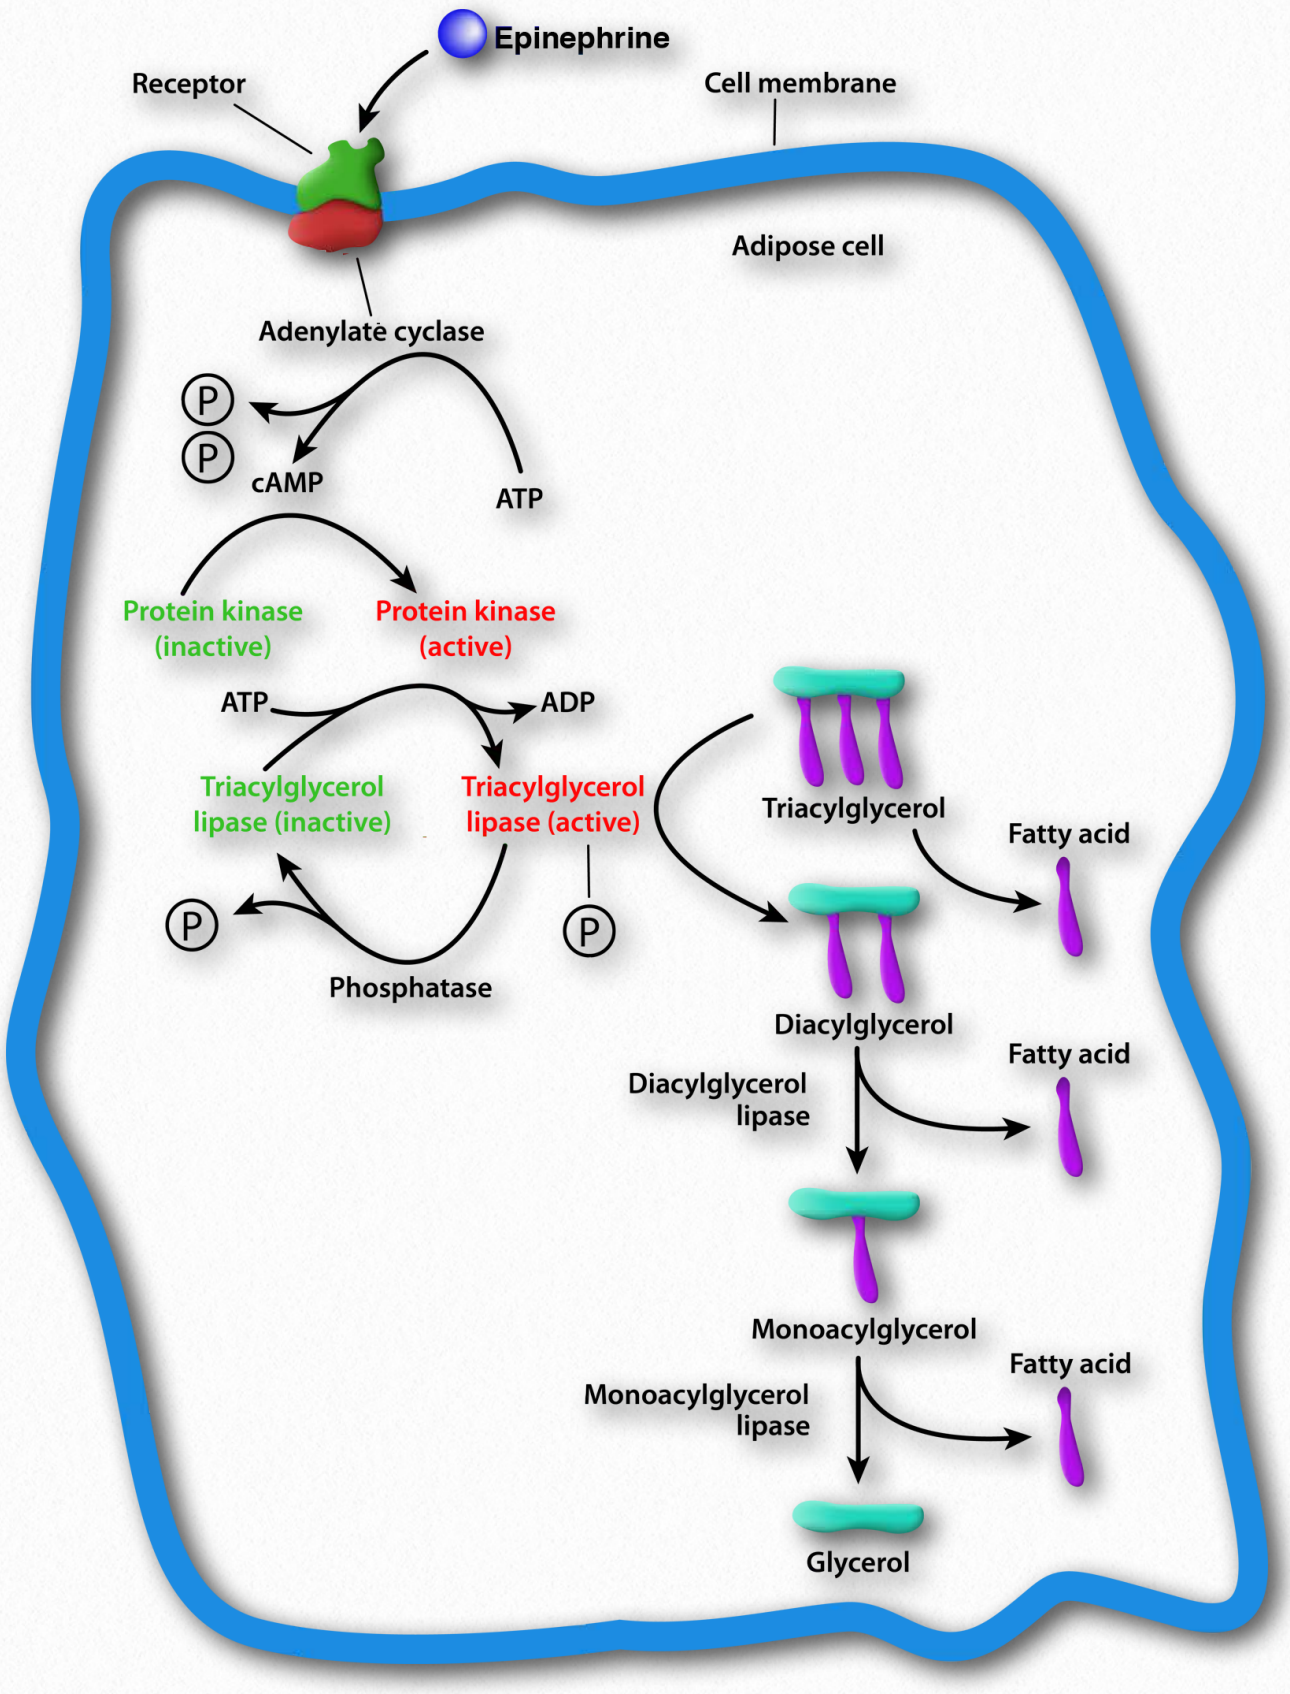

Figure 6.84 - Breakdown of fat in adipocytes

Image by Pehr Jacobson

of these is controlled by binding of hormones to the cell membrane (Figure 6.84). It is the only regulated enzyme of fat breakdown and is known as hormone sensitive triacylglycerol lipase. It removes the first fatty acid from the fat. Diacylglyceride lipase removes the second one and monoacylglyceride lipase removes the third. As noted, only the first one is regulated and it appears to be the rate limiting reaction when active.

Epinephrine activation

As shown in Figure 6.84, activation of hormone sensitive triacylglycerol lipase (HSTL) is accomplished by epinephrine stimulation process and that it overlaps with the same activation that stimulates glycogen breakdown and gluconeogenesis.

This coordination is very important. Each of the pathways stimulated by the epinephrine signaling system aims to provide the body with more materials to catabolize for energy - sugars and fatty acids. The HSTL is inhibited

Synthesis of Phosphatidic Acid from Glycerol-3-phosphate

1. **Glycerol-3-phosphate** + Acyl-CoA <=> Monoacylglycerol phosphate + CoA-SH

2. Monoacylglycerol phosphate + Acyl-CoA <=> **Phosphatidic acid** + CoA-SH

by dephospohrylation and this is stimulated by binding of insulin to its cell membrane receptor.

Perilipin

A protein playing an important roles in regulation of fat breakdown is perilipin. Perilipin associates with fat droplets and helps regulate action of HSTL, the enzyme catalyzing the first reaction in fat catabolism. When perilipin is not phosphorylated, it coats the fat droplet and prevents HSTL from getting access to it. Activation of protein kinase A in the epinephrine cascade, however, results in phosphorylation of both perilipin and HSTL. When this occurs, perilipin loosens its tight binding to the fat droplet, allowing digestion of the fat to begin by HSTL.

Perilipin expression is high in obese organisms and some mutational variants have been associated with obesity in women. Another mutation reduces perilipin expression and is associated with greater lipolysis (fat breakdown) in women. Mice lacking perilipin eat more food than wild-type mice, but gain 1/3 less weight when on the same diet.

Fat synthesis

Synthesis of fat requires action of acyl transferase enzymes, such as glycerol-3 O-phosphate acyl transferase, which catalyzes addition of fatty acids to the glycerol backbone (reaction #1 above). The process requires glycerol-3-phosphate (or DHAP) and three fatty acids. In the first reaction, glycerol-3-phosphate is esterified at position 1 with a fatty acid, followed by a duplicate re-

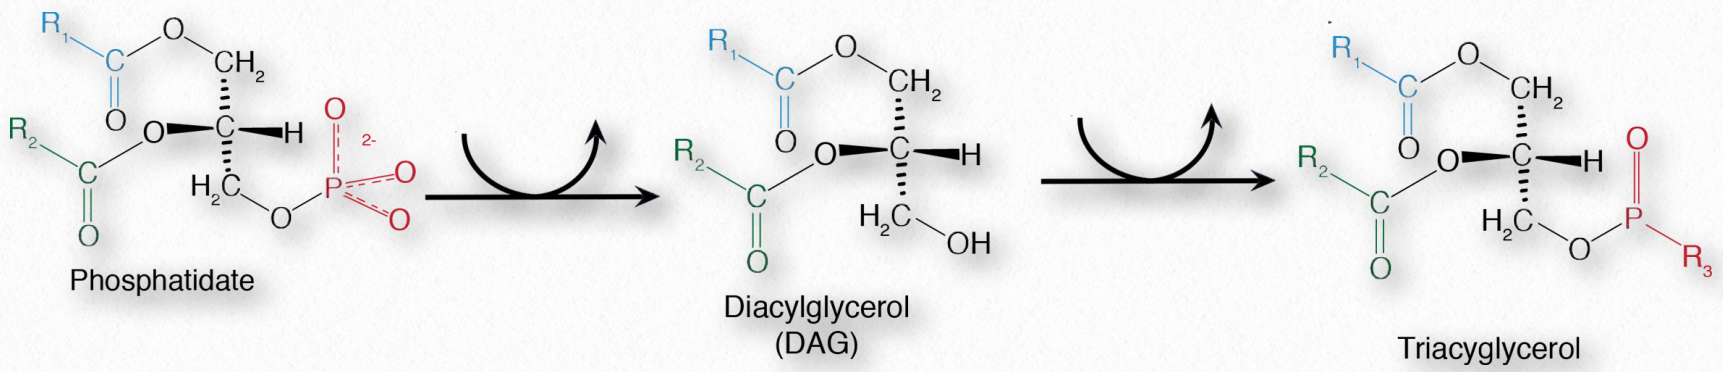

Figure 6.85 - Synthesis of fat from phosphatidic acid (phosphatidate)

Image by Penelope Irving

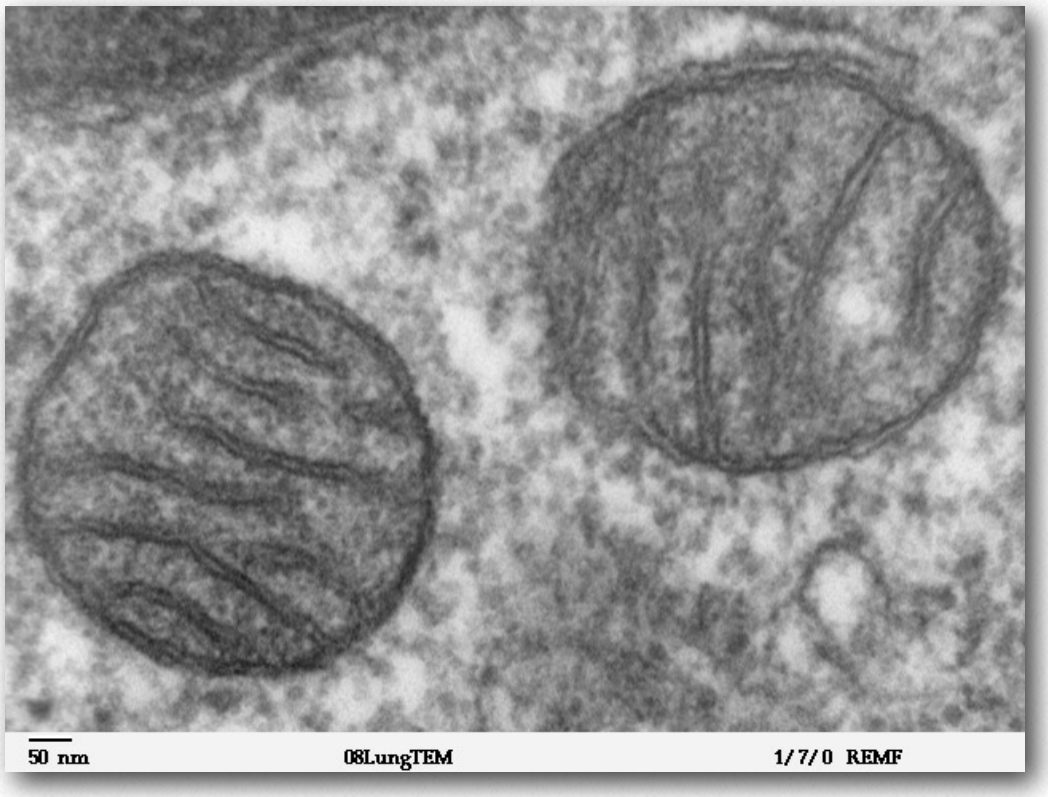

Figure 6.86 - Mitochondria - site of β-oxidation

action at position 2 to make phosphatidic acid (diacylglycerol phosphate). This molecule, which is an intermediate in the synthesis of both fats and phosphoglycerides, gets dephosphorylated to form diacylglycerol before the esterification of the third fatty acid to the molecule to make a fat.

Fatty acids released from adipocytes travel in the bloodstream bound to serum albumin. Arriving at target cells, fatty acids are taken up by membrane-associated fatty acid binding proteins, which help control cellular fatty acid uptake by transport proteins. Players in this process include CD36, plasma membrane-associated fatty acid-binding protein, and a family of fatty acid transport proteins (called FATP1-6).

Fatty acid oxidation

Upon arrival inside of target cells, fatty acids are oxidized in a process that chops off two carbons at a time

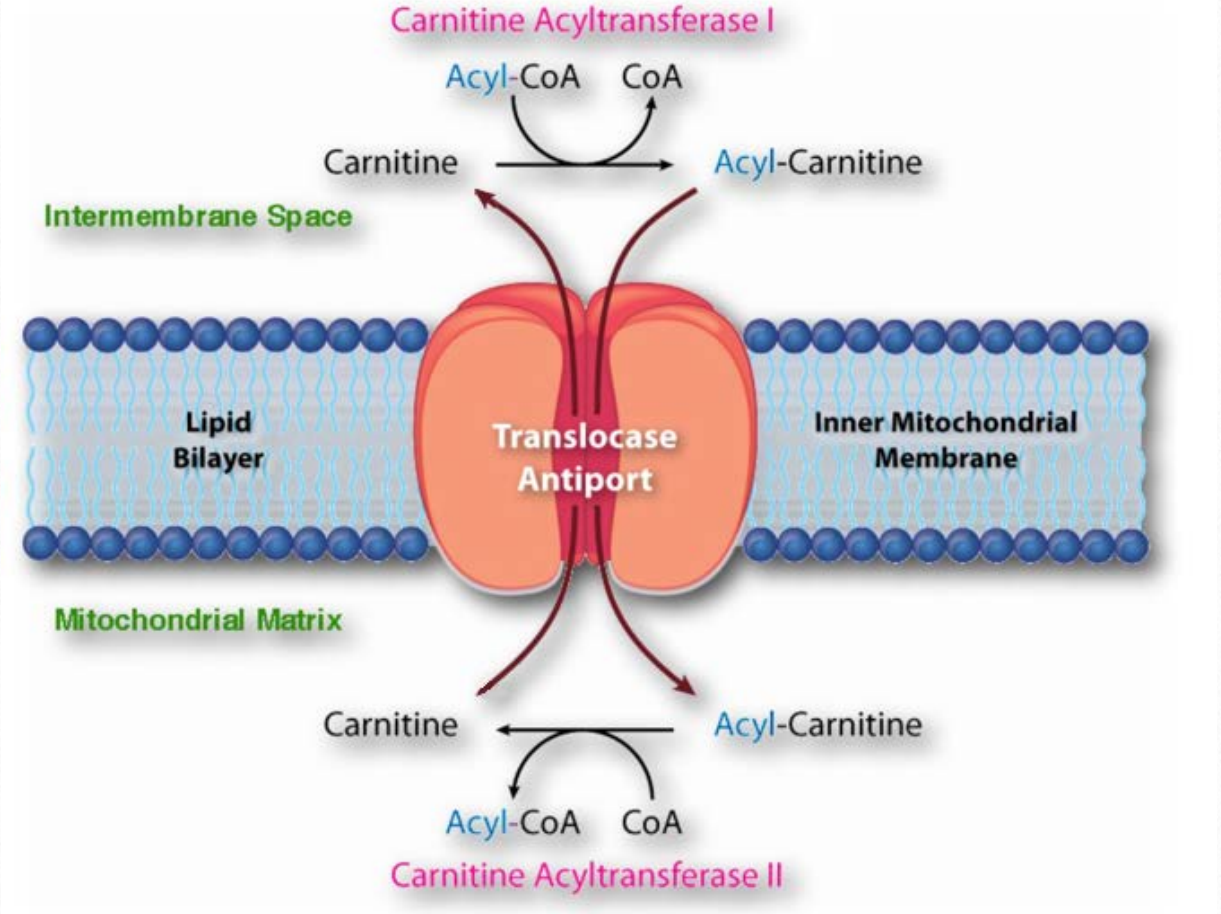

Figure 6.87 - Transport of fatty acid (acyl group) across mitochondrial inner membrane

Image by Aleia Kim

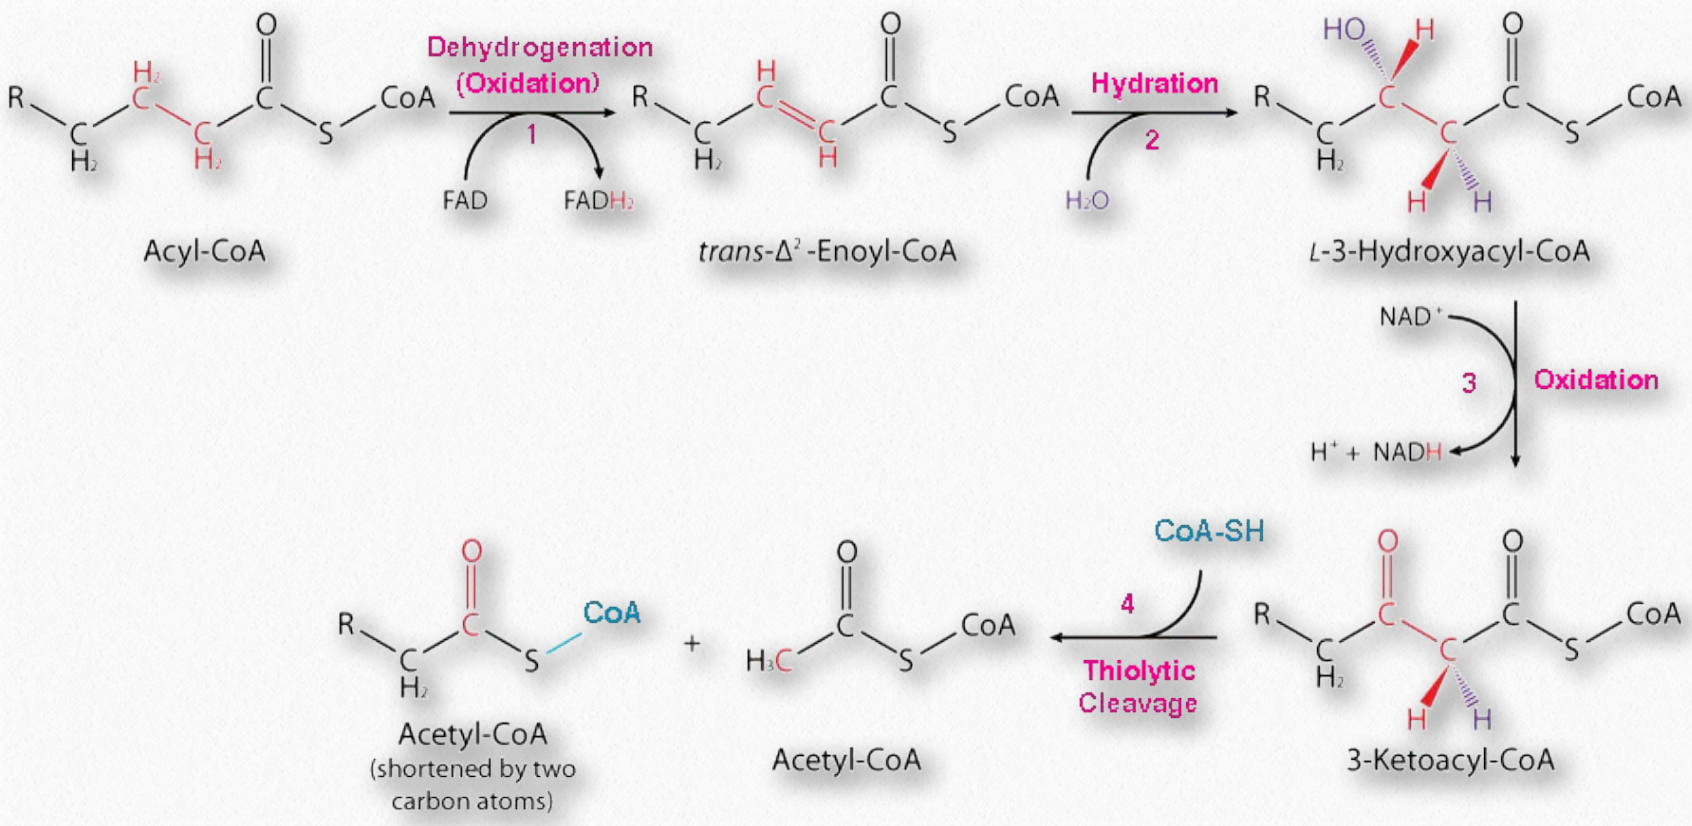

Figure 6.88 - Four reactions in β-oxidation

Image by Aleia Kim

to make acetyl-CoA, which is subsequently oxidized in the citric acid cycle. Depending on the size of the fatty acid, this process (called β-oxidation) will begin in either the mitochondrion (Figure 6.86) or the peroxisomes (see HERE).

Transport

To be oxidized in the mitochondrion, fatty acids must first be attached to coenzyme A (CoA-SH or CoA) and transported through the cytoplasm and the outer mitochondrial membrane. In the mitochondrion's intermembrane space, the CoA on the fatty acid is replaced by a carnitine (Figure 6.87) in order to be moved into the matrix. After this is done, the fatty acid linked to carnitine is transported into the mitochondrial matrix and in the matrix the carnitine is replaced again by coenzyme A. It is in the mitochondrial matrix where the oxidation occurs. The fatty acid linked to CoA (called an acyl-CoA) is the substrate for fatty acid oxidation.

YouTube Lectures by Kevin HERE & HERE

Steps

The process of fatty acid oxidation (Figure 6.88) is fairly simple. The reactions all occur between carbons 2 and 3 (with #1 being the one linked to the CoA) and sequentially include the following steps 1) dehydrogenation to create $FADH_2$ and a fatty acyl group with a double bond between carbons 2 and 3 in the *trans* configuration; 2) hydration across the double bond to put a hydroxyl group on carbon 3 in the L configuration; 3) oxidation of the

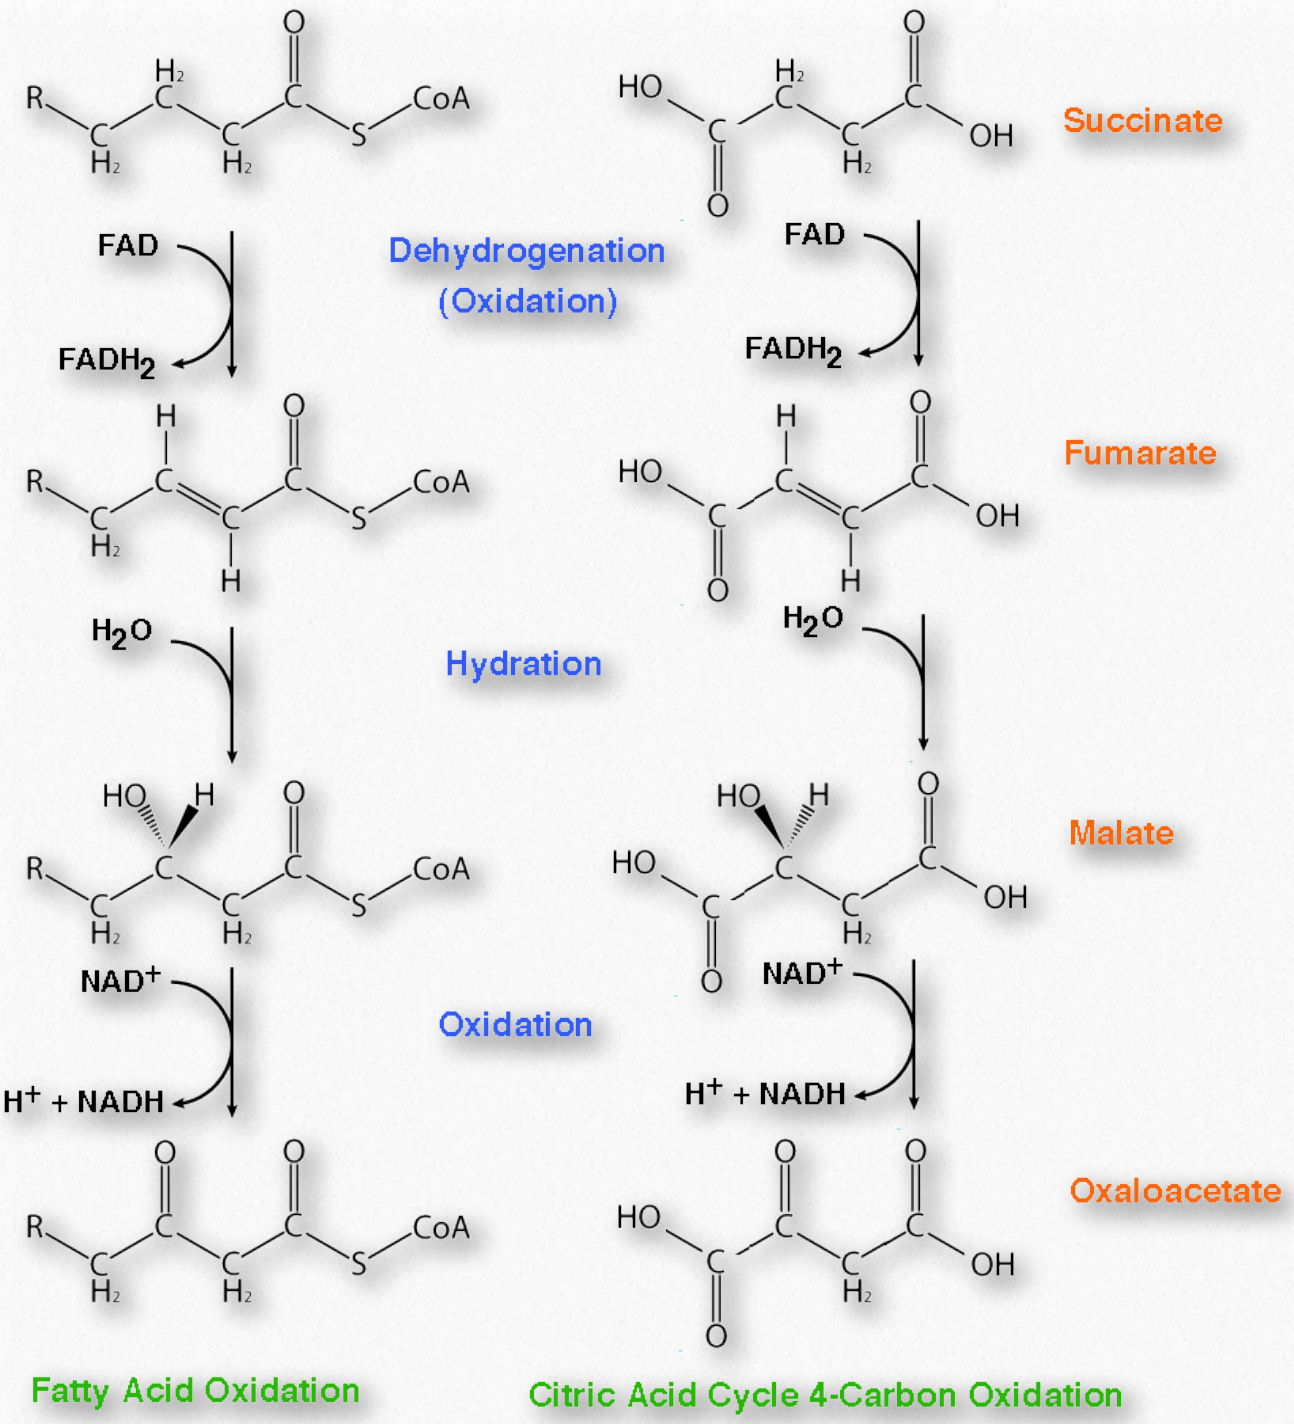

Figure 6.89 - Similar reactions for fatty acid oxidation and oxidation of 4-carbon compounds in the citric acid cycle

Image by Aleia Kim

which catalyzes the dehydrogenation in the first reaction and yields $FADH_2$. The enzyme comes in three different forms – ones specific for long, medium, or short chain length fatty acids. The first of these is sequestered in the peroxisomes of animals (see below) whereas the ones that work on medium and shorter chain fatty acids are found in the mitochondria. Action of all three enzymes is typically needed to oxidize a fatty acid. Plants and yeast perform β-oxidation exclusively in peroxisomes.

hydroxyl group to make a ketone; and 4) thiolytic cleavage to release acetyl-CoA and a fatty acid two carbons shorter than the starting one.

Enzymes of β-oxidation

Two of the enzymes of β-oxidation are notable. The first is acyl-CoA dehydrogenase, The most interesting of the acyl-CoA dehydrogenases is the one that works on medium length fatty acids. This one, which is the one most commonly deficient in animals, has been associated with sudden infant death syndrome. Reactions two and three in β-oxidation are catalyzed by enoyl-CoA hy-

dratase and 3-hydroxyacyl-CoA dehydrogenase, respectively. The latter reaction yields an NADH.

Thiolase

The second notable enzyme of β-oxidation is thiolase because this enzyme not only catalyzes the formation of acetyl-CoAs in **β**-oxidation, but also the joining of two acetyl-CoAs (essentially the reversal of the last step of β-oxidation) to form acetoacetyl-CoA – essential for the pathways of ketone body synthesis and cholesterol biosynthesis.

Similarity to citric acid cycle oxidation

It is worth noting that oxidation of fatty acids is chemically very similar to oxidation of the four carbon compounds of the citric acid cycle (Figure 6.89). In fatty acid oxidation, dehydrogenation between carbons 2 and 3 generates electrons which are donated to FAD to make $FADH_2$ and a *trans*-bonded intermediate is formed.

The same thing happens in the citric acid cycle reaction catalyzed by succinate dehydrogenase - the *trans*-bonded molecule is fumarate. Addition of water in the second step of fatty acid oxidation occurs also in the next step of the citric acid cycle catalyzed by fumarase to create malate. Oxidation of the hydroxyl on carbon 3 in β-oxidation is repeated in the citric acid cycle reaction catalyzed by malate dehydrogenase yielding oxaloacetate.

Oxidation of odd chain fatty acids

Though most fatty acids of biological origin have even numbers of carbons, not all of them do. Oxidation of fatty acids with odd numbers of carbons ultimately produces an intermediate with three carbons called

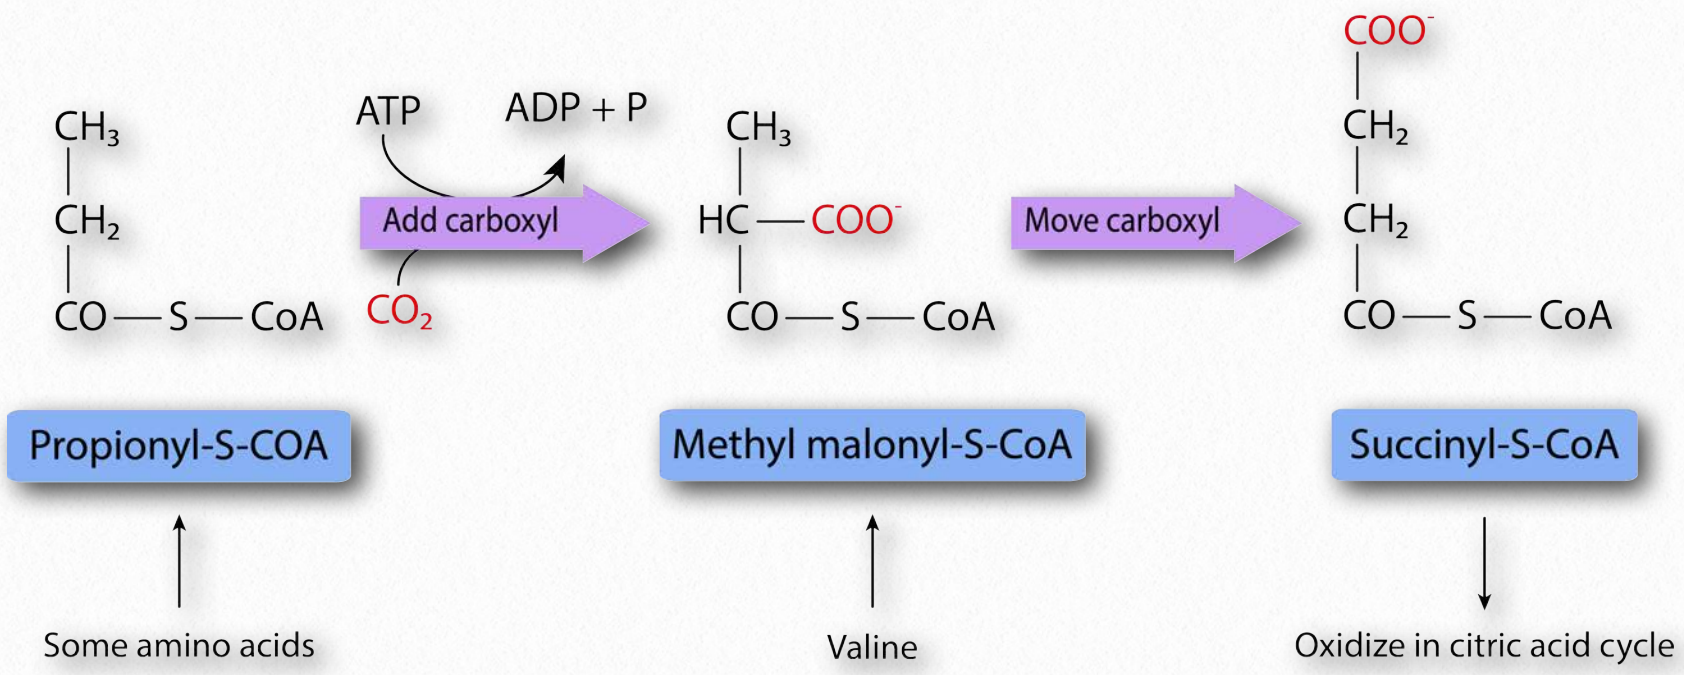

Figure 6.90 - Metabolism of propionyl-CoA

Image by Pehr Jacobson

In beta oxidation, it just occurred to me
The process all takes place 'tween carbons two and three
Some hydrogens are first removed to $FADH_2$
Then water adds across the bond, the H to carbon two
Hydroxyl oxidation's next, a ketone carbon three
Then thiolase catalysis dissects the last two C's
The products of the path, of course, are acetyl-CoAs
Unless there were odd carbons, hence propionyl-CoA

propionyl-CoA, which cannot be oxidized further in the β-oxidation pathway.

Metabolism of this intermediate is odd. Sequentially, the following steps occur (Figure 6.90) – 1) carboxylation to make D-methylmalonyl-CoA; 2) isomerization to L-methylmalonyl-CoA; 3) rearrangement to form succinyl-CoA. The last step of the process utilizes the enzyme methylmalonyl-CoA mutase, which uses the B_{12} coenzyme in its catalytic cycle. Succinyl-CoA can be metabolized in the citric acid cycle.

Peroxisomal oxidation

Long chain fatty acids (typically 22 carbons or more - Figure 6.91) have their oxidation initiated in the peroxisomes, due to the localization of the long acyl-CoA dehydrogenase in that organelle. Peroxisomal fatty acid oxidation is chemically similar to β-oxidation of mitochondria, but there are some differences in the overall process.

Differences

First, since there is no electron transport system in peroxisomes, the reduced electron carriers produced in oxidation there must have their own recycling process. Peroxisomes accomplish this by transferring electrons and protons from $FADH_2$ to O_2 to form hydrogen peroxide (H_2O_2). As a result of this, the lack of electron transport means no proton pump and, consequently, no ATP produced from $FADH_2$ for peroxisomal fatty acid oxidation, making it less efficient that mitochondrial β-oxidation.

Electrons from NADH produced in the third step of the fatty acid oxidation must be shuttled to the cytoplasm and ultimately to the mitochondrion for ATP generation. Peroxisomal oxidation is increased for individuals on a high fat diet. In addition to long chain fatty acids, peroxisomes are also involved in

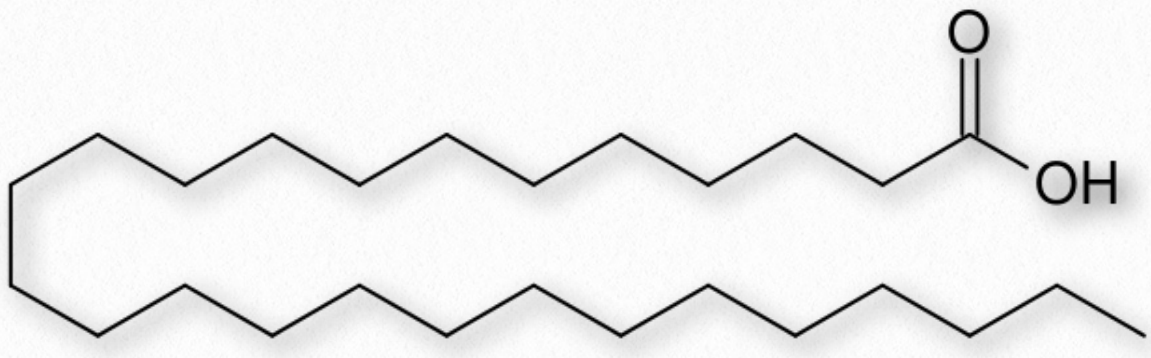

Figure 6.91 - Cerotic acid - A long chain fatty acid with 26 carbons

oxidation of branched chain fatty acids, leukotrienes, and some prostaglandins.

Unsaturated fatty acid oxidation

Unsaturated fatty acids complicate the oxidation process a bit (see below), primarily because they have *cis* bonds, for the most part, if they are of biological origin, and these must be converted to the relevant *trans* intermediates for β-oxidation. Sometimes the bond must be moved down the chain, as well, in order to be positioned properly. Two enzymes (described below) handle all the necessary isomerizations and moves necessary to oxidize all of the unsaturated fatty acids (Figure 6.92).

YouTube Lectures by Kevin
HERE & HERE

Extra enzymes

As noted above, oxidation of unsaturated fatty acids requires two additional enzymes to the complement of enzymes for β-oxidation. If the β-oxidation of the fatty acid produces an intermediate with a *cis* bond between carbons three and four, *cis*-Δ3-enoyl-CoA isomerase will convert the bond to a *trans* bond between carbons two and three and β-oxidation can proceed as normal.

On the other hand, if β-oxidation produces an intermediate with a *cis* double bond between carbons four and five, the first step of β-oxidation (dehydrogenation between car-

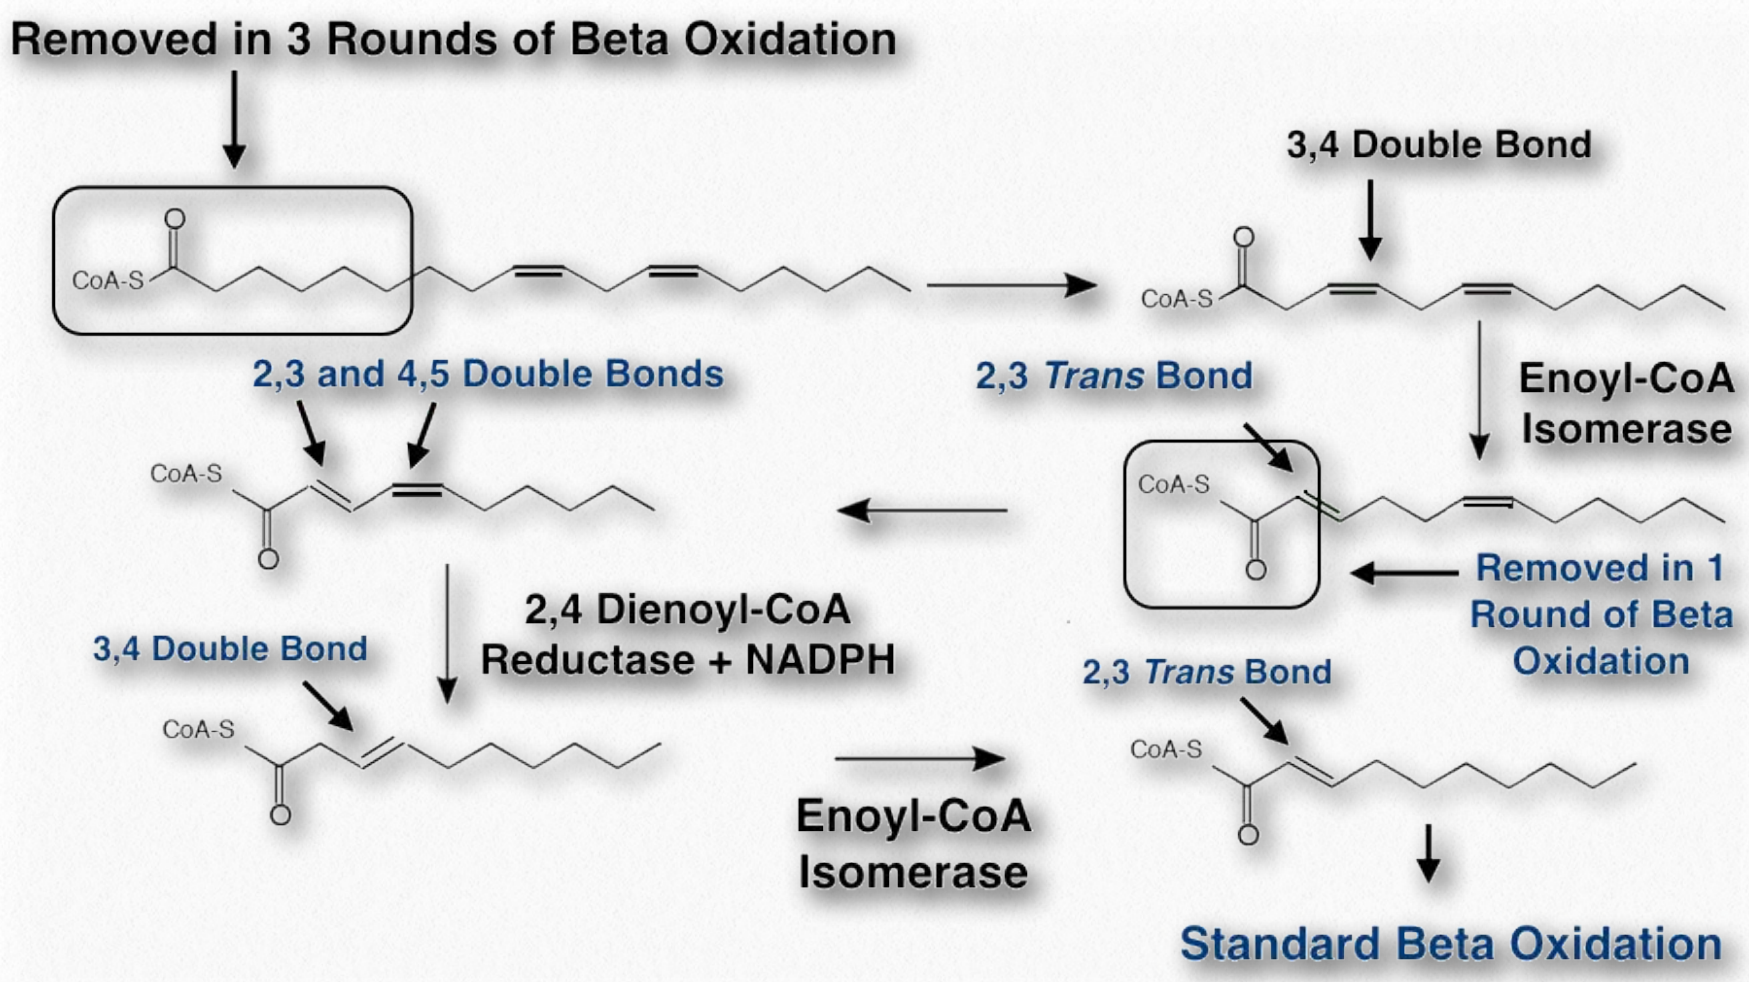

Figure 6.92 - Unsaturated fatty acid oxidation

bons two and three) occurs to produce an intermediate with a *trans* double bond between carbons two and three and a *cis* double bond between carbons four and five.

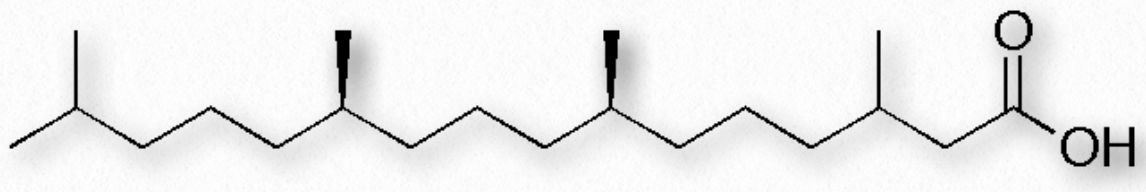

Figure 6.93 - Phytanic acid

2,4 dienoyl-CoA reductase

The enzyme 2,4 dienoyl CoA reductase reduces this intermediate (using NADPH) to one with a single *cis* bond between carbons three and four. The newly created *cis*-bonded molecule is then identical to the one acted on by *cis*-Δ3-enoyl-CoA isomerase above, which converts it into a regular **β**-oxidation intermediate, as noted above.

α-oxidation

Yet another consideration for oxidation of fatty acids is **α**-oxidation. This pathway, which occurs in peroxisomes, is necessary for catabolism of fatty acids that have branches in their chains. For example, breakdown of chlorophyll's phytol group yields phytanic acid (Figure 6.93), which undergoes hydroxylation and oxidation on carbon number two (in contrast to carbon three of β-oxidation), followed by decarboxylation and production of an unbranched intermediate that can be further oxidized by the β-oxidation pathway. Though **α**-oxidation is a relatively minor metabolic pathway, the inability to perform the reactions of the pathway leads to Refsum's disease where accumulation of phytanic acid leads to neurological damage.

ω-oxidation of fatty acids

In addition to **β**-oxidation and **α**-oxidation of fatty acids, which occur in the mitochondria and peroxisomes of eukaryotic cells respectively, another fatty acid oxidation pathway known as **ω**-oxidation also occurs in the smooth endoplasmic reticulum of liver and kidney cells. It is normally a minor oxidation pathway operating on medium chain fatty acids (10-12 carbons), but gains importance 1) when **β**-oxidation is not functional or 2) for production of long chain intermediates, such as 20-HETE (20-hydroxyeicosatetraenoic acid), that can function in signaling.

Steps in the process involve 1) oxidation of the terminal methyl group of the fatty acid to an alcohol; 2) oxidation of the alcohol to an aldehyde, and 3) oxidation of the aldehyde group to a carboxylic acid (Figure 6.94). The first oxidation is catalyzed by a mixed function oxidase, and yields 20-HETE if the starting material is arachidonic acid.

The last two reactions are catalyzed by alcohol dehydrogenase and each requires NAD^+. After the last oxidation, the fatty acid has carboxyl groups at each end and can be attached to coenzyme A at either end and subsequently oxidized, ultimately yielding succinate.

Regulation of fatty acid oxidation

Breakdown of fatty acids is controlled at different levels. The first is by control of the availability of fatty acids from the breakdown of fat. As noted above, this process is by regulating the activity of hormone-sensitive triacylglycerol lipase (HSTL) activity by epinephrine (stimulates) and insulin (inhibits).

A second level of control of fatty acid availability is by regulation of carnitine acyl transferase (Figure 6.87 - see HERE). This enzyme controls the swapping of CoA on an acyl-CoA molecule for carnitine, a necessary step for the fatty acid to be imported into the mitochondrion for oxidation.

The enzyme is inhibited by malonyl-CoA, an intermediate in fatty acid synthesis. Thus, when fatty acids are being synthesized, import of them into the mitochondrion for oxidation is inhibited. Last, the last enzyme in the β-oxidation cycle, thiolase, is inhibited by acetyl-CoA.

Fatty acid synthesis

Synthesis of fatty acids occurs in the cytoplasm and endoplasmic reticulum of the cell and is chemically similar to the reverse of the β-oxidation process, but with a couple of key differences (Figure 6.95). The first of these occur in preparing substrates for the reactions that grow the fatty acid. Fatty acid synthesis occurs in the cytoplasm of eukary-

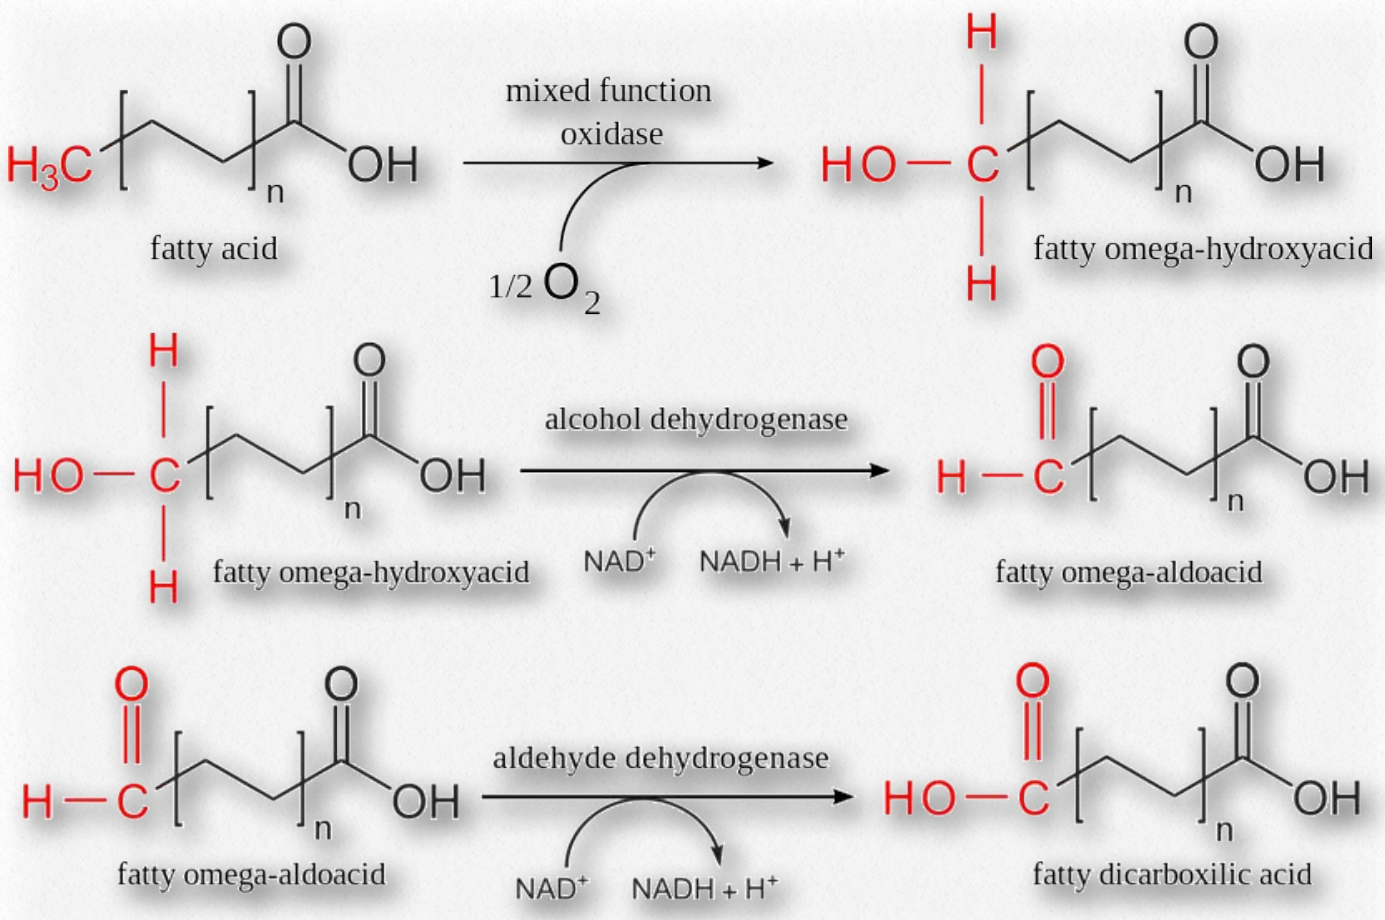

Figure 6.94 - ω Oxidation

Wikipedia

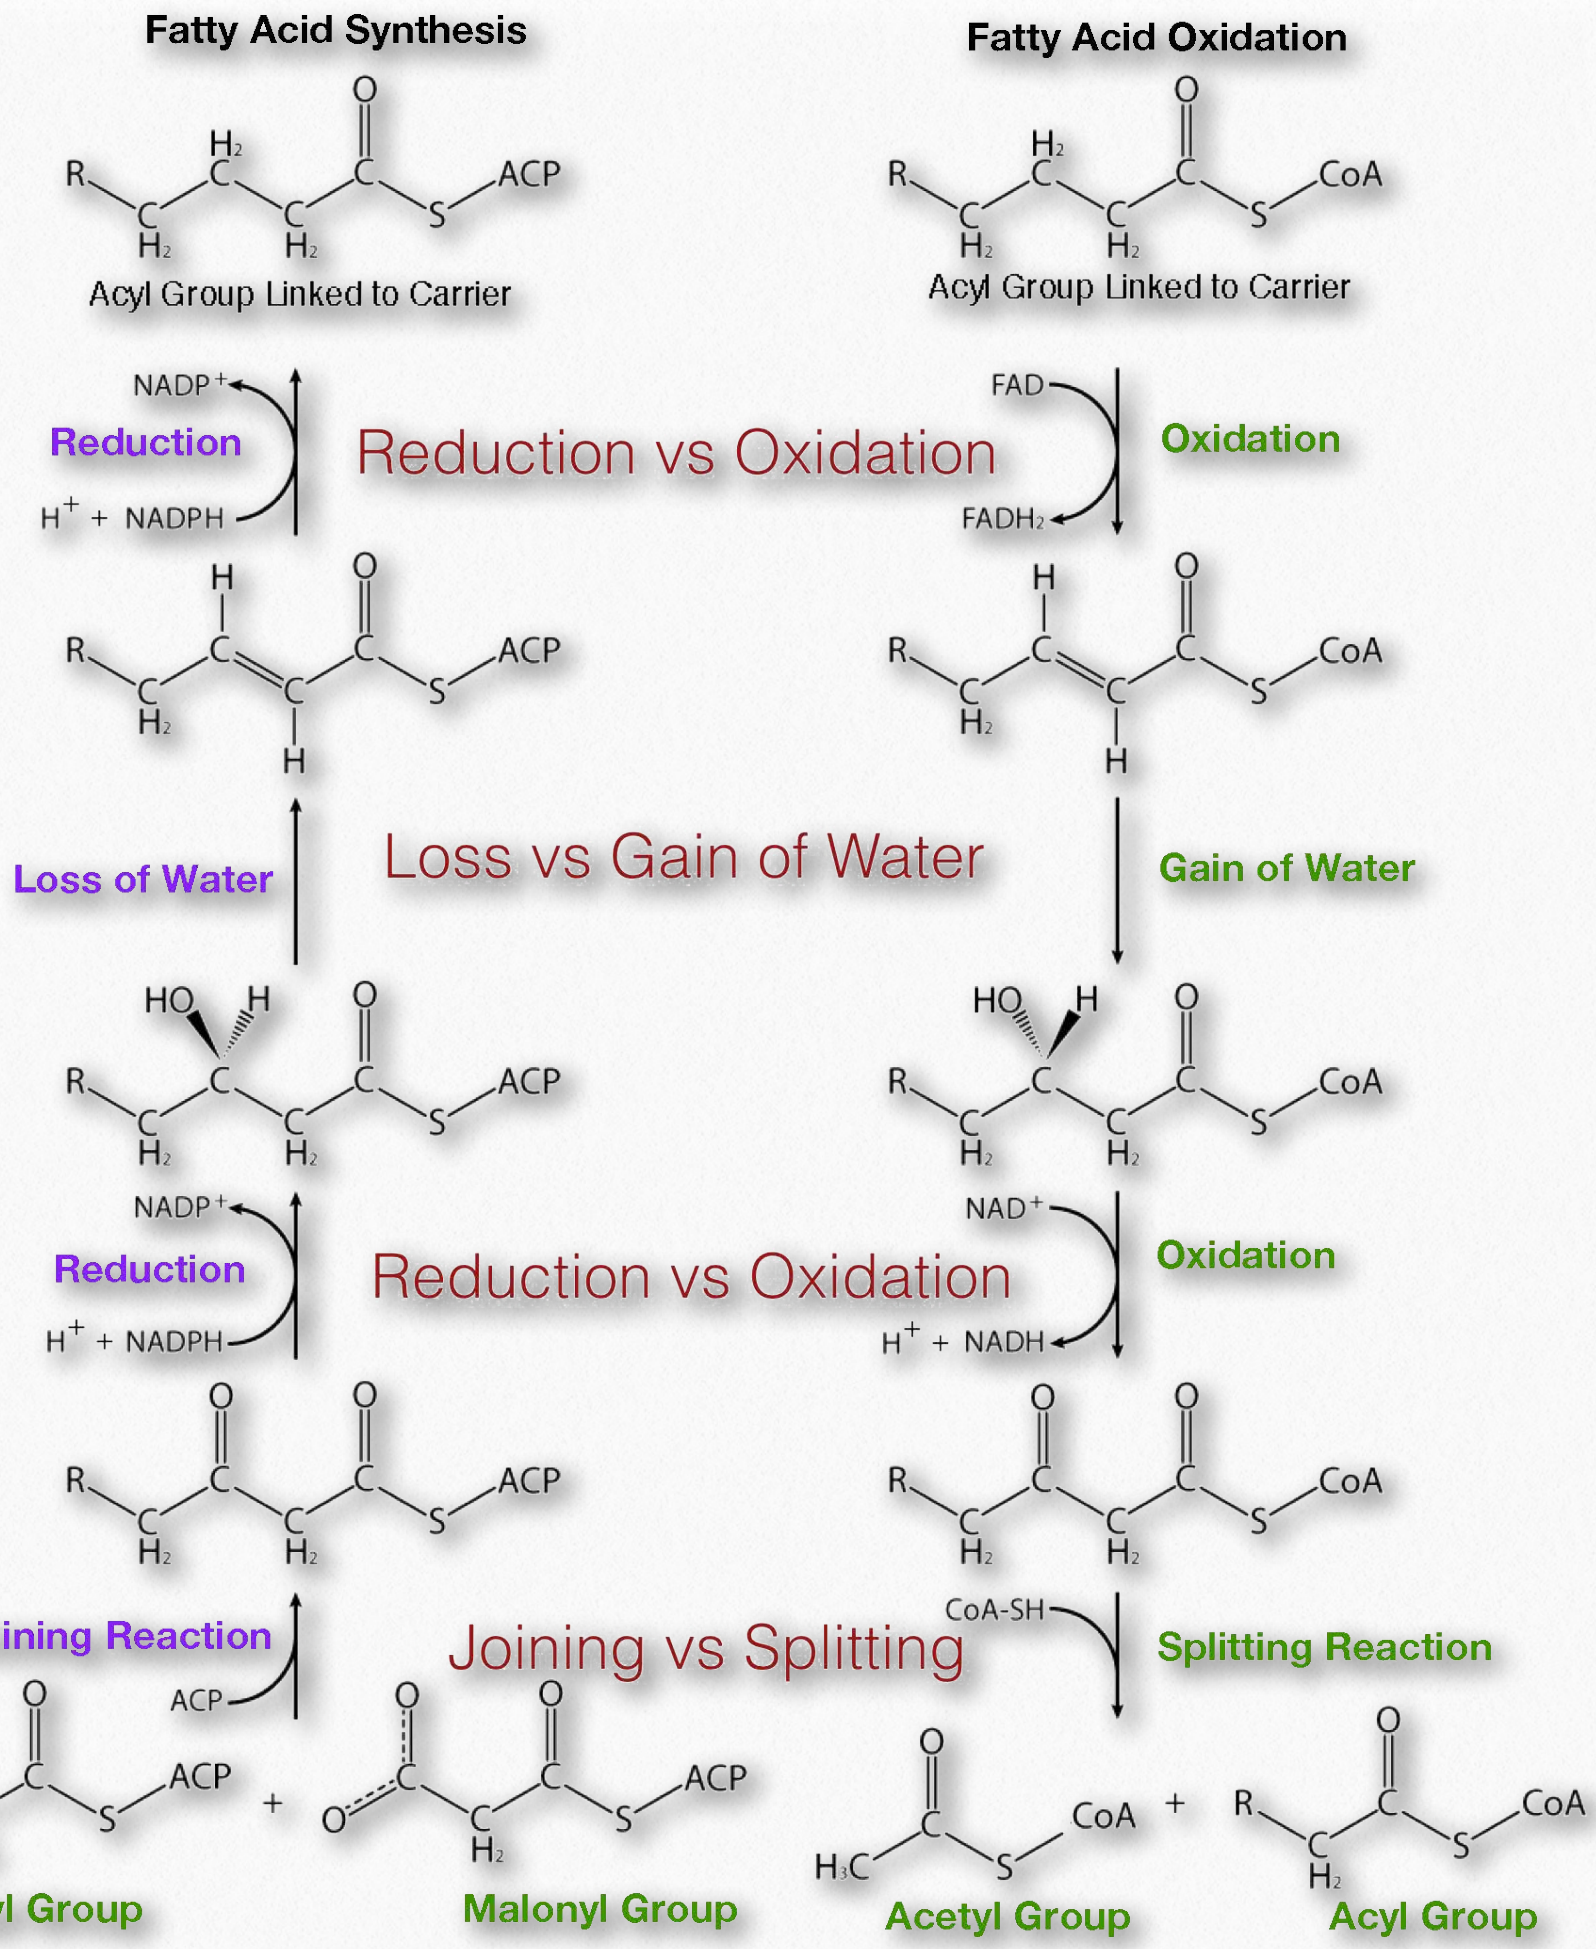

Figure 6.95 - Fatty acid synthesis is the reverse of fatty acid oxidation chemically

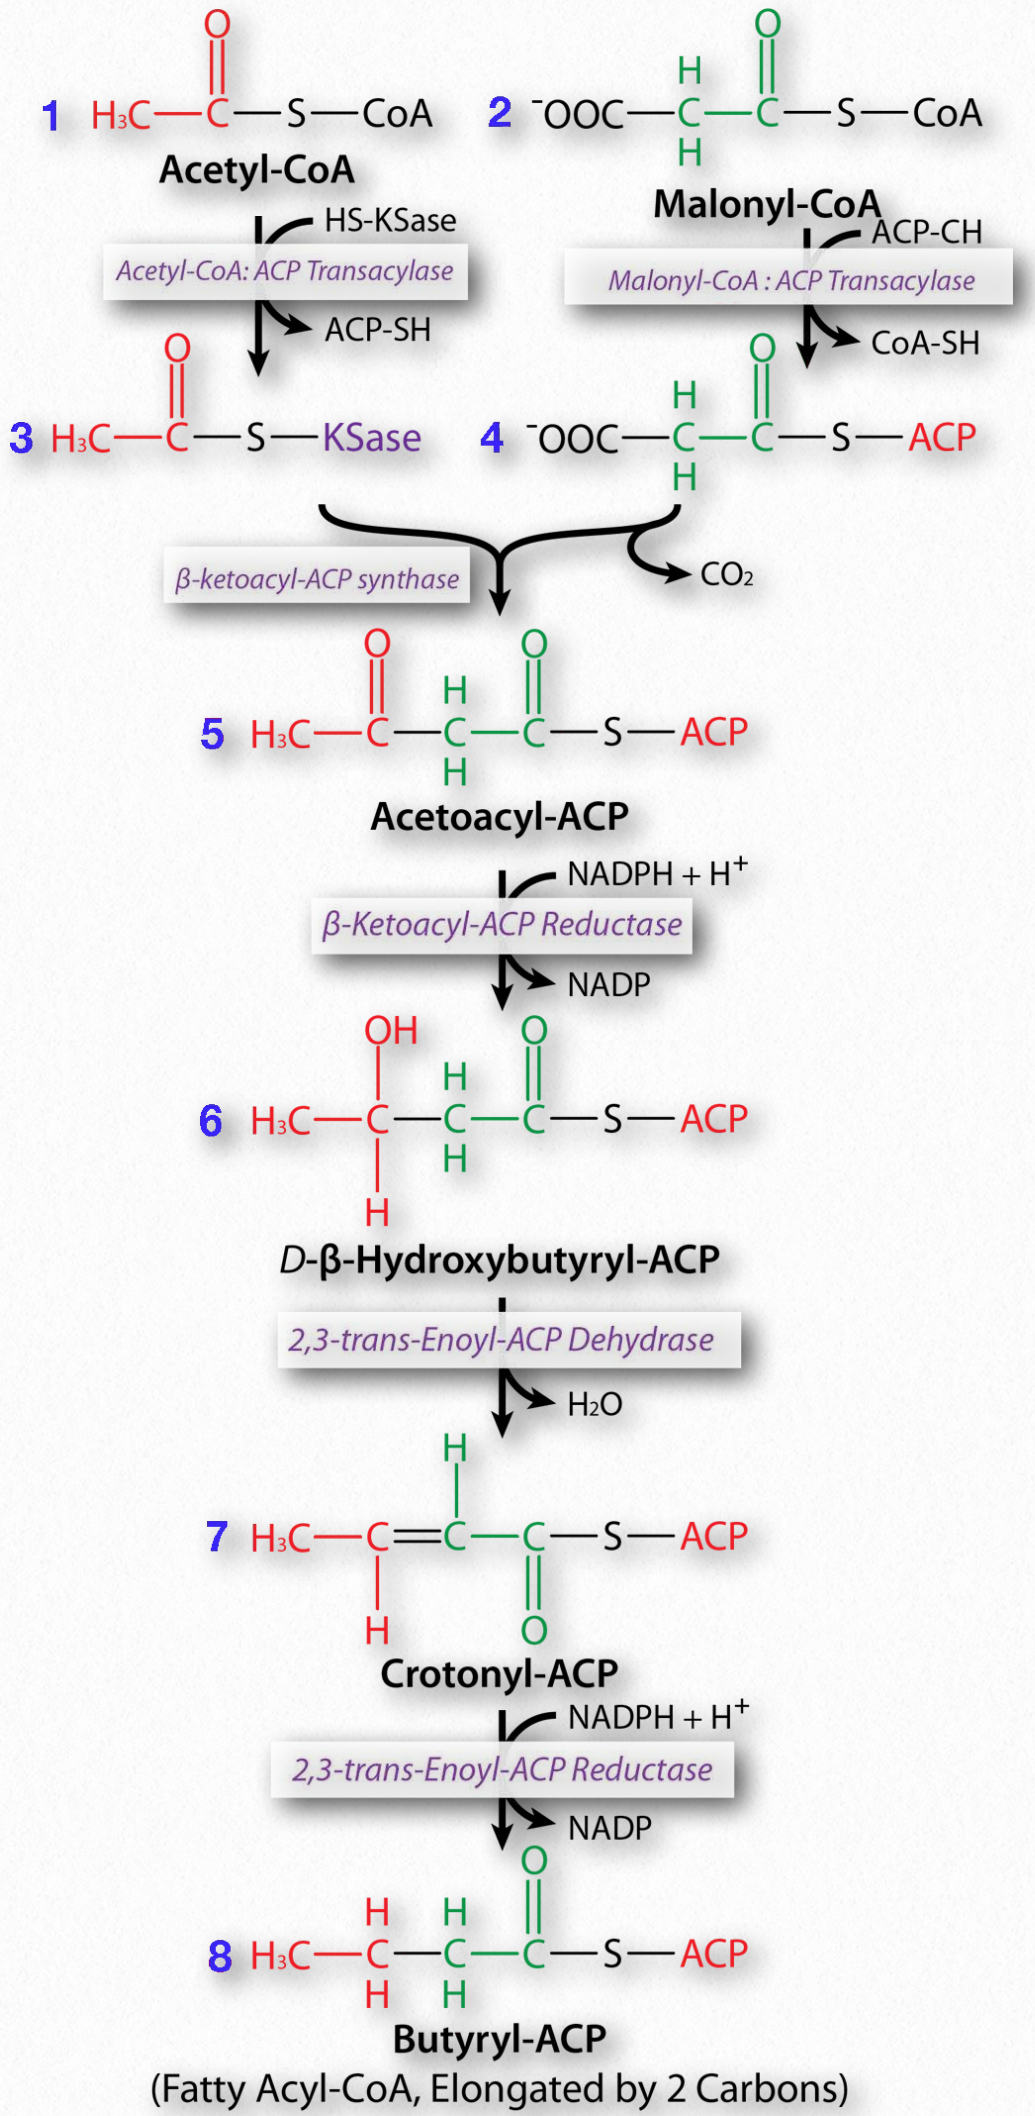

Figure 6.96 - One round of fatty acid synthesis

image by Aleia Kim

otic cells. Transport of acetyl-CoA from the mitochondrial matrix occurs when it begins to build up. This happens when the citric acid cycle slows or stops from lack of exercise.

Two molecules can play roles in moving acetyl-CoA to the cytoplasm – citrate and acetylcarnitine. Joining of oxaloacetate with acetyl-CoA in the mitochondrion creates citrate which gets transported across the membrane, followed by action of citrate lyase in the cytoplasm of the cell to release acetyl-CoA and oxaloacetate. Additionally, when free acetyl-CoA accumulates in the mitochondrion, it may combine with carnitine and be transported out to the cytoplasm.

Fatty acid synthase

In animals, six different catalytic activities necessary to fully make palmitoyl-CoA are contained in a single complex called Fatty Acid Synthase. As shown in Figures 6.96 and 6.97, these include 1) transacylases (MAT) for swapping CoA-SH with ACP-SH on acetyl-CoA and malonyl-CoA; 2) a synthase (KS) to catalyze addition of the two carbon unit from the three carbon malonyl-ACP in the first step of the elongation process; 3) a reductase (KR) to

reduce the ketone; 4) a dehydrase (DH) to catalyze removal of water; 5) a reductase (ER) to reduce the *trans* double bond and 6) a thioesterase (TE) to cleave the finished palmitoyl-CoA into palmitic acid and CoA-SH.

In the middle of the complex is a site for binding the ACP portion of the growing fatty acid chain to hold it as the other part of the fatty acid is rotated into positions around the enzyme complex for each catalysis. In bacteria, these six activities are found on separate enzymes and are not part of a complex.

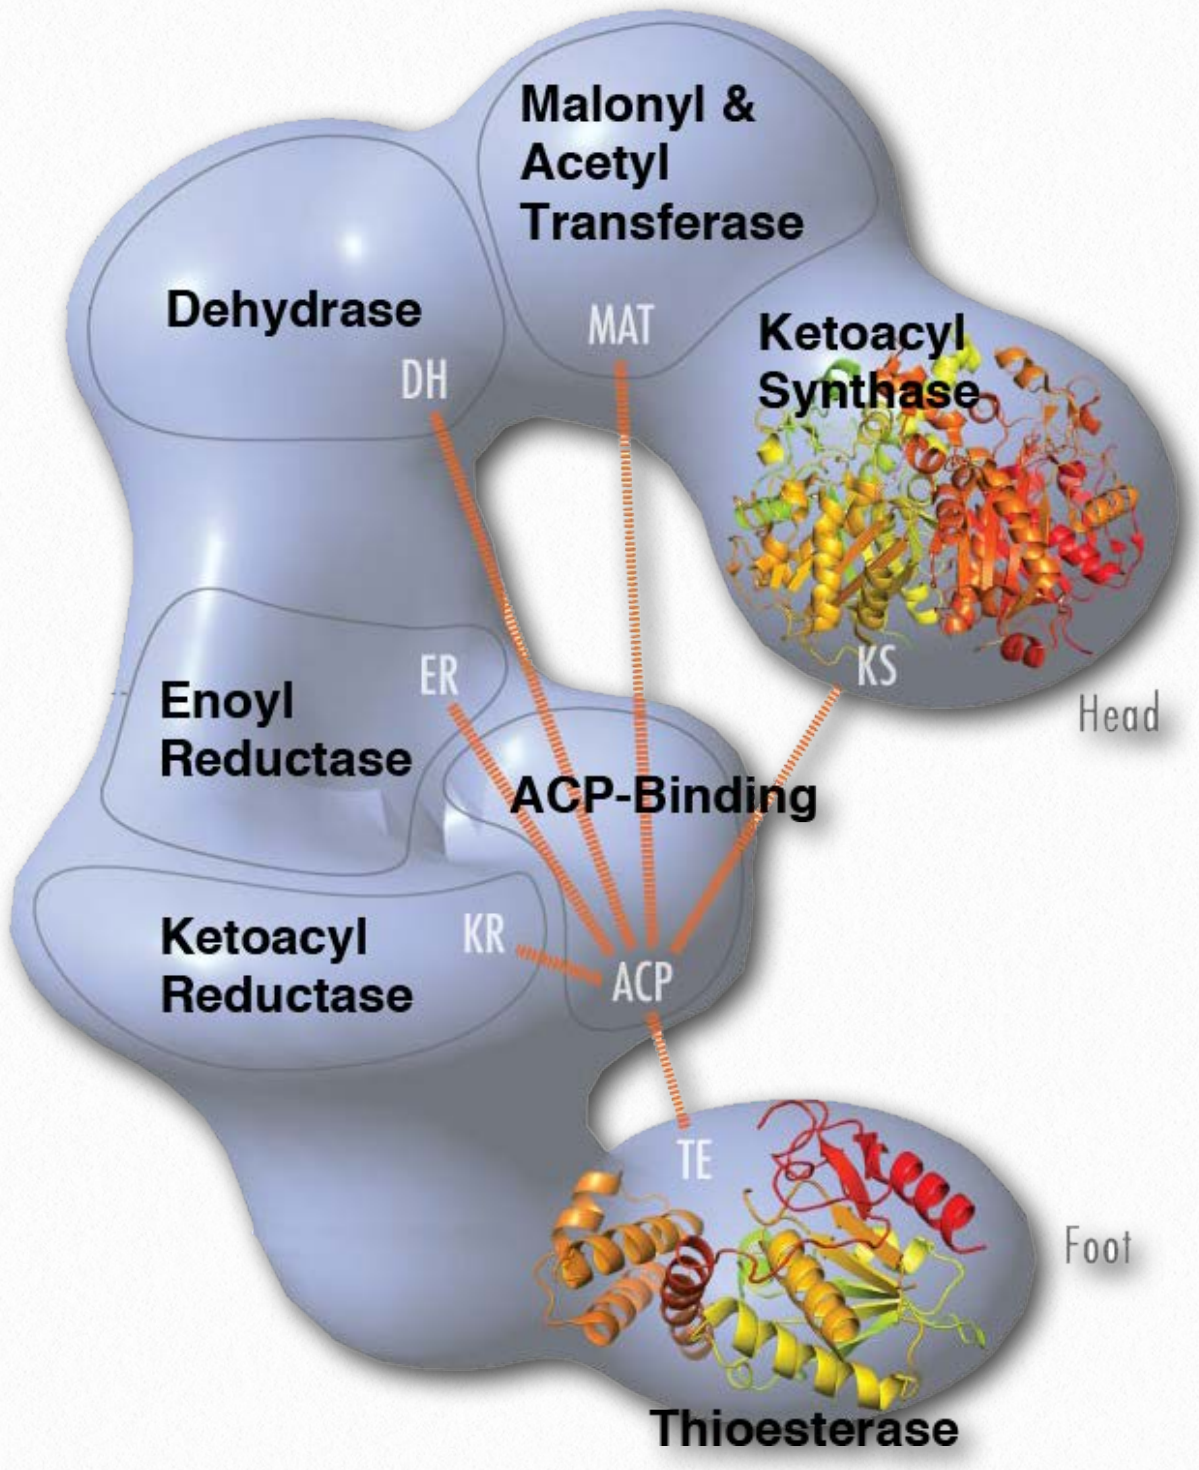

Figure 6.97 - Fatty acid synthase complex

Cytoplasmic reactions

The process of making a fatty acid in the cytoplasm starts with two acetyl-CoA molecules. One is converted to malonyl-CoA by adding a carboxyl group. This reaction is catalyzed by the enzyme acetyl-CoA carboxylase (ACC), the only regulated enzyme of fatty acid synthesis (see below) and the only one separate from the fatty acid synthase. Next, both acetyl-CoA and malonyl-CoA have their CoA portions replaced by a carrier protein known as ACP (acyl-carrier protein) to form acetyl-ACP (catalyzed by acetyl-CoA : ACP transacylase - MAT in Figure 6.97) and malonyl-ACP (catalyzed by malonyl-CoA : ACP transacylase - MAT in Figure 6.97). Joining of a fatty acyl-ACP (in this case, acetyl-ACP) with malonyl-ACP splits out the car-

For fatty acid synthesis, I must reverse the path
Of breaking fatty acids, though you'll wonder 'bout the math

Each cycle of addition starts with carbons one two three
Yet products of reactions number carbons evenly

The reason is that CO_2 plays peek-a-boo like games
By linking to an Ac-CoA then popping off again

Reactions are like oxidations 'cept they're backwards here
Reduction, dehydration, then two hydrogens appear

The product of the process is a 16 carbon chain
The bonds are saturated. No double ones remain

For them desaturases toil to put in links of *cis*
In animals to delta nine, but no more go past this

They're made by elongases in the *e. reticulum*

Kevin Ahern

boxyl group from malonyl-ACP that was added to it and creates the acetoacyl-ACP intermediate (catalyzed by **β**-ketoacyl-ACP synthase - KS on Figure 6.97) .

From this point forward, the chemical reactions resemble those of β-oxidation reversed. First, the ketone is reduced to a hydroxyl using NADPH (catalyzed by **β**-ketoacyl-ACP reductase - KR on Figure 6.97). In contrast to the hydroxylated intermediate of **β**-oxidation, the intermediate here (D-β- hydroxybutyryl-ACP) is in the D-configuration.

Dehydration

Next, water is removed from carbons 2 and 3 of the hydroxyl intermediate in a reaction catalyzed by 2,3-*trans*-enoyl-ACP dehydrase - DH on Figure 6.97. This yields a *trans* doubled-bonded molecule. Last, the double bond is hydrogenated to yield a saturated intermediate by 2,3-trans-enoyl-ACP reductase - ER on Figure 6.97. This completes the first cycle of synthesis.

Additional cycles involve addition of more two-carbon units from malonyl-ACP to the growing chain until ultimately an intermediate with 16 carbons is produced (palmitoyl-ACP). At this point, a thioesterase cleaves the ACP from the palmitoyl-ACP to yield palmitic acid and the cytoplasmic synthesis ceases.

Regulation of fatty acid synthesis

Acetyl-CoA carboxylase, which catalyzes synthesis of malonyl-CoA, is the only regulated enzyme in fatty acid synthesis. Its regulation involves both allosteric control and covalent modification. The enzyme is known to be phosphorylated

YouTube Lectures by Kevin HERE & HERE

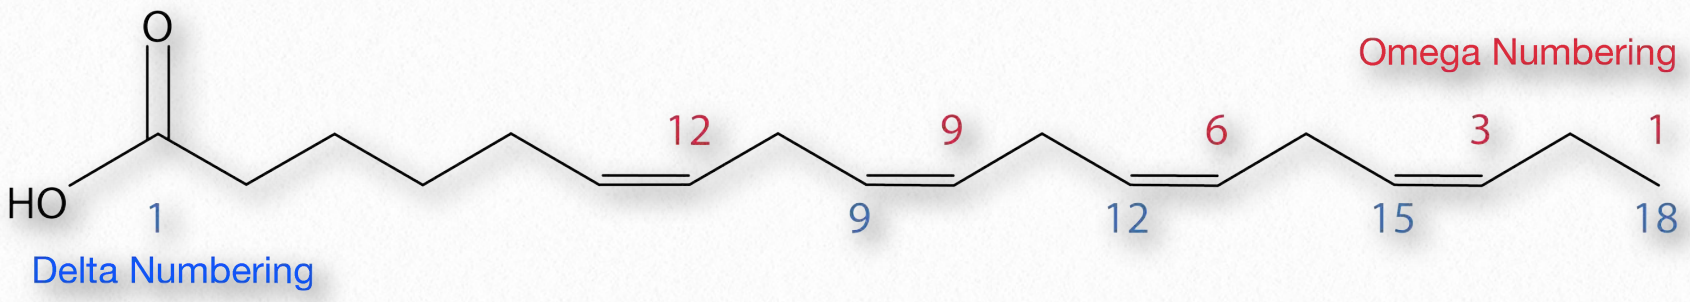

Figure 6.98 - Carbon numbering schemes for fatty acids

Image by Pehr Jacobson

by both AMP Kinase and Protein Kinase A.

Dephosphorylation is stimulated by phosphatases activated by insulin binding. Dephosphorylation activates the enzyme and favors its assembly into a long polymer, while phosphorylation reverses the process. Citrate acts as an allosteric activator and may also favor polymerization. Palmitoyl-CoA allosterically inactivates it.

Elongation past 16 carbons

Elongation to make fatty acids longer than 16 carbons occurs in the endoplasmic reticulum and is catalyzed by enzymes described as elongases. Mitochondria also can elongate fatty acids, but their starting materials are generally longer than 16 carbons long.

The mechanisms in both environments are similar to those in the cytoplasm (a malonyl group is used to add two carbons, for example), but CoA is attached to the intermediates, not ACP. Further, whereas cytoplasmic synthesis employs the fatty acid synthase complex, the enzymes in these organelles are separable and not part of a complex.

Desaturation of fatty acids

Fatty acids are synthesized in the saturated form and desaturation occurs later - in the endoplasmic reticulum. Reactions to elongate the fatty acid (with elongases) may also occur to make unsaturated fatty acids of varying lengths. Desaturases are named according to the location of the double bonds they introduce in fatty acids. The delta (Δ) system numbers the carbon at the carboxyl end as number 1 and the omega (ω) number system numbers the carbon at the methyl end as number 1 (Figure 6.98). Humans have desaturases named as Δ5, Δ6, and Δ9. A Δ9 desaturase, for example, could convert stearic acid into oleic acid, because stearic acid (see HERE) is a saturated 18 carbon fatty acid and oleic acid is an 18 carbon fatty acid with only one double bond - at position Δ9.

Polyunsaturated fatty acids

Polyunsaturated fatty acids require the action of multiple enzymes and (in some cases)

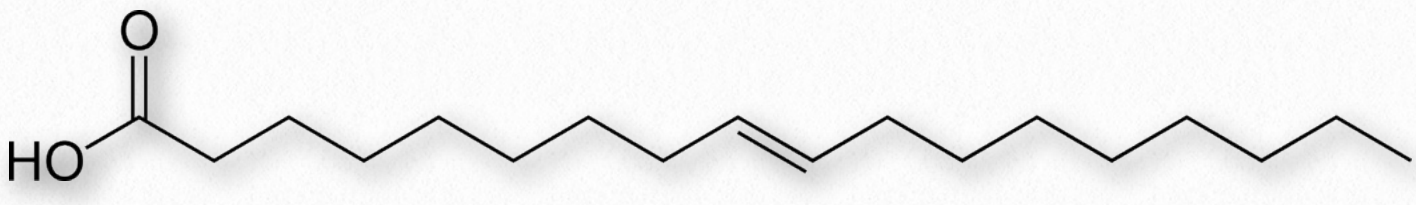

Figure 6.99 - Elaidic acid - A rare *trans* fatty acid in biology

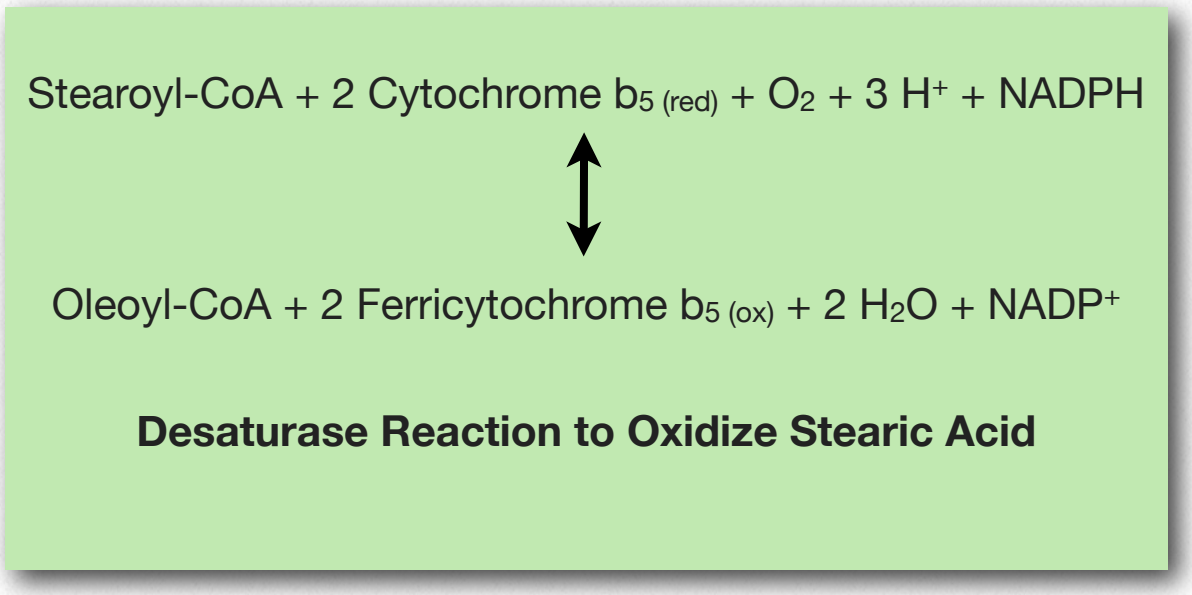
the action of elongases. Arachidonic acid, for example, is a 20 carbon fatty acid with four double bonds and its synthesis requires both an elongase (to increase the length of the fatty acid from 16 to 20) and multiple desaturases - one for each desaturated double bond.

Animals are limited in the fatty acids they can make, due to an inability of their desaturases to catalyze reactions beyond carbons Δ9. Thus, humans can make oleic acid, but cannot synthesize linoleic acid (Δ9,12) or linolenic acid (Δ9,12,15). Consequently, these two must be provided in the diet and are referred to as essential fatty acids.

Almost all desaturases make *cis*, not *trans* double bonds. There are a few minor exceptions to this, in cattle, for example (Figure 6.99). The *trans* fatty acids found in *trans* fat of prepared food are produced not by biological processes, but rather by the process of partial hydrogenation of unsaturated fats.

Unusual oxidation reaction

Removal of electrons and protons from a fatty acid to create a double bond is an oxidation reaction and these electrons, must have a destination. The path they take is a bit complex. It involves NAD(P)H, O_2, two membrane-bound cytochromes, the membrane bound desaturase, and the fatty acid.



Desaturase Reaction to Oxidize Stearic Acid

In the electron transfer, the O_2 is reduced to two molecules of H_2O. This reduction requires four electrons and four protons. Two electrons and two protons come from the fatty acid to form the double bond on it. Two electrons come from the NAD(P)H via the cytochromes and two protons come from the aqueous solution.

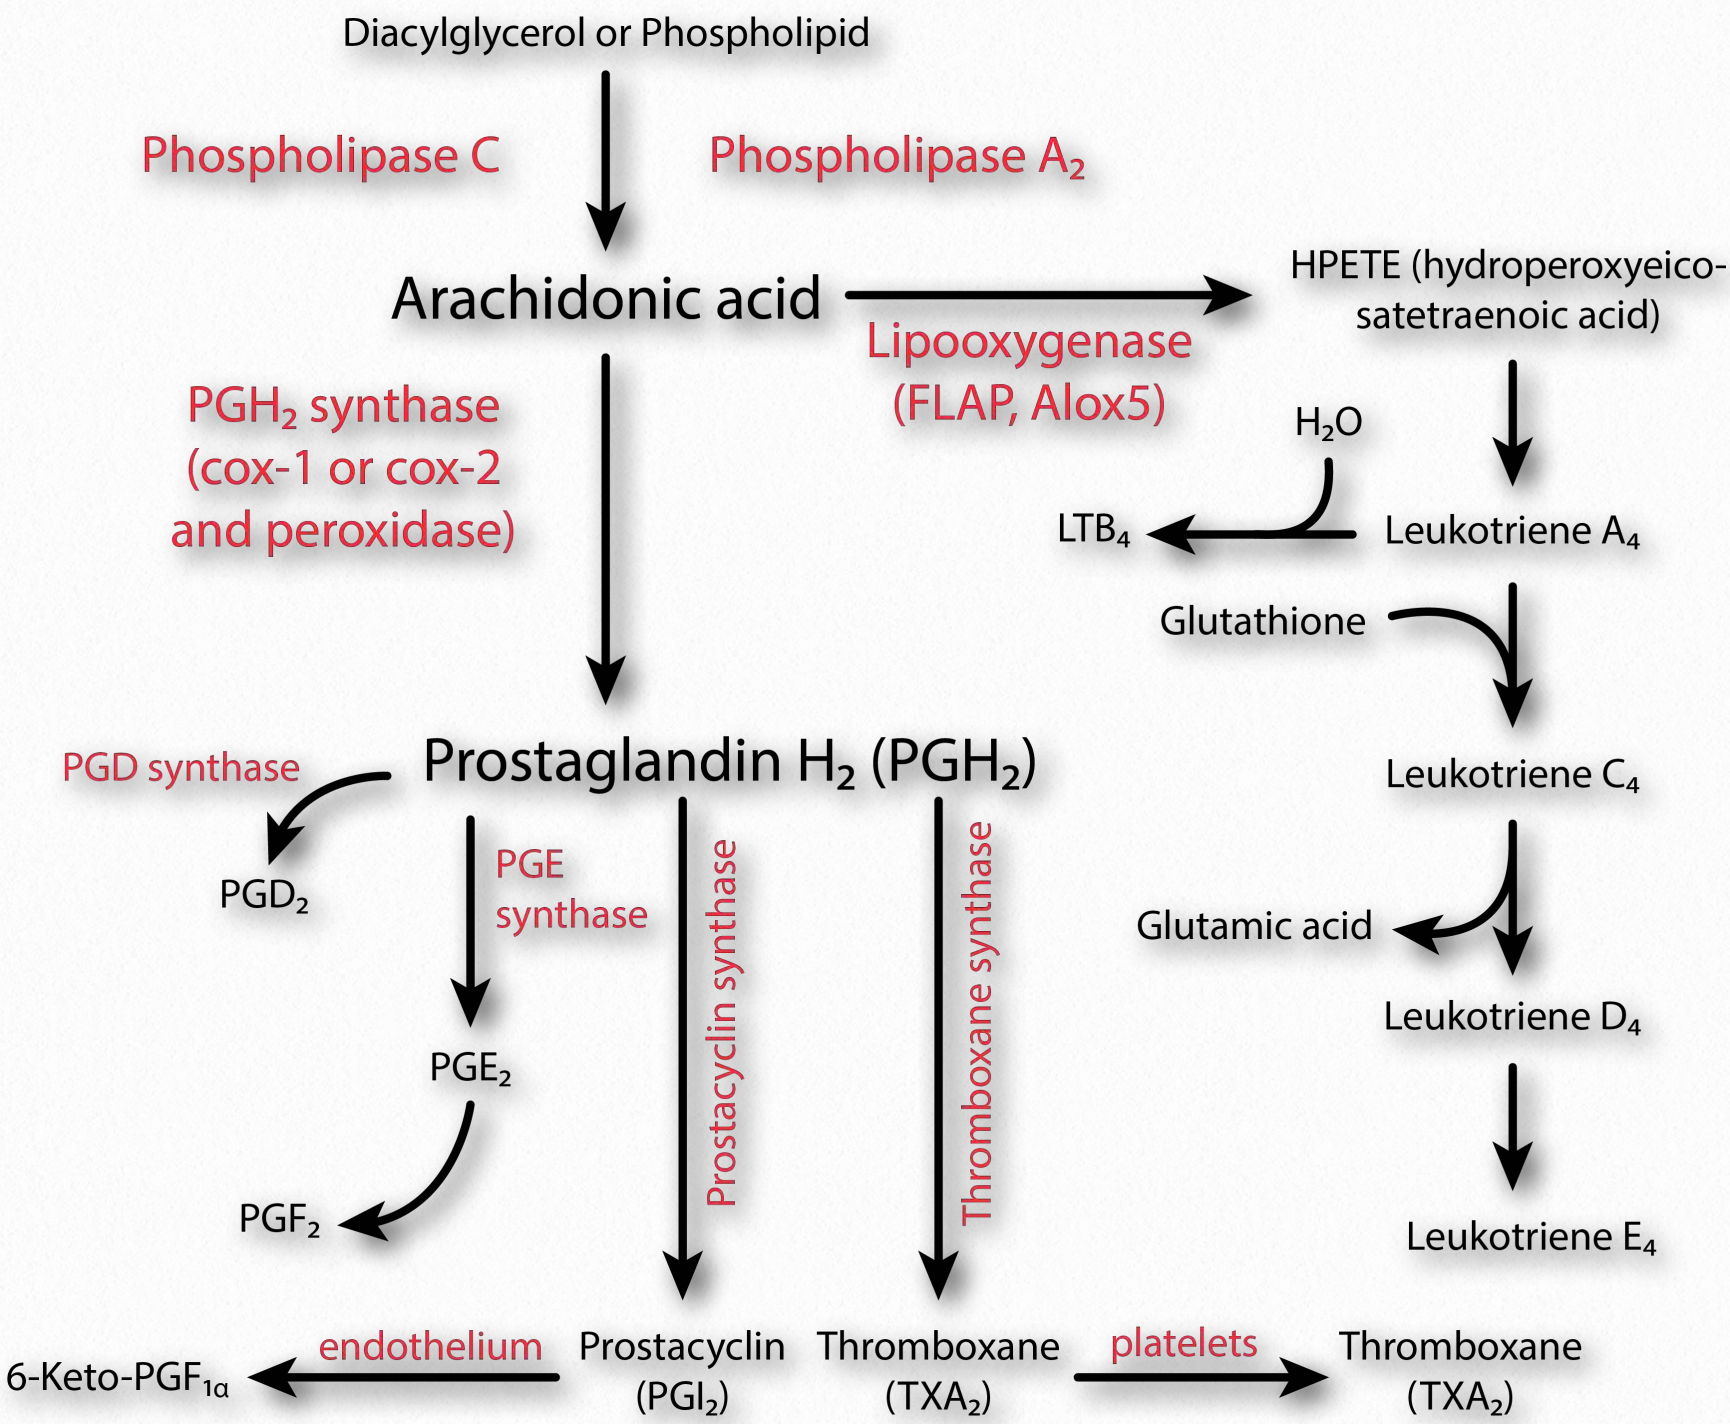


Figure 6.100 - Eicosanoid synthesis pathways

Image by Pehr Jacobson

Prostaglandin synthesis

The pathway for making prostaglandins and related molecules, such as the leukotrienes, prostacyclin, and thromboxanes is an extension of the synthesis of fatty acids (Figure 6.100).

Prostaglandins, known as eicosanoids because they contain 20 carbons, are synthesized in cells from arachidonic acid whenever it has been cleaved from membrane lipids. Prostaglandins are important for many physiological phenomena in the body, including swelling and pain and reduction of their levels is a strategy of some painkillers, such as aspirin (see below). Inflammation arising from bee stings, for example, occurs because bee (and snake) venom contains mellitin, an activator of PLA2 activity (Figure 6.100). There are two strategies for reducing prosta-

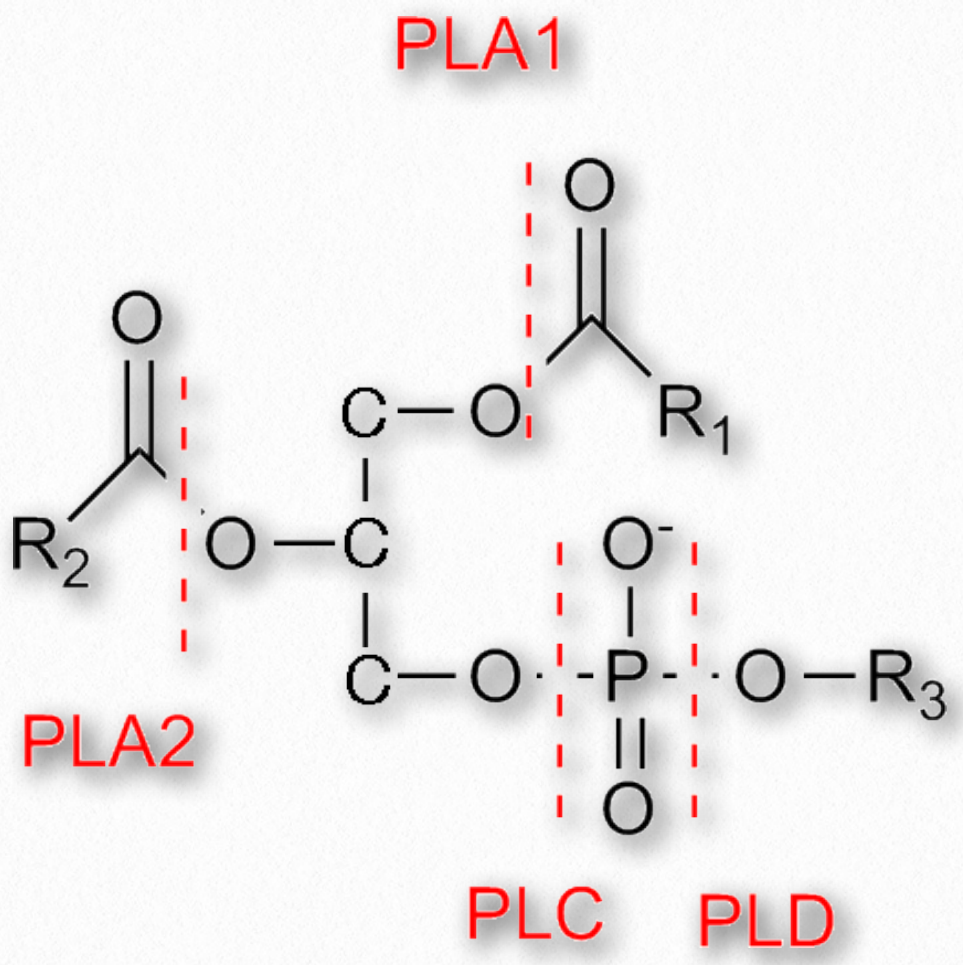

Figure 6.101 - Cleavage sites for four phospholipiases on a glycerophospholipid - phospholipases A_1 (PLA1), A_2 (PLA2), C (PLC), and D (PLD)

glandin production and the pain associated with it.

Phospholipase A_2

Action of phospholipase enzymes on glycerophospholipids produces fatty acids and either glycerol-3-phosphate or other substances. Figure 6.101 shows cleavage sites on phospholipids that are targeted by different phospholipases. Phospholipase A_1 (PLA1), for example, cleaves the fatty acid from position one of the glycerophospholipid and phospholipiase D (PLD) cleaves the R group from the phosphate part of the molecule.

Since the fatty acid on position #2 (where PLA_2 cuts) is most commonly unsaturated, PLA_2 is an important phosopholipase for hydrolyzing the unsaturated fatty acid known as arachidonic acid from glycerophospholipids. Release of arachidonic acid from membranes is necessary for synthesis of prostaglandins.

Inhibition of the release of arachidonic acid from membranes is the mechanism of action of steroidal anti-inflammatory drugs. They block action of phospholipase A_2 (PLA2 - Figure 6.101) which cleaves arachidonic acid from membrane lipids.

YouTube Lectures by Kevin HERE & HERE

Lipocortin

Lipocortin (also called annexin) is a protein that inhibits action of PLA2. Synthesis of lipocortin is stimulated by glucocorticoid hormones, such as cortisol, and is used in some treatments to reduce swelling/inflammation when it is severe and untreatable by non-steroidal drugs.

Second strategy

Synthesis of the prostanoid compounds (prostaglandins, prostacyclin, and thromboxanes) depends on conversion of arachi-

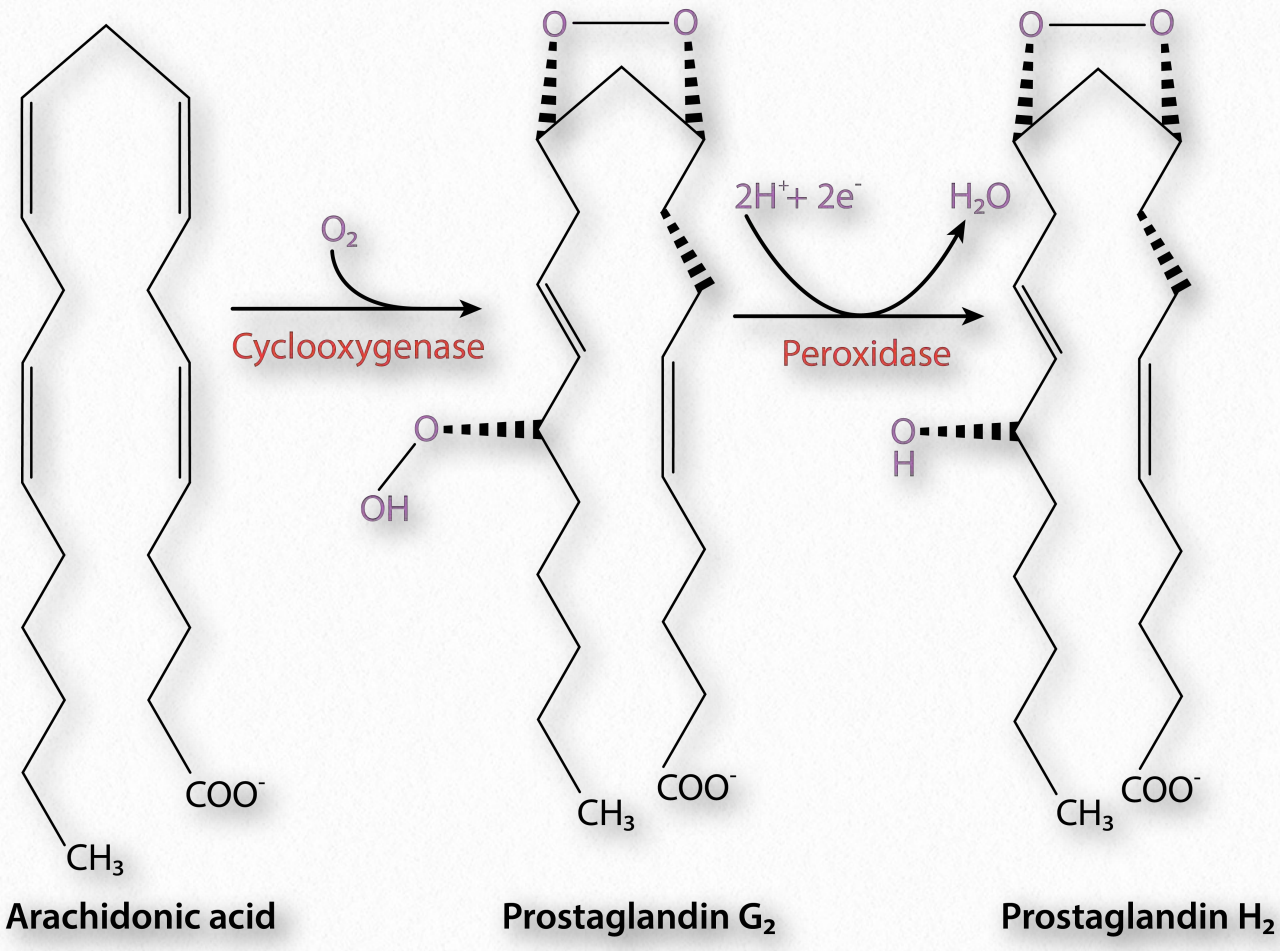

Figure 6.102 - Catalytic activity of cyclooxygenase and peroxidase in making prostaglandins

Image by Pehr Jacobson

donic acid to prostaglandins G_2 and H_2 by COX enzymes. A non-steroidal strategy for decreasing production of prostaglandins then is to inhibit the enzyme that catalyzes their synthesis from arachidonic acid (Figure 6.102). This enzyme is known as prostaglandin synthase, but is more commonly referred to as a cyclooxygenase (or COX) enzyme.

COX enzymes come in at least two forms in humans - COX-1, COX-2. A third form known as COX-3 has been reported as a splice variant of COX-1, but information about it is unclear. COX-1 and COX-2 are very similar in structure (70 kD and 72 kD, respectively, and 65% amino acid sequence homology), but coded by different genes.

COX-1 is synthesized constitutively whereas COX-2 displays inducible expression behavior and has a more specific pattern of tissue expression. COX-2 enzymes are expressed in increasing amounts in areas of growth and inflammation.

Non-steroidal drugs

Molecules inhibiting cyclooxygenases are known as non-steroidal anti-inflammatory drugs (NSAIDs). Molecules in this class include aspirin, ibuprofen, vioxx, and celebrex.

Targeting inhibitors

Some NSAID inhibitors, such as aspirin, bind to all types of COX enzymes. Newer COX inhibitors target the COX-2 enzyme specifically because it was believed to be a better target for relief of joint pain than COX-1 enzymes which are synthesized by most cells. COX-2 enzymes are found more specifically in joints so the thinking was that specific inhibition of them would not affect the COX-1 enzymes

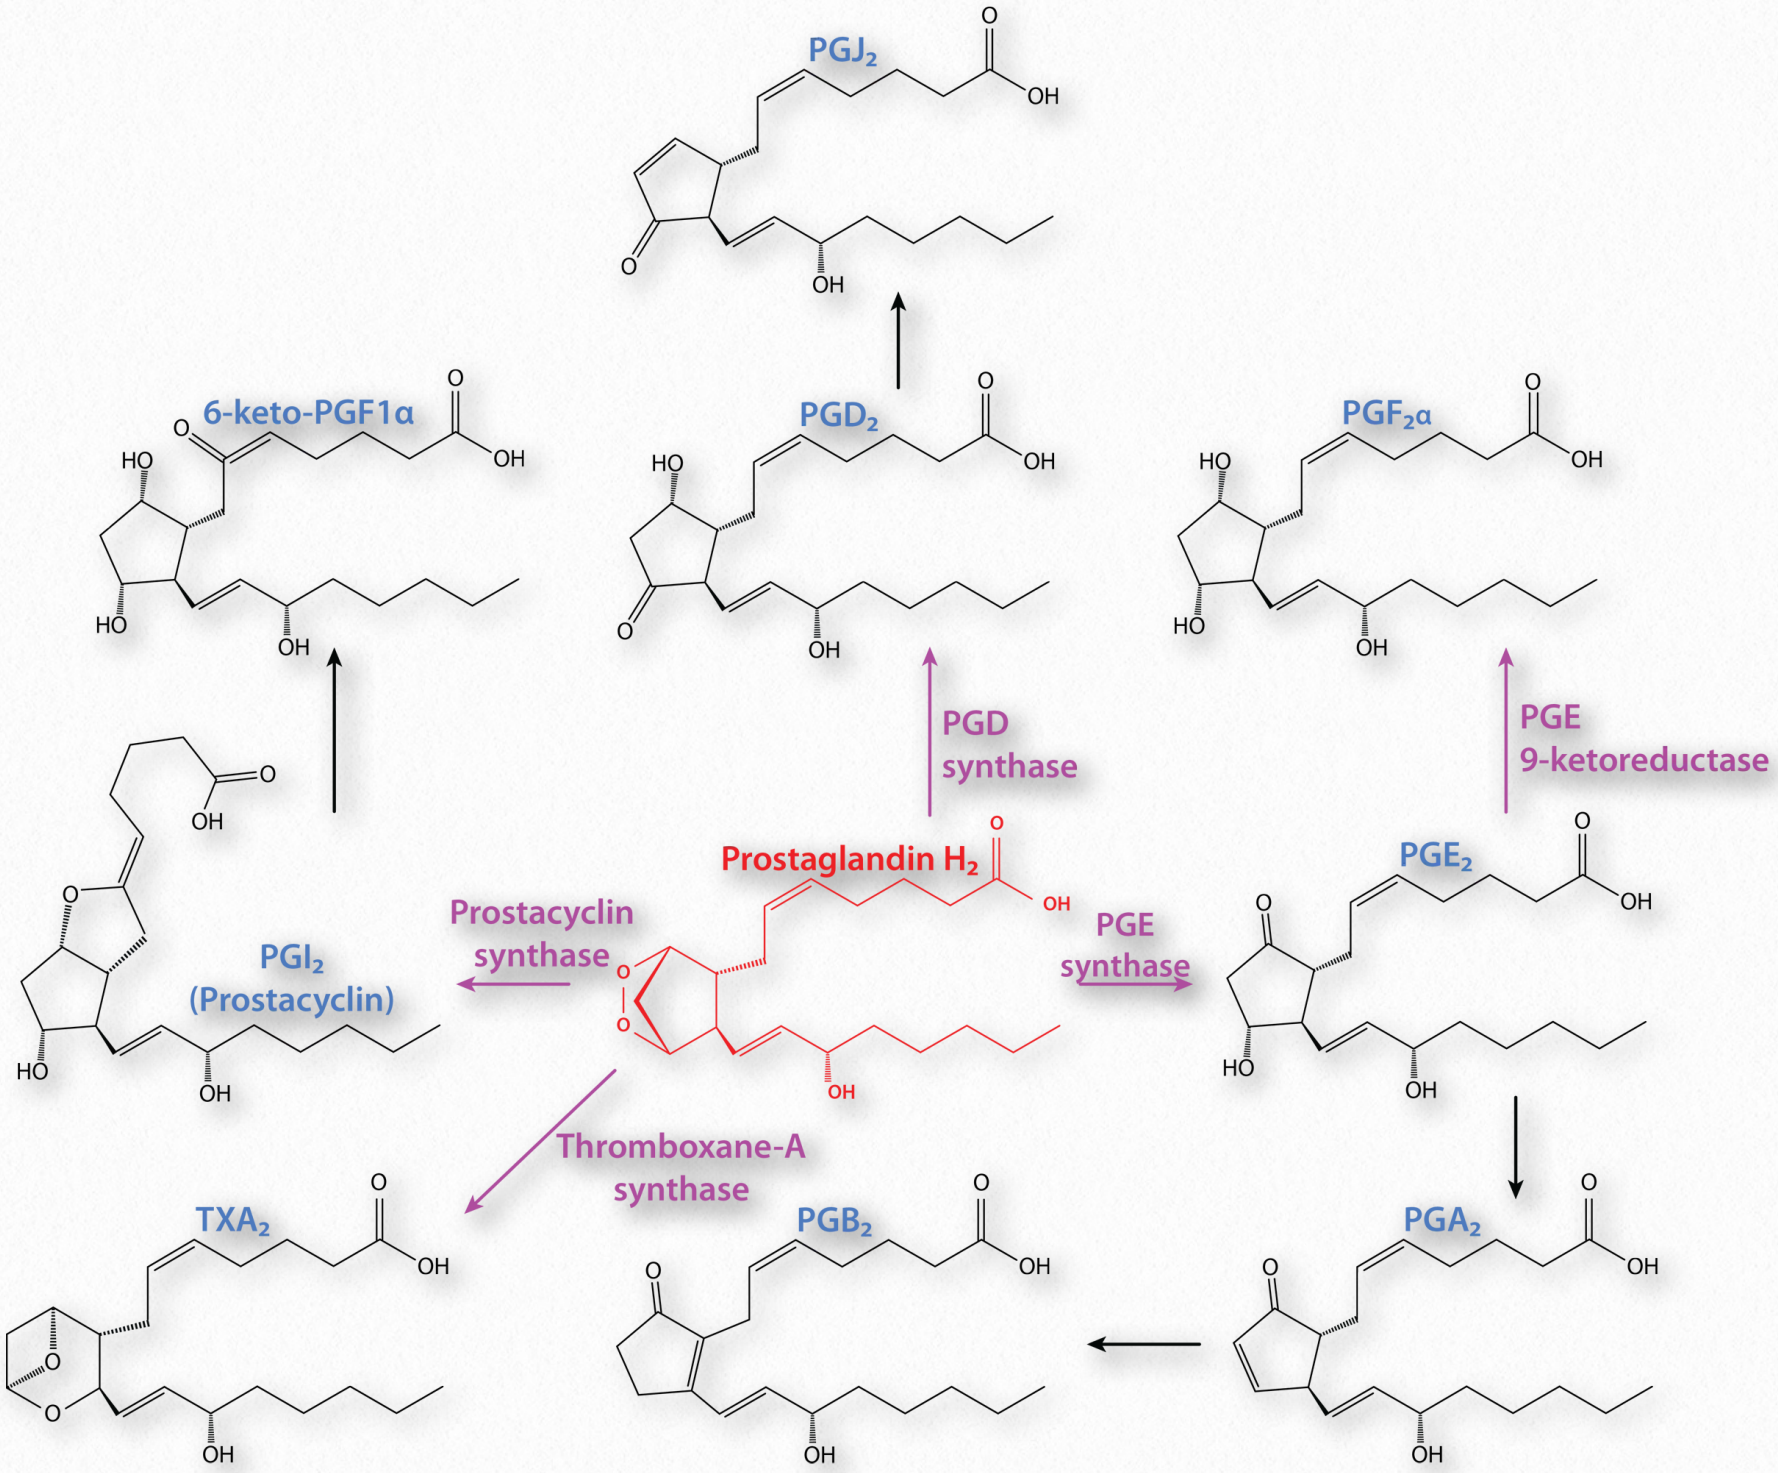

Figure 6.103 - Synthesis of prostaglandins from prostaglandin H_2 (red)

Image by Pehr Jacobson

which are important for producing prostaglandins that help maintain gastric tissue.

Numerous COX-2 - specific inhibitors were developed - celecoxib, etoricoxib, and rofecoxib (Vioxx), for example. Unfortunately, the COX-2 specific inhibitors are associated with some serious side effects, including a 37% increase in incidence of major cardiovascular events in addition to some of the gastrointestinal problems of NSAIDs.

Imbalance

The increased risk of heart attack, thrombosis, and stroke are apparently due to an imbalance between prostacyclin (reduced by inhibitors) and thromboxanes (not reduced by the inhibitors). Prostacyclin (made from

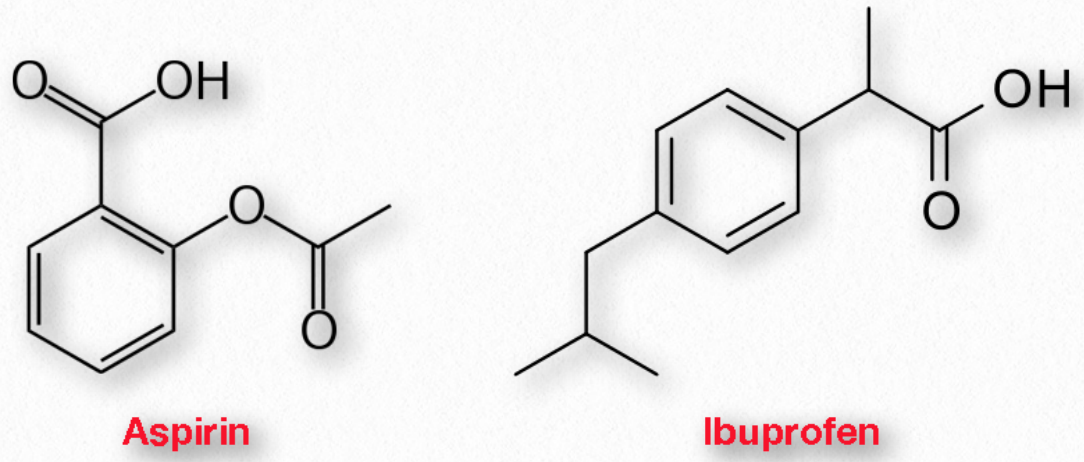

Figure 6.104 - Two NSAIDs

prostaglandin H_2 by prostacyclin synthase) is a special prostaglandin that inhibits activation of blood platelets in the blood clotting process and acts as a vasodilator. Thromboxanes counter prostacyclin, causing vasoconstriction and activating blood platelets for clotting. Due to imbalances in these opposite acting molecules resulting from COX-2-specific inhibition, Vioxx, was withdrawn from the market in September, 2004, due to health concerns.

Other compounds known to inhibit COX enzymes include some flavonoids, some components of fish oil, hyperforin, and vitamin D.

Connections to other pathways

There are several connections between fats and fatty acid metabolism and other metabolic pathways. Diacylglycerol (DAG - Figure 6.105), which is produced by removal of a phosphate from phosphatidic acid, is an intermediate in fat synthesis and also a messenger in some signaling systems. Phosphatidic acid, of course, is a branch intermediate in the synthesis of triacylglycerols and other lipids, including phosphoglycerides.

Fatty acids twenty carbons long based on arachidonic acid (also called eicosanoids) are precursors of the leukotrienes, prostaglandins, thromboxanes, and endocannabinoids.

Acetyl-CoA from β-oxidation can be assembled by the enzyme thiolase to make acetoacetyl-CoA, which is a precursor of both ketone bodies and the isoprenoids, a broad category of compounds that include steroid hormones, cholesterol, bile acids, and the fat soluble vitamins. In plants, acetyl-CoA can be made into carbohy-

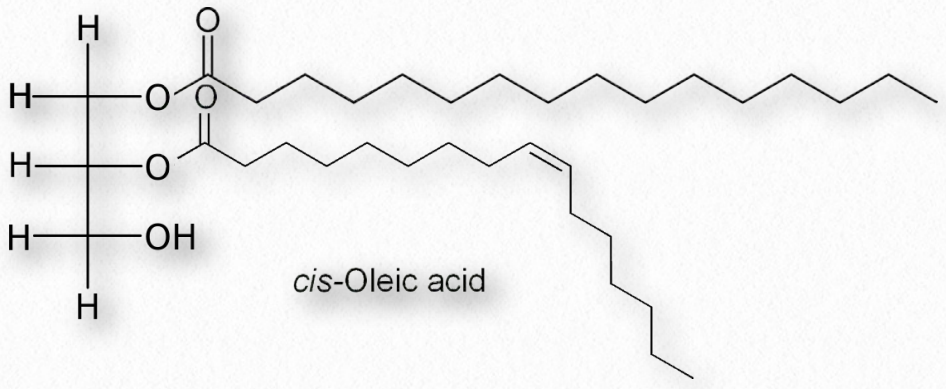

Figure 6.105 - Diacylglycerol

drates in net amounts via the glyoxylate cycle.

Fat, obesity, and hunger

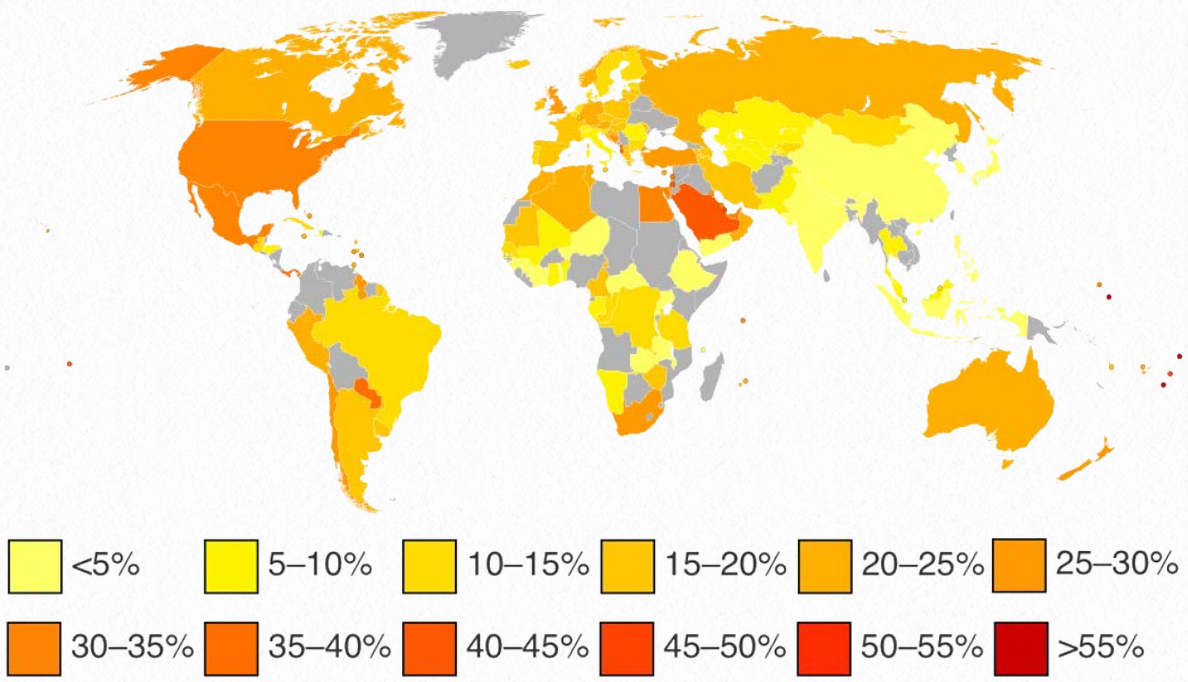
Obesity is an increasing problem in the western world. It is, in fact, the leading preventable cause of death worldwide. In 2014, over 600 million adults and 42 million children in the world were classified as obese, a condition when their body mass index is over 30 kg/m^2 (Figure 6.106). The body mass index of a person is obtained by dividing a person's weight by the square of their height. At a simple level, obesity arises from consumption of calories in excess of metabolic need, but there are many molecular factors to consider.

Adipokines

Adipokines are adipose tissue-synthesized cytokines. The class of molecules includes leptin (first discovered adipokine) and hundreds of other such compounds. These include adiponectin (regulates glucose levels and fatty acid oxidation), apelin (control of blood pressure, angiogenesis promotion, vasodilator release, increased water intake), chemerin (stimulation of lipolysis, adipocyte differentiation, link to insulin resistance), and resistin (links to obesity, type II diabetes, LDL production in liver), among others.

Resistin

Resistin is an adipokine peptide hormone with numerous associated negative health effects. Injection of the hormone into



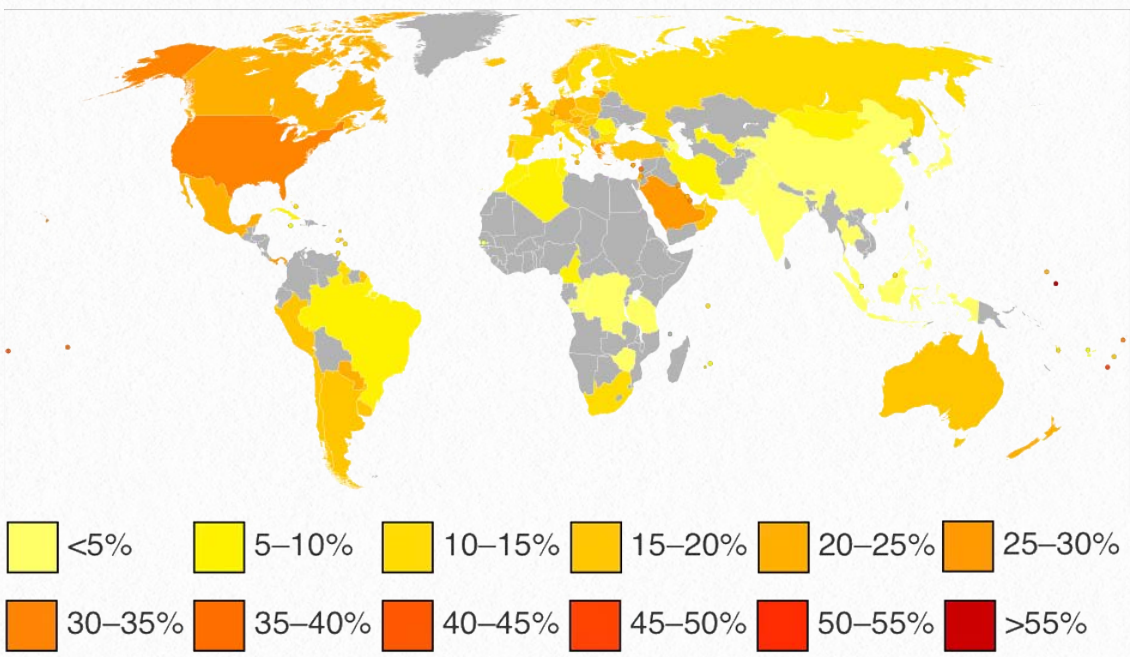


Figure 6.106 - Obesity worldwide - females (top) and males (bottom)

Wikipedia

mice results in increased resistance to insulin, a phenomenon of type 2 diabetes.

Resistin is linked to increased inflammation and serum levels of it correlate with increased obesity, though direct linkage of it to obesity is controversial. Resistin stimulates production of LDLs in the liver, supporting increased levels in the arteries. Resistin also adversely impacts the effects of statin drugs used to control levels of cholesterol in the body.

YouTube Lectures by Kevin HERE & HERE

Leptin

Leptin is a peptide hormone (adipokine) made in adipose cells that negatively impacts hunger and regulates energy balance. It is countered by ghrelin, also known as the hunger hormone. Both hormones act in the hypothalamus where hunger is controlled. When leptin levels are higher due to higher levels of body fat, hunger is suppressed, but when levels of leptin are lower (less body fat), then appetite increases.

Notably, leptin is also made in places besides adipose tissue and leptin receptors are found in places besides the hypothalamus, so the hormone has other effects in the body. When sensitivity to leptin changes, increased obesity can result. In mice, deletion of leptin function by mutation results in mice with voracious appetites and extreme obesity. Deletion of the leptin receptor gene in mice results in the same phenotype. Eight humans with leptin mutations all suffer from extreme obesity in infancy.

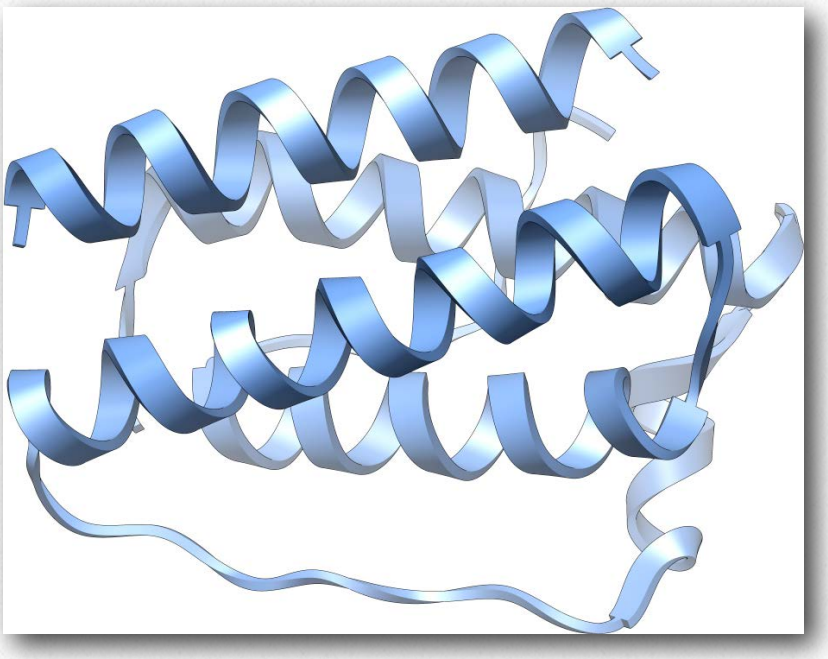

Figure 6.107 Leptin

Wikipedia

Physiology

Leptin is produced primarily by cells in white adipose tissue, but is also made in brown adipose tissue, ovaries, skeletal muscle, stomach, mammary epithelial cells and bone marrow.

Leptin levels

Leptin levels in the body are highest between midnight and early morning, presumably to suppress appetite. Though it is produced by fat cells, levels of leptin in humans do not strictly reflect levels of fat. For example, early in fasting, leptin levels fall before fat levels fall. Sleep deprivation can reduce leptin levels, as can increasing levels of testosterone and physical exercise.

Increasing estrogen, however, increases leptin levels. Emotional stress and insulin can increase leptin levels. Obesity increases leptin levels, but doesn't fully suppress appetite. Leptin resistance in these individuals is an important consideration, lessening the effects of the hormone on appetite.

Blocking leptin action

In the medial hypothalamus, leptin stimulates satiety and in the lateral hypothalamus, leptin inhibits hunger. Lesions in the lateral hypothalamus that block the ability to sense hunger result in anorexia (there are other causes of anorexia, though) and lesions in the medial hypothalamus cause excess hunger (no satiety). Neuropeptide Y is a potent hunger promoter whose receptors in the arcuate nucleus can be bound and blocked by leptin. Leptin levels are more sensitive to decreasing food intake than increasing food intake meaning that in humans the hormone plays a bigger role with respect to appetite than to levels of fat in the body.

At the molecular level, binding of leptin to the Ob-Rb receptor causes down-regulation of synthesis of endocannabinoids, whose normal function is to increase hunger. High fructose diets have been associated with reduced levels of leptin and of leptin receptor.

Ghrelin

Ghrelin is a peptide hormone made by cells in the gastrointestinal tract when the stomach is empty. Stretching of the stomach reduces the expression of the hormone. Ghrelin exerts its effects on the central nervous system to increase appetite and it is an unusual peptide in being able to cross the blood-brain barrier. The ghrelin receptor in the brain is found on the same cells as the leptin receptor (arcuate nucleus). Leptin can counter the ghrelin effect by decreasing hunger.

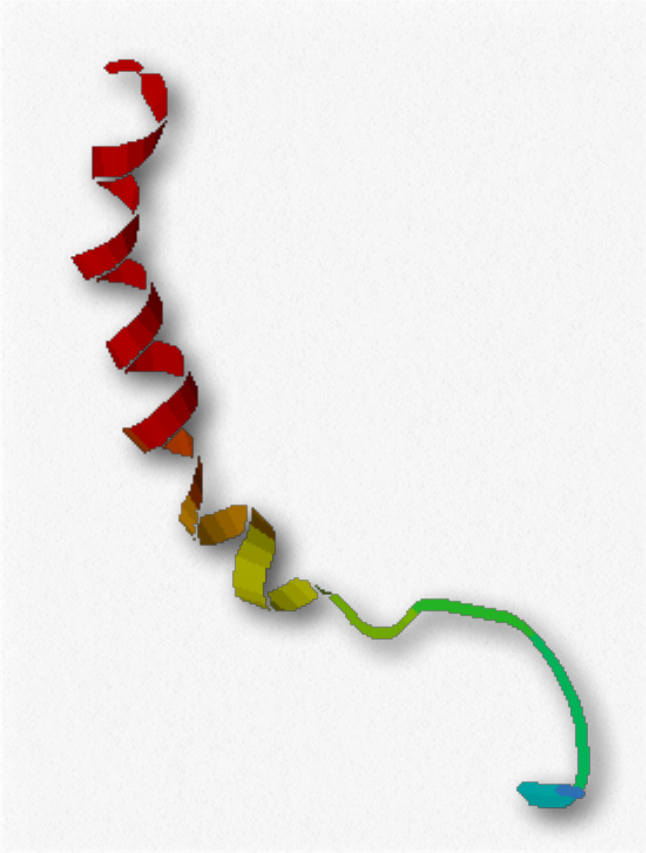

Figure 6.108 **Neuropeptide Y**

Behavioral effects

Activation of ghrelin occurs after processing the zymogen form of the hormone (preproghrelin) followed by linkage of an octanoic acid to a serine at position 3. Circulating levels of ghrelin increase before eating and decrease afterwards. There appears to be a

dose dependence for ghrelin on the amount of food consumed. Ghrelin increases food seeking behavior and there is a negative correlation between levels of ghrelin and weight.

Neuropeptide Y

Neuropeptide Y is a neuropeptide neurotransmitter produced by neurons of the sympathetic nervous system. It acts as a vasoconstrictor and favors growth of fat tissue. It appears to stimulate food intake, fat storage, relieve anxiety/stress, reduce pain perception, and lower blood pressure. Blockage of neuropeptide Y receptors in the brain of rats decreases food intake.

Stress effects

In mice and monkeys, repeated stress and high fat, high sugar diets stimulate neuropeptide Y levels and cause abdominal fat to increase.

High levels of neuropeptide Y may also help individuals to recover from post-traumatic stress disorder and to reduce the fear response. It may also protect against alcoholism. Mice lacking the ability to make neuropeptide Y have a higher voluntary consumption of alcohol and are less sensitive to its effects. The neuropeptide Y receptor is a G-protein-coupled receptor in the 7-transmembrane domain family.

When Acids Get Oxidized

To the tune of "*When Johnny Comes Marching Home*"

Metabolic Melodies Website HERE

The fatty acids carried by
CoA, CoA
Are oxidized inside the
mi-to-chon-dri-ay

They get to there as you have seen
By hitching rides on carnitine
Then it goes away
When acids get oxidized

Electrons move through membranes, yes
It's true, it's true
They jump from complex I onto
Co-Q, Co-Q

The action can be quite intense
When building proton gradients
And its good for you
When acids get oxidized

The protons pass through complex V
You see, you see
They do this to make lots of
A-TP, TP

The mechanism you should know
Goes through the stages L-T-O
So there's energy
When acids get oxidized

Recording by Tim Karplus
Lyrics by Kevin Ahern

When Acids Are Synthesized

To the tune of "*When Johnny Comes Marching Home*"

Metabolic Melodies Website HERE

The 16 carbon fatty acid, palmitate
Gets all the carbons that it needs from acetate
Which citric acid helps release
From mitochondri - matrices
Oh a shuttle's great
When acids are synthesized

Carboxylase takes substrate and it puts within
Dioxy carbon carried on a biotin
CoA's all gain a quick release
Replaced by larger ACPs
And it all begins
When acids are synthesized

A malonate contributes to the growing chain
Two carbons seven times around again, again
For saturated acyl-ates
There's lots of N-A-DPH
That you must obtain
When acids are synthesized

Palmitic acid made this way all gets released
Desaturases act to make omega-threes
The finished products big and small
Form esters with a glycerol
So you get obese
When acids are synthesized

Recording by Tim Karplus
Lyrics by Kevin Ahern

Metabolism: Other Lipids

Sugars are the building blocks of carbohydrates, amino acids are the building blocks of proteins and nucleotides are the building blocks of the nucleic acids - DNA and RNA. Another crucial building block is acetyl-CoA, which is used to build many lipid substances, including fatty acids, cholesterol, fat soluble vitamins, steroid hormones, prostaglandins, endocannabinoids, and the bile acids. Indeed, acetyl-CoA goes into more different classes of molecule than any other building block.

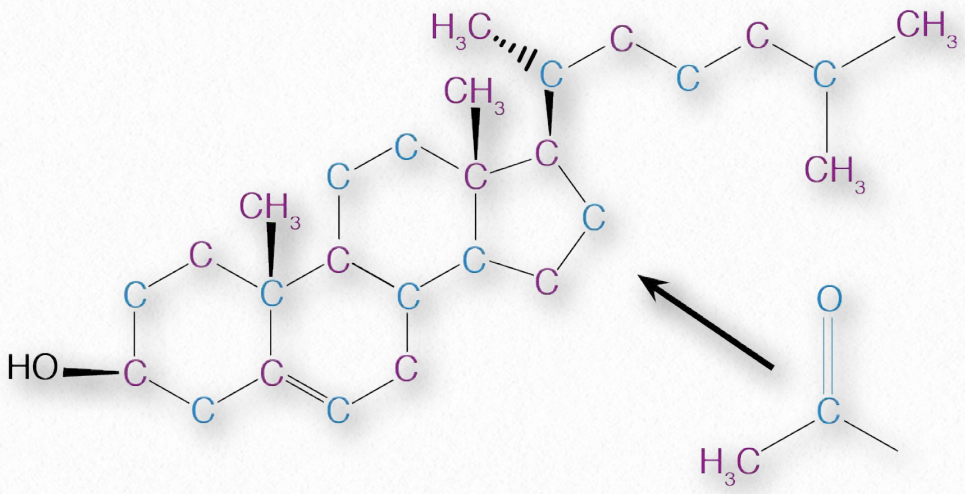

Figure 6.110 - Acetyl-CoA's carbons mapped onto cholesterol

Image by Penelope Irving

Mevalonate pathway

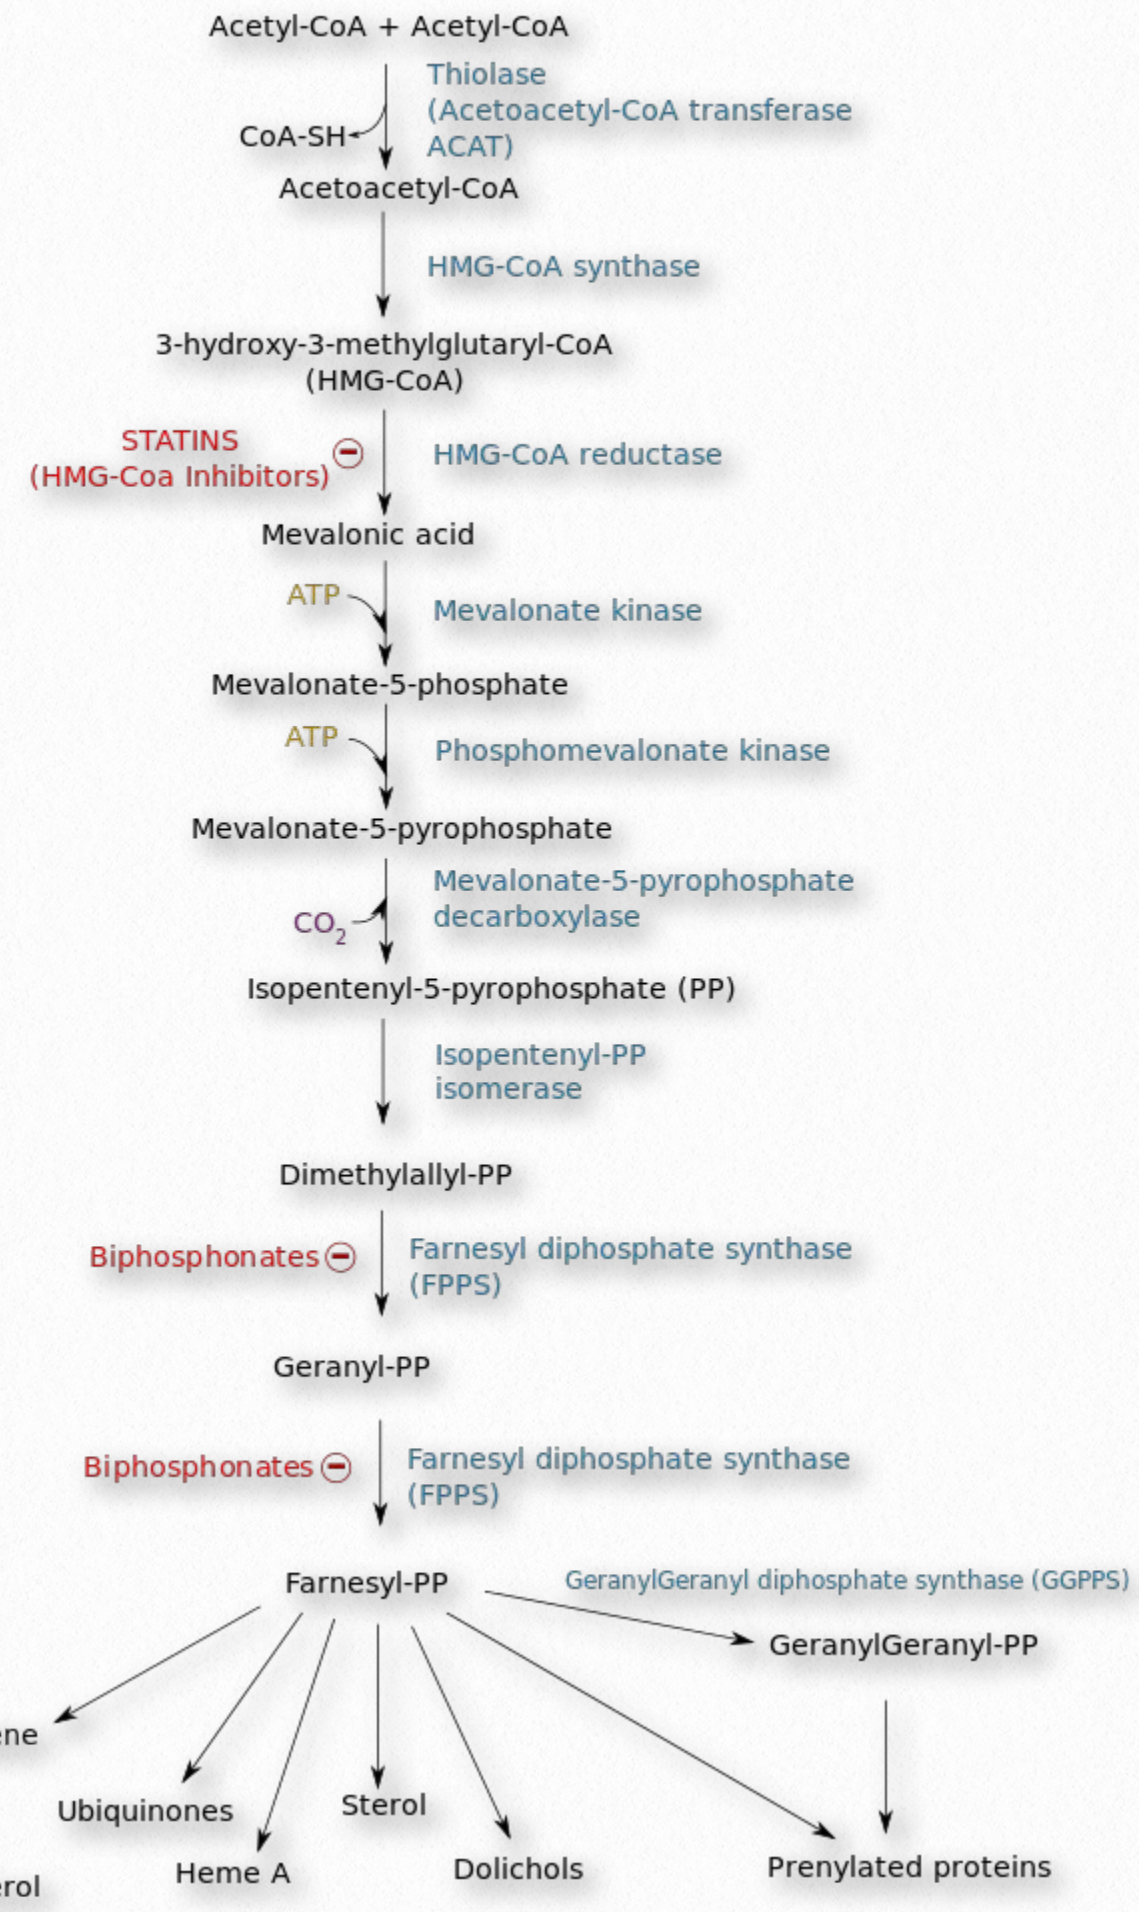

Figure 6.111 - Synthesis of isoprenoids from acetyl-CoA

Isoprenoids

We focus our attention here on a group of molecules made from acetyl-CoA that are known as as the isoprenoids. Isoprenoids are a large, diverse and ancient group of molecules that are found in all three domains of life. As noted earlier, they are components of membrane lipids in the cell membranes of archaebacteria, but beyond this, they serve an astonishing variety of functions. From photosynthetic pigments to plant defense compounds, from flavor compounds in cinnamon, mint, ginger and cloves to plant and animal hormones, from the cannabinoids in marijuana to the lycopene that gives tomatoes their color, and from heme to the quinones in the electron transport chain, isoprenoids are ubiquitous in cells. Isoprenoids derive their name from the fact that they are, in fact, made from five carbon building blocks called isoprenes that are derived from acetyl-CoA. The synthesis of the two isoprene units - isopentenyl pyrophosphate and dimethylallyl pyrophosphate is shown in Figure 6.111 and Figure 6.112.

YouTube Lectures by Kevin HERE & HERE

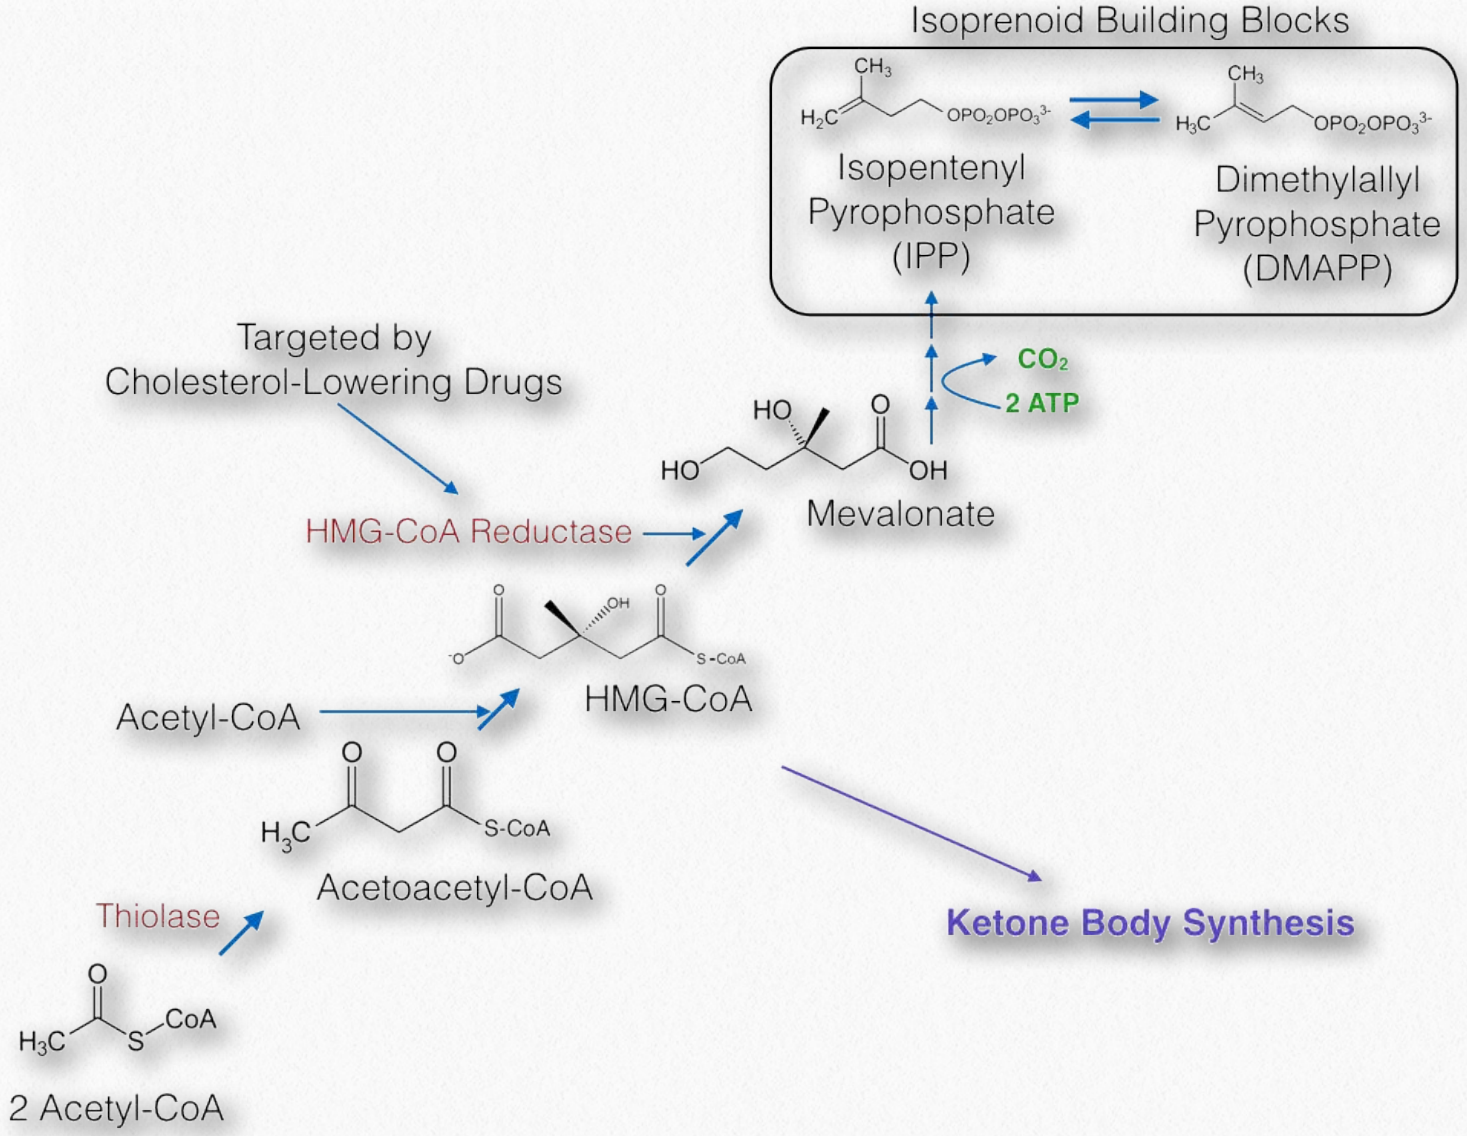

Figure 6.112 - Reactions to make isoprenes from acetyl-CoA

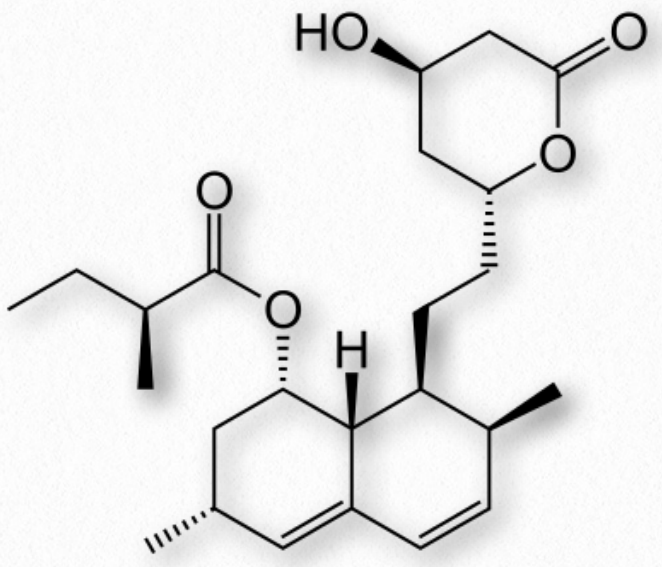

Figure 6.113 - Lovastatin

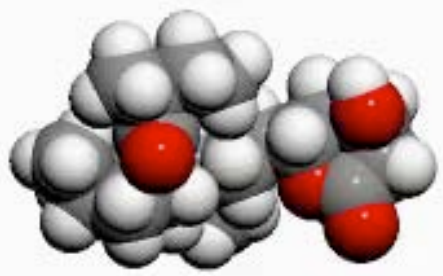
Wikipedia

The pathway leading up to isoprene synthesis overlaps with that of ketone body synthesis, for the two reactions (Figure 6.112), as has been discussed earlier in this book (see HERE). Thiolase catalyzes the initial reaction, joining together two acetyl-CoA molecules to make acetoacetyl-CoA. In the second reaction catalyzed by HMG-CoA synthase, a third acetyl-CoA is joined to form the six carbon compound known as hydroxymethyl glutaryl-CoA (HMG-CoA). Reaction three is an important one biologically and medically because of the enzyme catalyzing it - HMG-CoA reductase.

Statins

Medically, HMG-CoA reductase is the target of a class of drugs known as statins (Figure 6.113 & Movie 6.1), which are used to reduce cholesterol levels in people. These competitive inhibitors, which compete with HMG-CoA for binding have two effects. First, they reduce the production of mevalonate, which restricts the amount of substrate available to make cholesterol. Second, and perhaps more importantly, they increase production of LDL receptors in the liver, which favors uptake and destruction of LDLs, thus lowering serum cholesterol levels.



Movie 6.1 - Lovastatin

Wikipedia

Regulation

Biologically, the HMG-CoA reductase enzyme is also of importance because it is the primary regulatory point in cholesterol synthesis. Control of it is complex. First, it is feedback inhibited by cholesterol itself. High levels of glucose in the blood activate the enzyme. Phosphorylation by AMP-activated protein kinase inhibits its activity. Interestingly, the same enzyme phosphorylates and inactivates acetyl-CoA carboxylase - the only regulatory enzyme controlling fatty acid synthesis. Transcription of the gene encoding HMG-CoA reductase

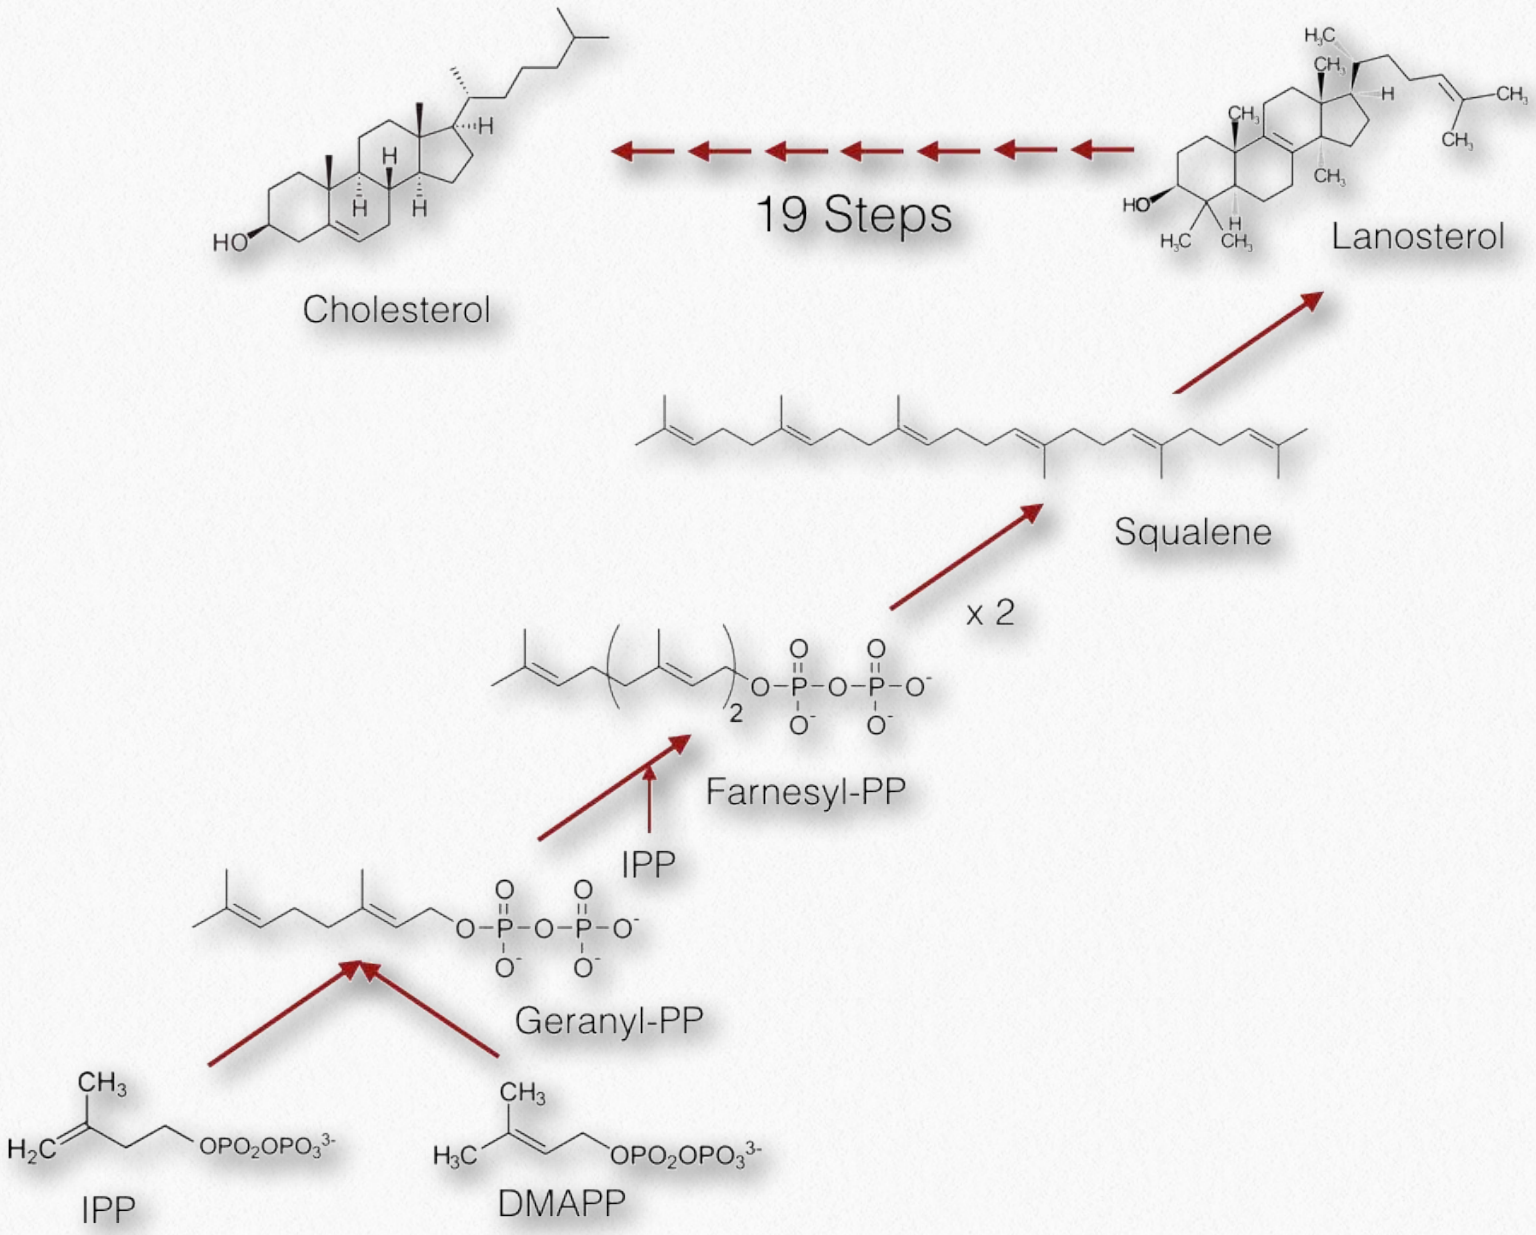


Figure 6.114 - Synthesis of cholesterol from isoprene units - isopentenyl pyrophosphate (IPP) and dimethylallyl pyrophosphate (DMAPP)

is enhanced by binding of the sterol regulatory element binding protein (SREBP) to the sterol recognition element (SRE) located near the gene coding sequence. As cholesterol levels rise, SREBP is proteolytically cleaved and transcription stops.

From HMG-CoA, the enzyme HMG-CoA reductase catalyzes the formation of mevalonate. This reaction requires NADPH and results in release of coenzyme A. Mevalonate gets phosphorylated twice and then decarboxylated to yield the five carbon intermediate known as isopentenyl-pyrophosphate (IPP). IPP is readily converted to the other important isoprenoid unit, dimethylallylpyrophosphate (DMAPP).

Isoprenes

These two five carbon compounds, IPP and DMAPP, are also called isoprenes (Figure 6.115) and are the building blocks for the syn-

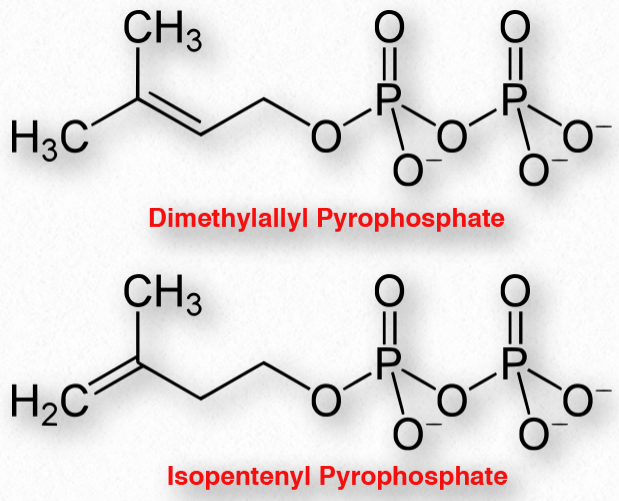

Figure 6.115 - Isoprene building blocks

thesis of cholesterol and related compounds. This pathway proceeds in the direction of cholesterol starting with the joining of IPP and DMAPP to form geranyl-pyrophosphate. Geranyl-pyrophosphate combines with another IPP to make farnesyl-pyrophosphate, a 15-carbon compound.

Squalene

Two farnesyl-pyrophosphates join to create the 30-carbon compound known as squalene. Squalene, in a complicated rearrangement involving reduction and molecular oxygen forms a cyclic intermediate known as lanosterol (Figure 6.116) that resembles cholesterol. Conversion of lanosterol to cholesterol is a lengthy process involving 19 steps that occur in the endoplasmic reticulum.

The cholesterol biosynthesis pathway from lanosterol is a long one and requires significant amounts of reductive and ATP energy. As noted earlier (see HERE), cholesterol has

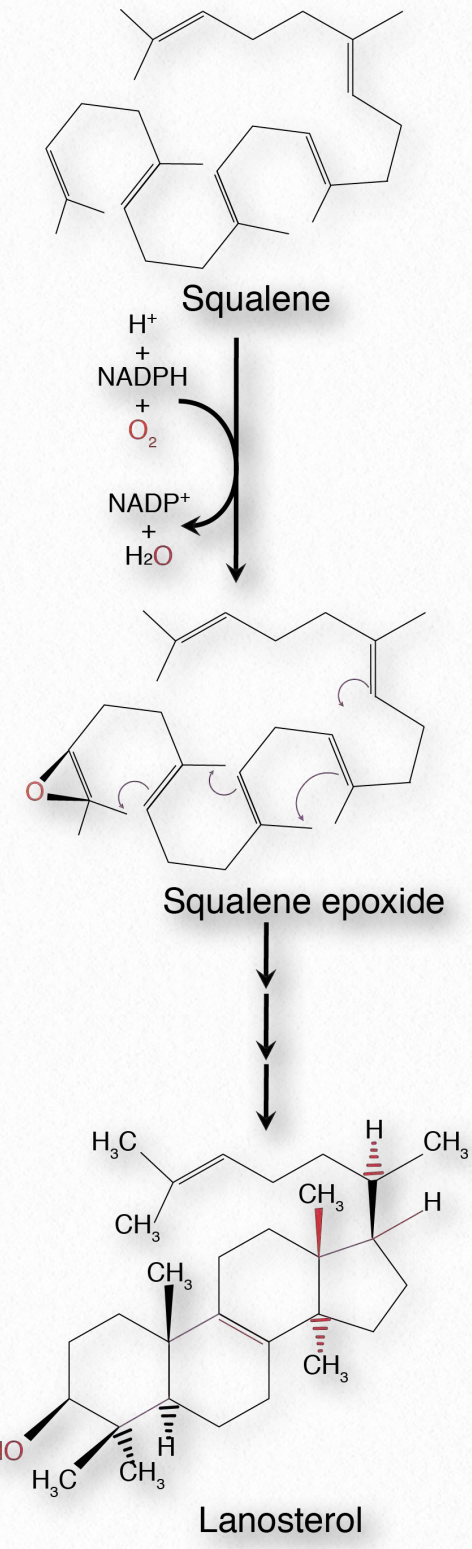

Figure 6.116 - Synthesis of lanosterol from squalene

Image by Penelope Irving

an important role in membranes. It is also a precursor of steroid hormones and bile acids and its immediate metabolic precursor, 7-dehydrocholesterol (Figure 6.117), branches to form vitamin D (Figure 6.118).

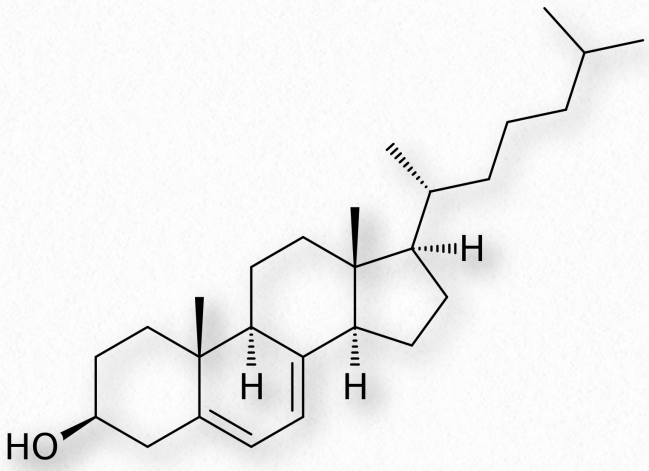

Figure 6.117 - 7-Dehydrocholesterol - A precursor of cholesterol and vitamin D

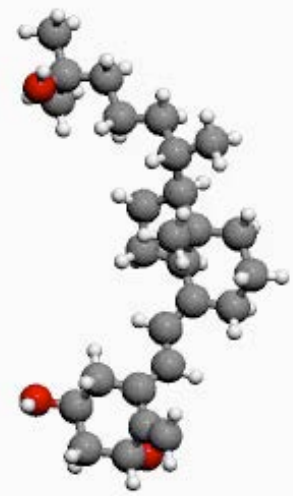
All steroid hormones in animals are made from cholesterol and include the progestagens, androgens, estrogens, mineralocorticoids, and the glucocorticoids. The branch molecule for all of the steroid hormones is the cholesterol metabolite (and progestagen) known as pregnenalone (Figure 6.119). The progestagens are thus precursors of all of the other classes of steroid hormones.



Movie 6.2 - Calcitriol - The active form of vitamin D

Wikipedia

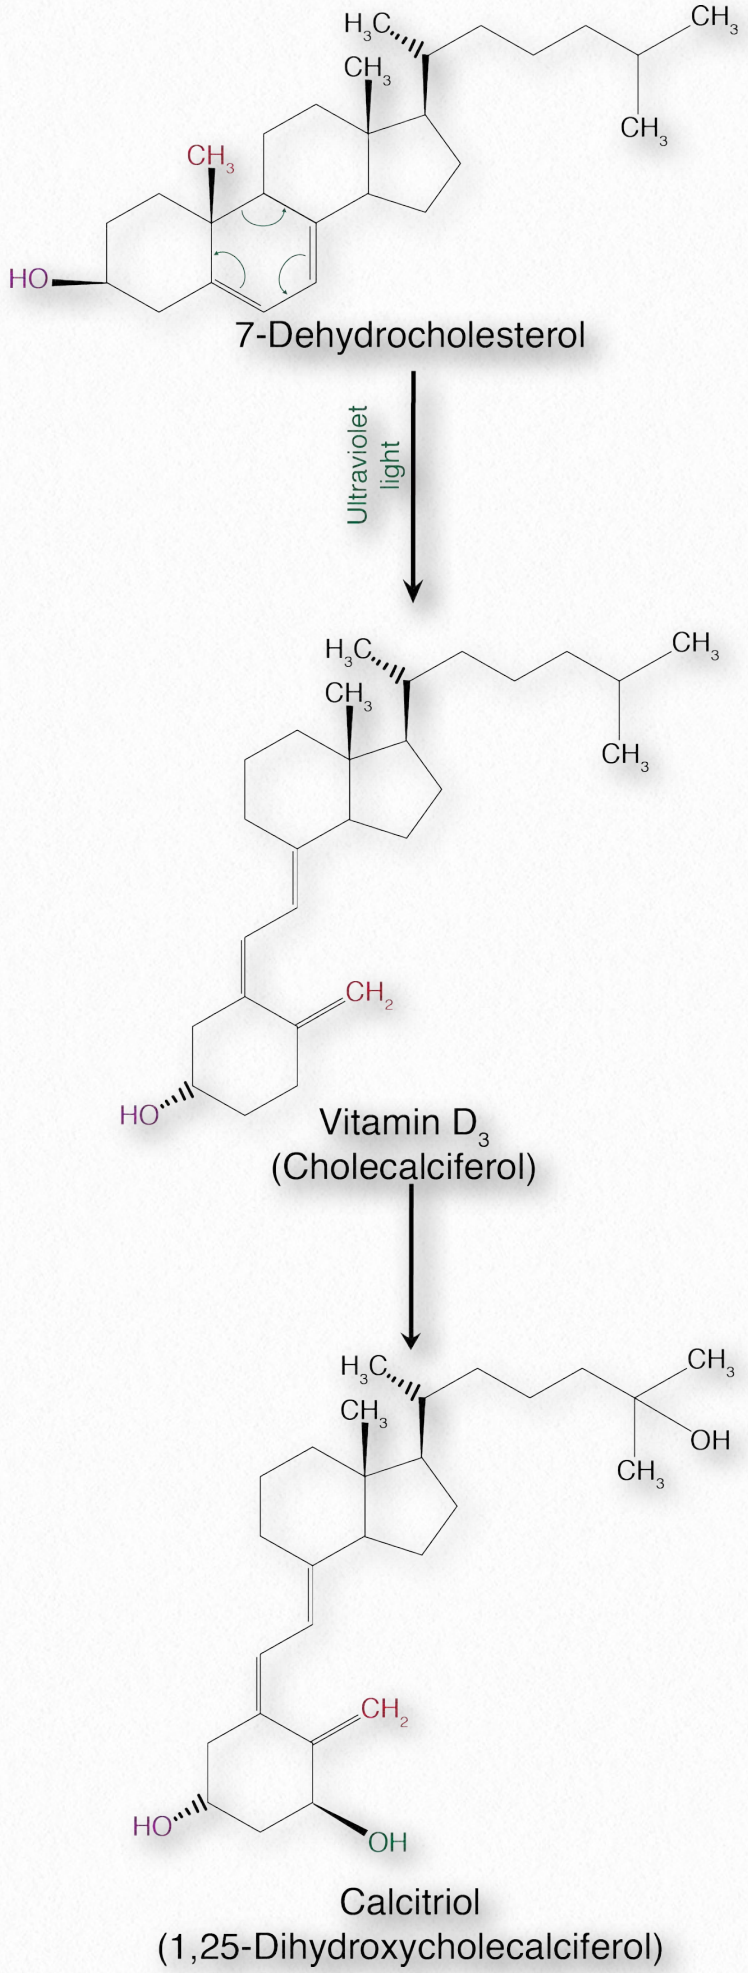


Figure 6.118 - Synthesis of the active form of vitamin D

Image by Penelope Irving

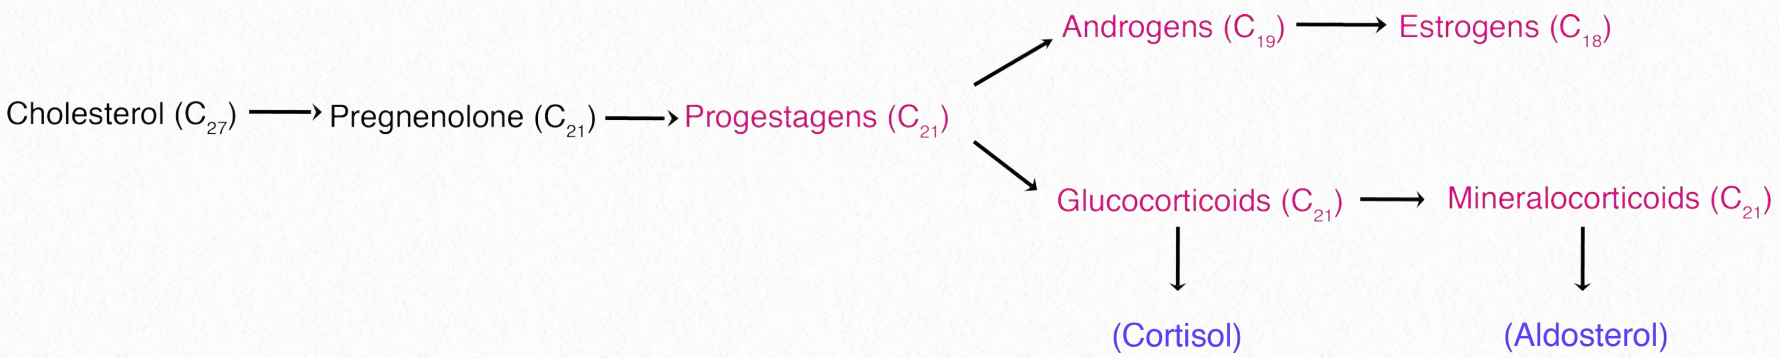

Figure 6.119 - Synthesis of steroid hormones from cholesterol. Example glucocorticoids and mineralocorticoids shown in blue.

Image by Penelope Irving

The estrogens are derived from the androgens in an interesting reaction that required formation of an aromatic ring (Figure 6.120). The enzyme catalyzing this reaction is known as an aromatase and it is of medical significance. The growth of some tumors is stimulated by estrogens, so aromatase inhibitors are prescribed to prevent the formation of estrogens and slow tumor growth. Two commonly used inhibitors include exemestane (a suicide inhibitor - Figure 6.121) and anastrozole (a competitive inhibitor).

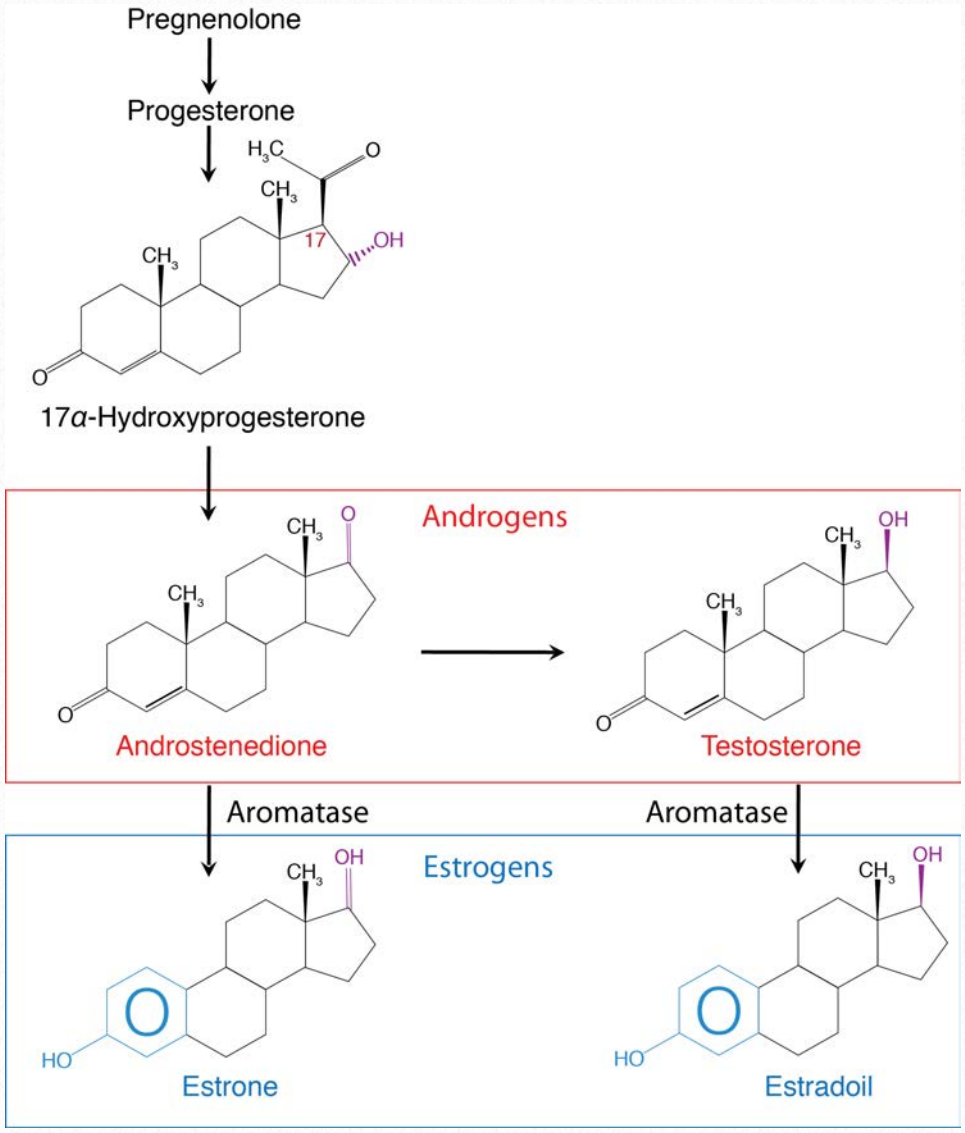

Figure 6.120 - Synthesis of Estrogens from Androgens

Image by Penelope Irving

Other fat-soluble vitamins

Synthesis of other fat soluble vitamins and chlorophyll also branches from the isoprenoid synthesis pathway at geranyl pyrophosphate. Joining of two geranylgeranyl pyrophosphates oc-

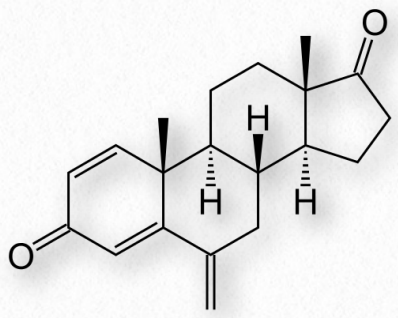

Figure 6.121 - Exemestane - A suicide inhibitor of aromatase

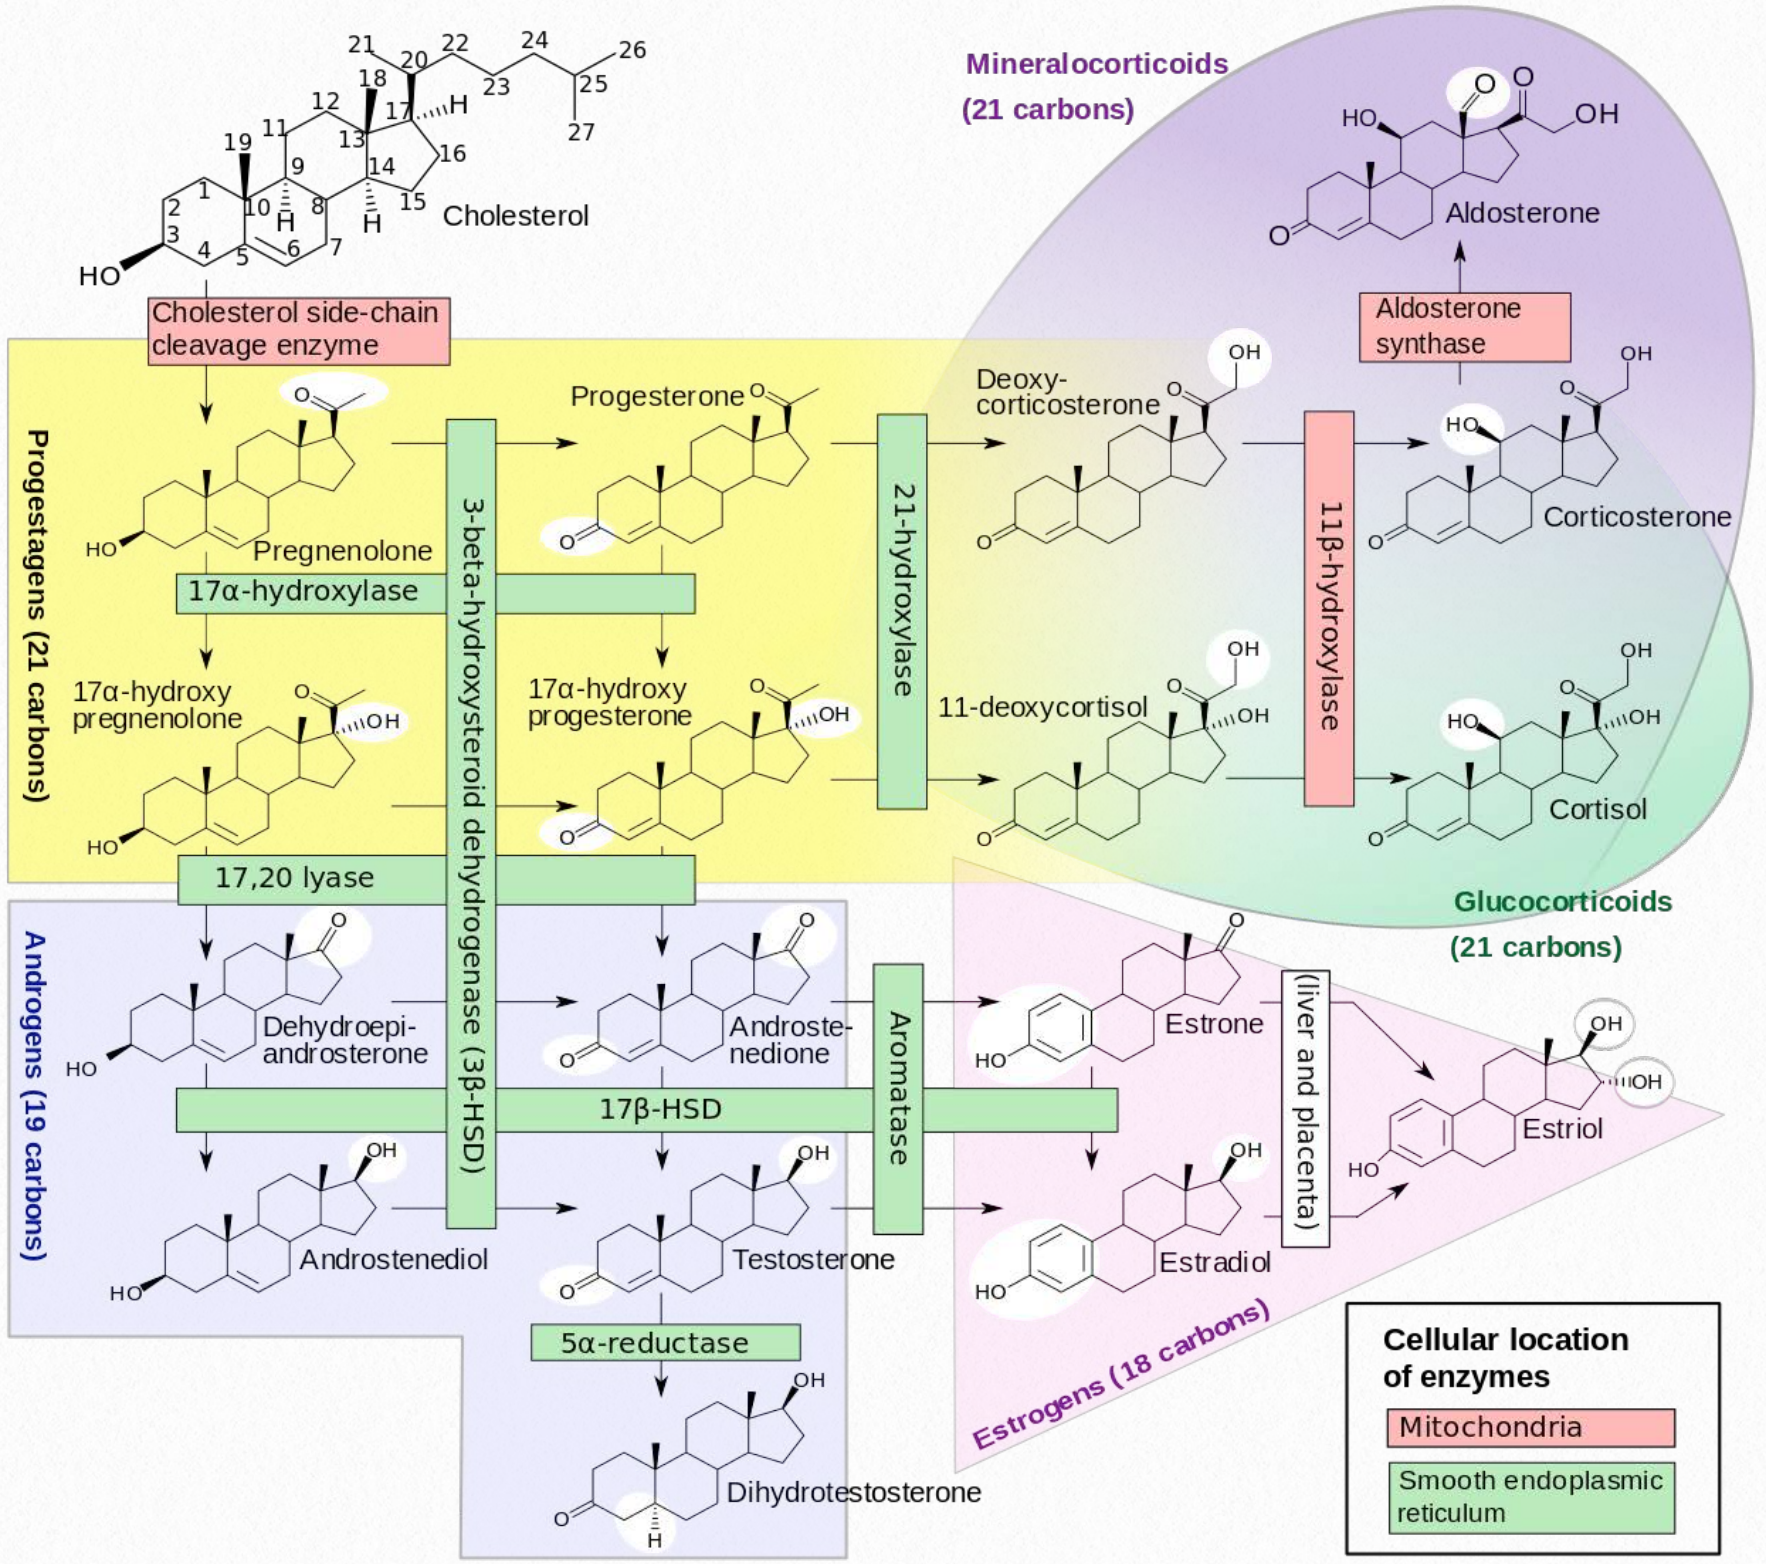

Figure 6.122 - Synthesis of steroid hormones from cholesterol

Wikipedia

curs in plants and bacteria and leads to synthesis of lycopene, which, in turn is a precursor of β-carotene, the final precursor of Vitamin A (see below also). Vitamins E and K, as well as chlorophyll are all also synthesized from geranylgeranyl pyrophosphate.

YouTube Lectures by Kevin HERE & HERE

Bile acid metabolism

Another metabolic pathway from cholesterol leads to the polar bile acids, which are important for the solubilization of dietary fat

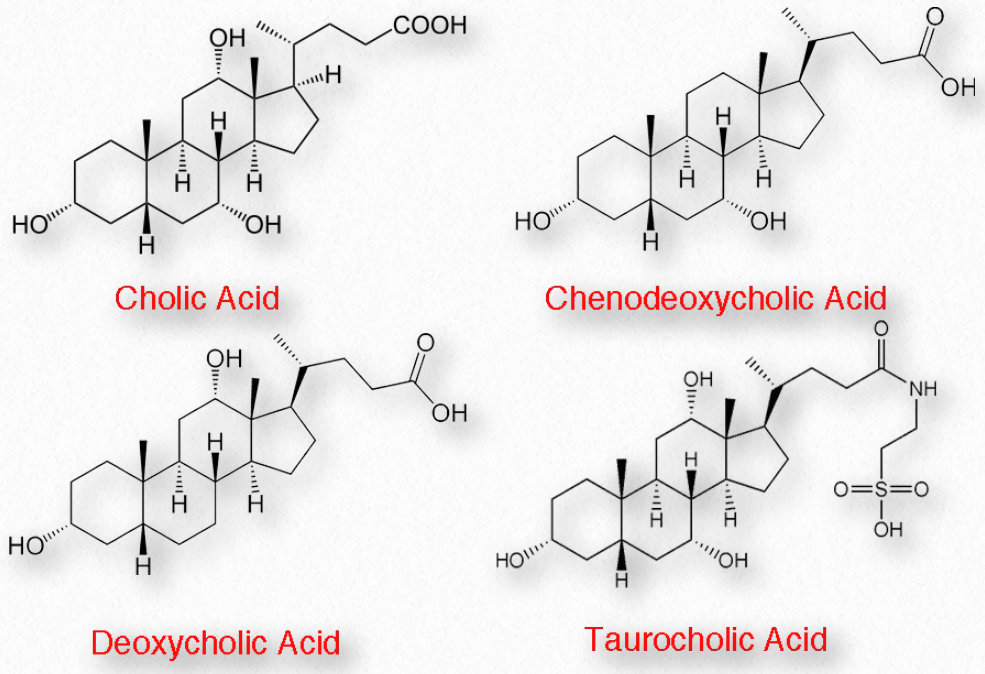

Figure 6.123 - Four bile acids

during digestion. Converting the very non-polar cholesterol to a bile acid involves oxidation of the terminal carbon on the side chain off the rings. Other alterations to increase the polarity of these compounds include hydroxylation of the rings and linkage to other polar compounds.

Common bile acids include cholic acid, chenodeoxycholic acid, glycocholic acid, taurocholic acid, and deoxycholic acid (Figure 6.123). Another important consideration about bile acids is that their synthesis reduces the amount of cholesterol available and promotes uptake of LDLs by the liver. Normally bile acids are recycled efficiently resulting in limited reduction of cholesterol levels. However, inhibitors of the recycling promote reduction of cholesterol levels.

Vitamin A Synthesis

Vitamin A is important for many cellular functions related to growth, differentiation and organogenesis during embryonic development, tissue maintenance, and vision, to name a few.

There are three main active forms of the vitamin, retinal, retinol and retinoic acid, each with its own set of functions. Retinal, complexed with the protein, opsin, is found in the rod cells of the retina and is necessary for vision. Retinol and retinoic acid both function as signaling molecules that can modulate gene expression during development.

Synthesis of vitamin A occurs as a branch in synthesis of isoprenoids. Addition of isopentenyl pyrophosphate to farnesyl pyrophosphate creates a 20-carbon intermediate, geranylgeranyl pyrophosphate (GGPP - Figure 6.124).

Joining of two GGPPs creates a 40 carbon intermediate that is unstable and decomposes to phytoene. Desaturases oxidize two single bonds in phytoene, creating lycopene.

Lycopene is a linear 40 carbon unsaturated molecule found in tomatoes and other red vegetables and it gives them their color. Cyclization of end portions of lycopene give rise to β-carotene, the precursor of vitamin A (retinal/retinol - Figure 6.124).

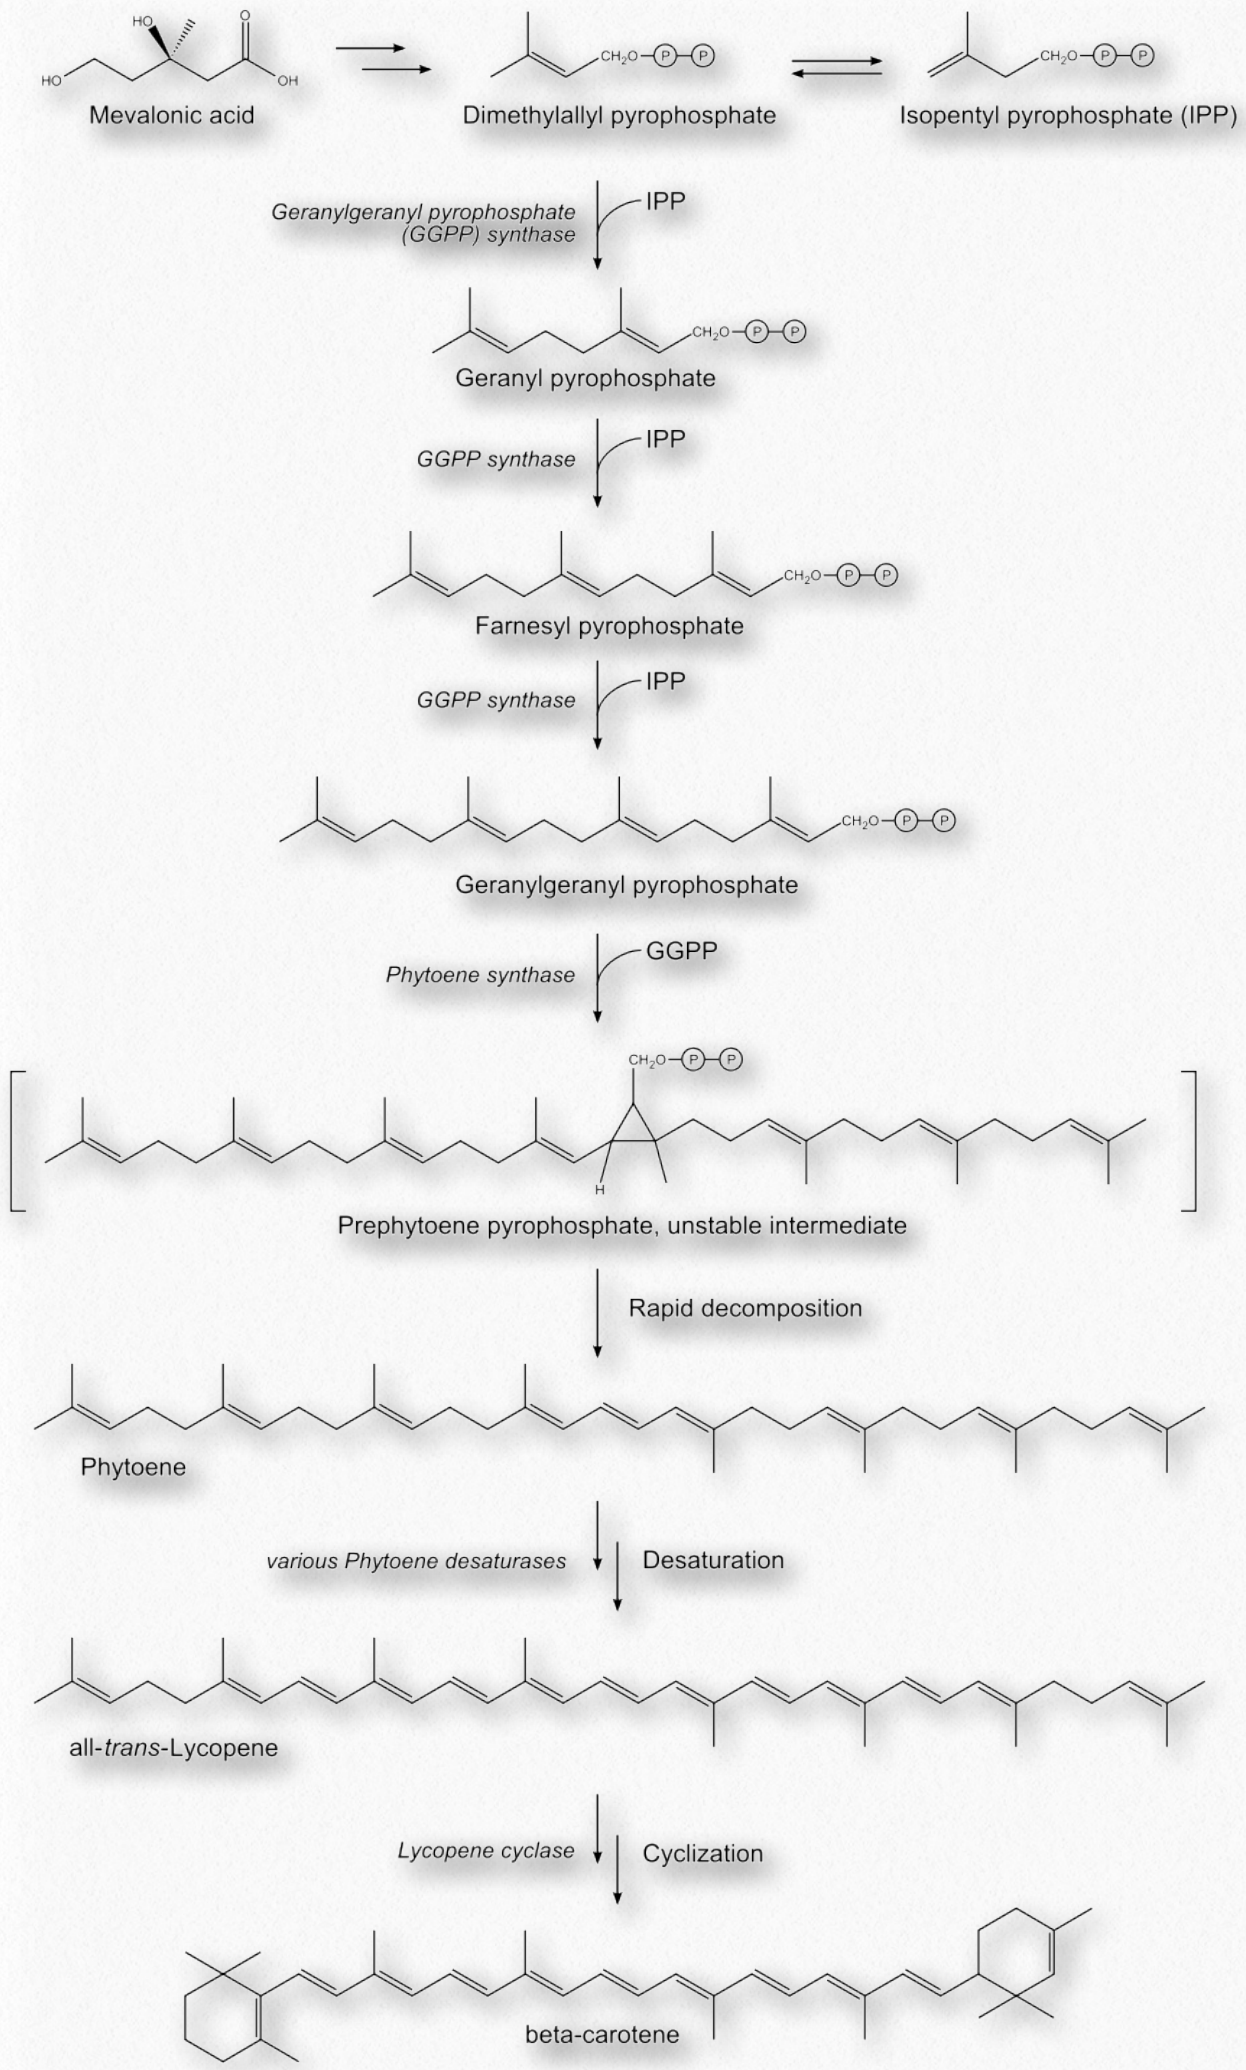

Figure 6.124 - Synthesis of β-carotene from mevalonate

Wikipedia

β-carotene is found in carrots and other orange vegetables, and is converted in the body to vitamin A. Catalytic action by β-Carotene 15,15' monooxygenase cleaves β-carotene to form retinal (the aldehyde form used in vision).

The enzyme retinol dehydrogenase catalyzes reduction of retinal to retinol (storage form). Oxidation of retinal creates another important retinoid known as retinoic acid. This form of vitamin A cannot be reduced back to retinal and thus cannot be used for vision or storage.

Instead, retinoic acid has roles in embryonic development. Retinoic acid acts through binding to the Retinoic Acid Receptor (RAR).

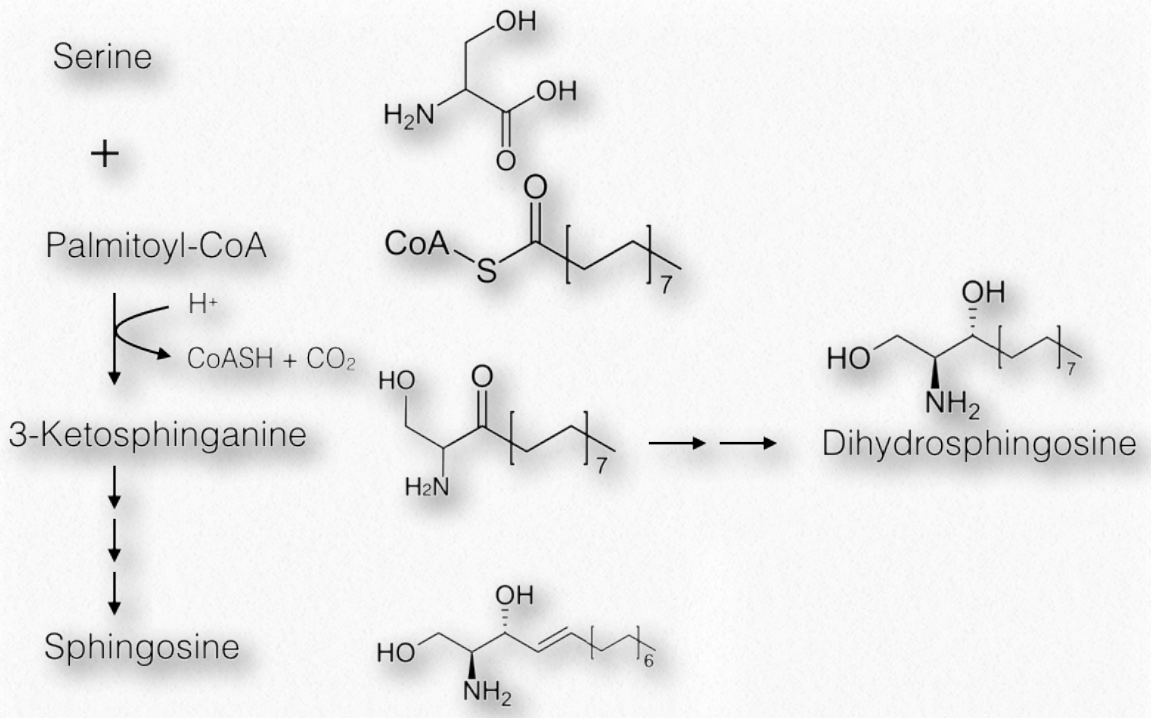

Figure 6.125 - Synthesis of dihydrosphingosine from serine and palmitoyl-CoA

RAR binds to DNA and affects transcription of several important sets of genes important for differentiation. These include the Hox genes, which control anterior/posterior patterning in early embryonic development.

Sphingolipid synthesis

Synthesis of sphingolipids, which are found primarily in brain and nerve tissue, begins with palmitoyl-CoA and serine that combine to make an 18-carbon amine called 3-keto-sphinganine (Figure 6.125). Reduction of that by NADPH yields dihydrosphingosine and addition of a fatty acid from an acyl-CoA yields N-acylsphinganine, which is a ceramide (Figure 6.126). A ceramide can be converted into a cerebroside by addition of a glucose from UDP-glucose (Figure 6.127).

If a few other simple sugars are added to the cerebroside, a globoside is created. If, instead of adding sugar, a phosphocholine is added from phosphatidylcholine, then sphingomyelin is created (Figure 6.127). If a complex set of sugars are added to to a cerebroside, then a ganglioside results (Figure 6.127).

Sphingolipid breakdown

In the overall metabolism of sphingolipids, the greatest problems arise with their catabolism. Figure 6.128 illustrates the nu-

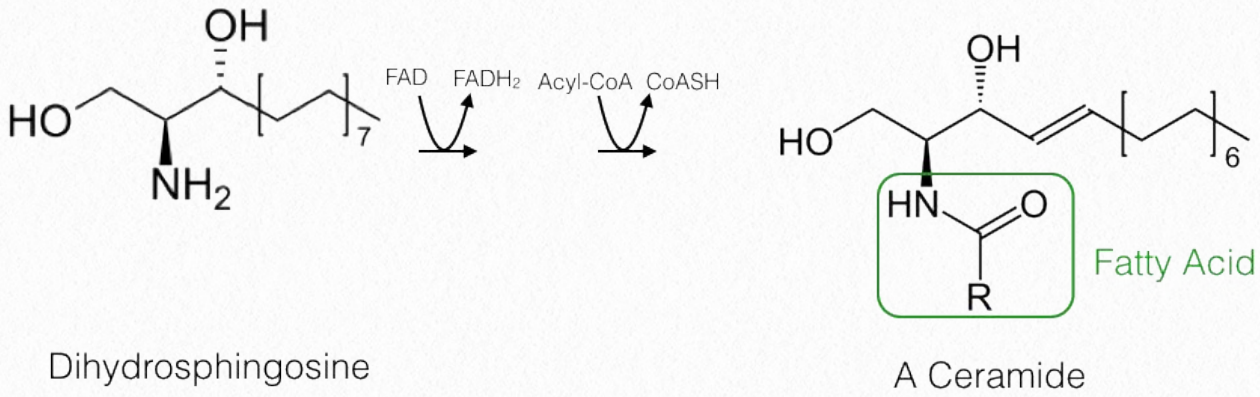

Figure 6.126 - Conversion of dihydrosphingosine to a ceramide

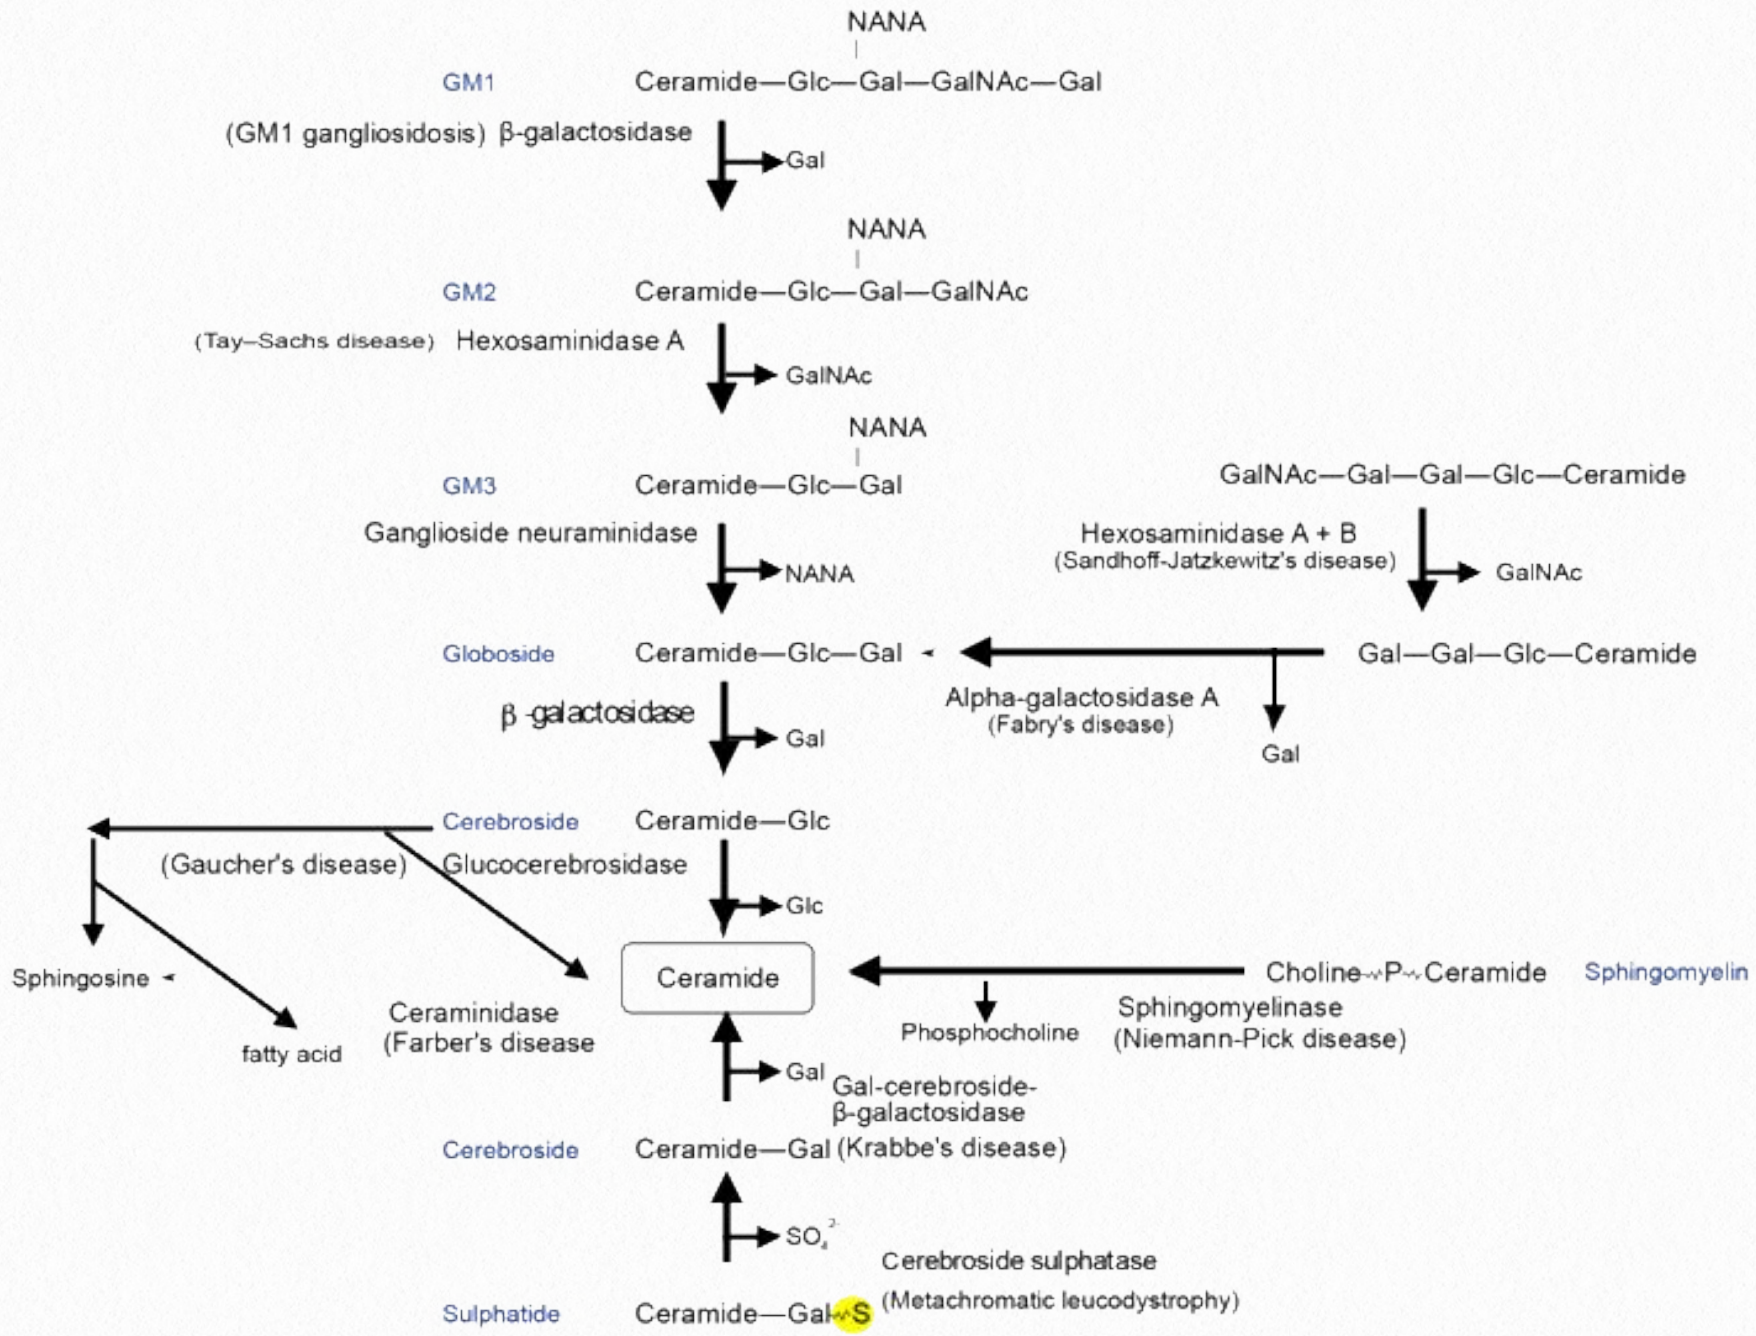

Figure 6.128 - Enzymes involved in sphingolipid breakdown and the diseases associated with their absence in parentheses. NANA = N-acetyl-neuraminic Acid / Glc = glucose / Gal = galactose / GalNAc = N-acetyl-galactosamine

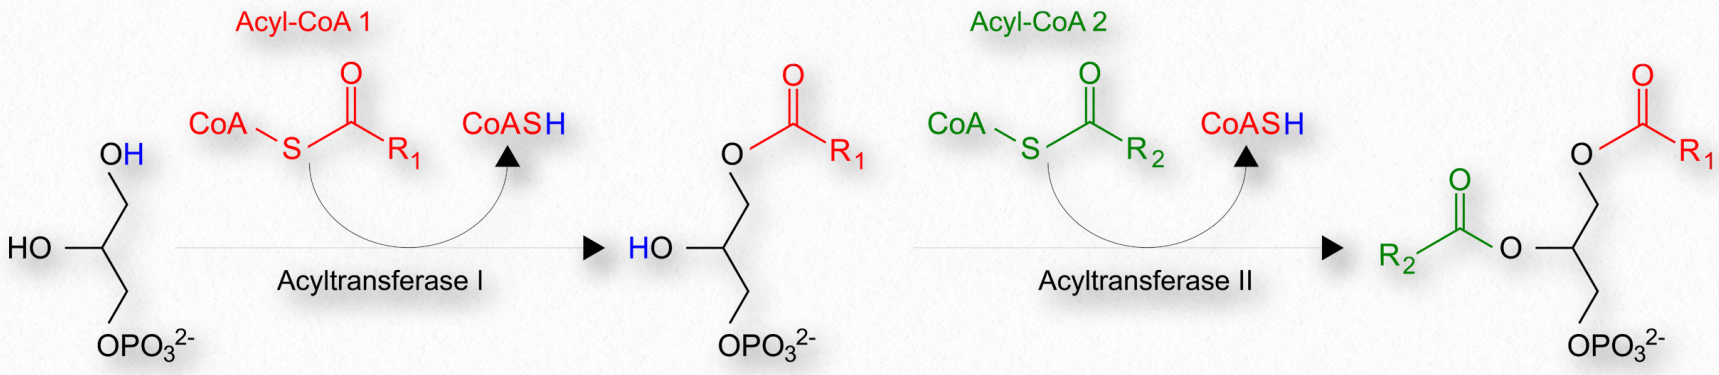
Wikipedia

merous genetic diseases arising from mutations in DNA coding for some of these enzymes. All are lysosomal storage diseases and many of these are quite severe. GM1 glandiosidoses (arising from inability to breakdown GM1 gangliosides) cause severe neurodegeneration and seizures. Individuals suffering from them typically die by age 3. Tay-Sachs disease usually causes death by age 4, though late-onset forms of the disease in adults are known.

YouTube Lectures by Kevin HERE & HERE

With Gaucher's disease, three different types have been described with widely varying effects. In some, the disease is fatal by age four and in others, it does not manifest until teens



Glycerol 3-phosphate Lysophosphatidic acid Phosphatidic acid

Figure 6.129 - Phosphatidic acid synthesis

Wikipedia

or even adulthood. Fabry's disease patients can live into their 50s, on average.

Glycerophospholipid metabolism

Glycerophospholipids are the major components of membranes. Synthesis of glycerophospholipids begins with glycerol-3-phosphate. In the first reaction, glycerol-3-phosphate gains a fatty acid at position one from an acyl-CoA, followed by a duplicate reaction at position two to make phosphatidic acid (Figure 6.129). This molecule, which can branch to other reactions to form fats, is an important intermediate in the synthesis of many glycerophospholipids. Glycerophospholipid compounds can often be made by more than one pathway. The nucleotide CDP plays an important role in glycerophospholipid synthesis, serving as part of an activated intermediate for synthesis of phosphatidyl compounds. This is necessary, because formation of the phosphodiester bonds of these compounds requires higher energy input.

Cells use two strategies to accomplish this. Both involve CDP. In the first, CTP combines with phosphatidic acid to make CDP-diacylglcyerol with release of a pyrophosphate. The reaction is catalyzed by phosphatidate cytidylyltransferase.

CTP + Phosphatidic acid ⇅ **CDP-diacylglycerol + PP_i**

CDP-diacylglycerol then serves as an activated intermediate to donate the phosphotidate part of itself to another molecule. The reaction below illustrates one example

CDP-diacylglycerol + Serine ⇅ **Phosphatidylserine + CMP**

The second strategy is to make a CDP derivative of the group being added to phosphatidic acid. An example is shown next

Phosphocholine + **CTP**

⇅

CDP-choline + **PPi**

Then the CDP donates the phosphocholine to a diacylglycerol to made phosphatidylcholine and CMP

CDP-choline + **Diacylglycerol**

⇅

Phosphatidylcholine + **CMP**

Synthesis of other important glycerophospholipids follows from these basic strategies. Phosphatidylethanolamine can be easily made from phosphatidylserine by decarboxylation.

Phosphatidylserine

⇅

Phosphatidylethanolamine + **CO_2**

Phosphatidylethanolamine can serve as a precursor in an alternative pathway for making phosphatidylcholine (SAM = S-Adenosyl Methioinine / SAH = S-Adenosyl Homocysteine)

Phosphatidylethanolamine + 3 **SAM**

⇅

Phosphatidylcholine + 3 **SAH**

Phosphatidylserine and phosphatidylethanolamine can swap groups reversibly in the reaction below

Phosphatidylethanolamine + **Serine**

⇅

Phosphatidylserine + **Ethanolamine**

Similarly, phosphatidylserine and phosphatidylcholine can be interchanged as follows:

Phosphatidylserine + **Choline**

⇅

Phosphatidylcholine + **Serine**

Phosphatidylglycerol can be made from glycerol-3-phosphate and CDP-diacylglycerol

CDP-diacylglycerol + **Glycerol-3-phosphate**

⇅

Phosphatidylglycerol + **CMP**

Cardiolipin, which is essentially a diphosphatidyl compound can be made by joining CDP-diacylglyerol with phosphatidylglycerol

Phosphatidylglycerol + **CDP-diacylglycerol**

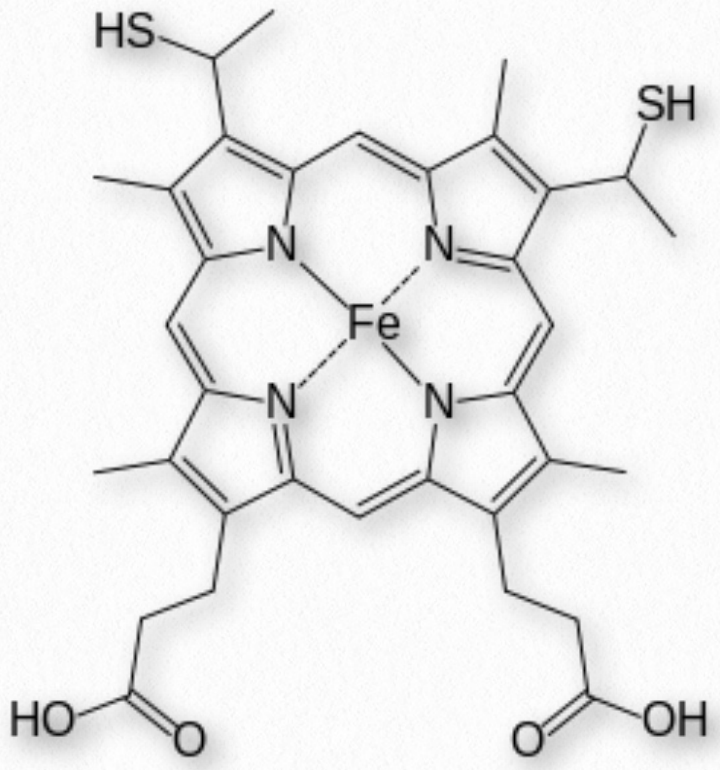

Figure 6.130 - Heme C

Phosphtidylinositol can be made from CDP-diacylglycerol and inositol.

CDP-diacylglycerol + **Inositol**

⇅

Phosphatidylinositol + **CMP**

Heme synthesis

The porphyrin ring found in the hemes of animals, fungi, and protozoa (Figure 6.130) is synthesized starting from very simple compounds (Figure 6.131). The process is a bit complicated, occurring between the cytoplasm and the mitochondrion. The first step is the creation of δ-aminolevulinic acid (also called aminolevulinic acid or dALA) from glycine and Succinyl-CoA.

Glycine + **Succinyl-CoA**

⇅

δ-aminolevulinic acid

Joining of two δ-aminolevulinic acid molecules together with splitting out of two molecules of water yields porphobilinogen.

2 **δ-aminolevulinic acid**

⇅

Porphobilinogen + $2H_2O$

Joining of four molecules of porphobilinogen together yields hydroxylmethylbilane (Figure 6.132).

4 **Porphobilinogen**

⇅

Hydroxymethylbilane

Next, a series of reactions involving 1) loss of water; 2) loss of four molecules of carbon dioxide; 3) loss of two more carbon dioxides, loss of six protons and electrons and (finally) 4) addition of Fe^{++} with loss of two protons yields heme. Individual heme molecules may be further processed.

Two enzymes in heme synthesis are sensitive to the presence of lead, and this is one of the primary causes of lead toxicity in humans. Inhibition of the enzymes leads to 1) anemia and 2) accumulation of δ-aminolevulinic acid,

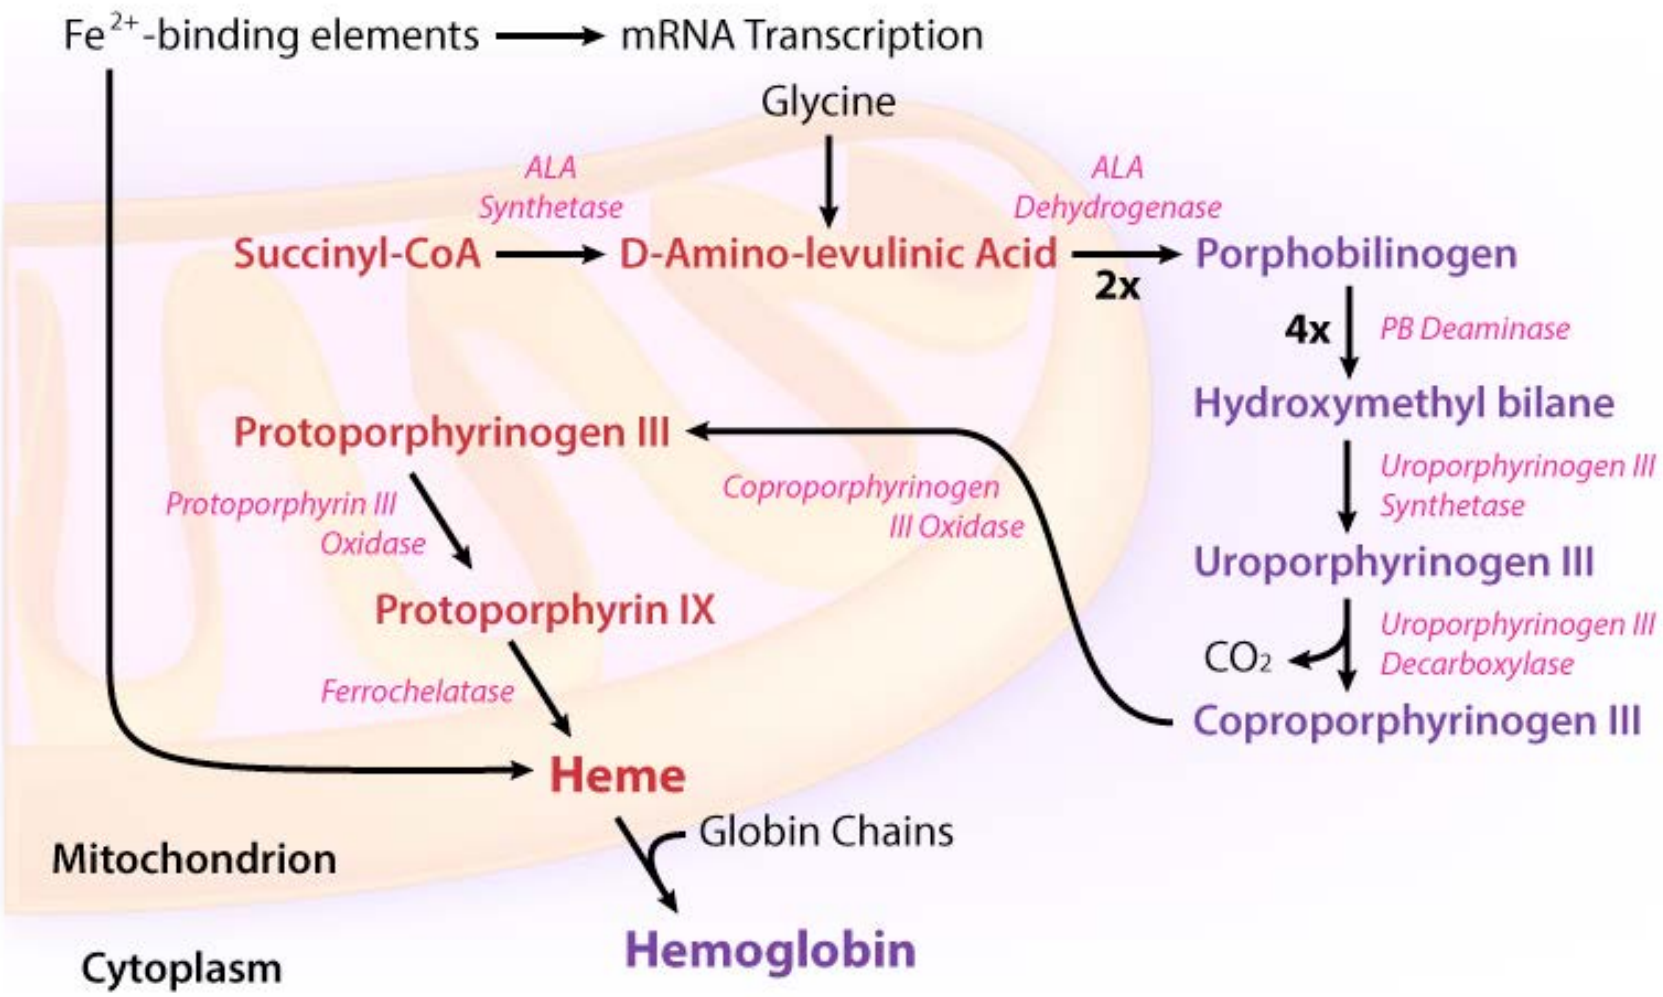

Figure 6.131 - Heme synthesis

Image by Aleia Kim

which can be harmful to neurons in development, resulting in learning deficiencies in children.

Porphyria

Defects in enzymes of the pathway can also lead to porphyrias, diseases in which one or more of the intermediates in the heme synthesis pathway accumulate due to deficiency of the enzyme necessary to convert the accumulating material into the next molecule in the pathway. The accumulation of purplish intermediates gave the diseases the name porphyria from the Greek word for purple.

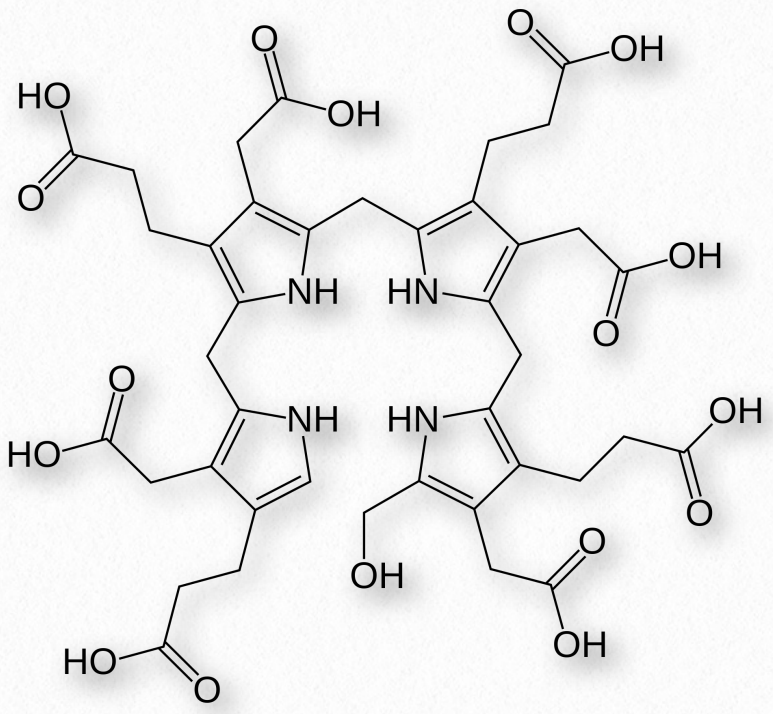

Figure 6.132 - Hydroxylmethylbilane - A precursor of heme

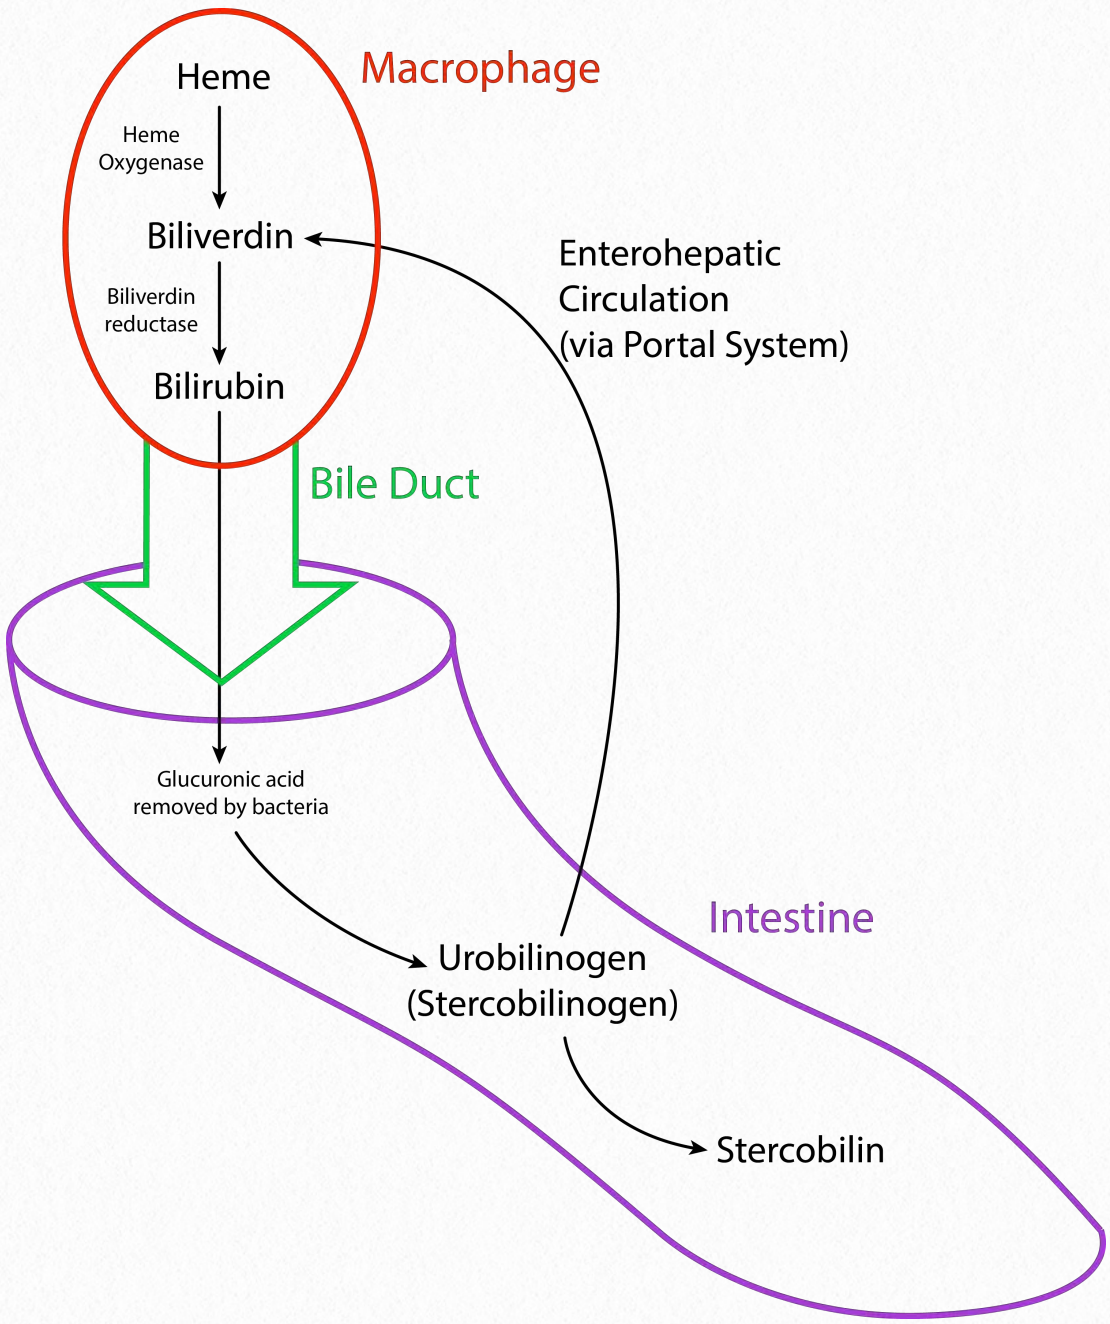

Figure 6.133 - Catabolism of heme

Image by Pehr Jacobson

Severe porphyrias can lead to brain damage, nerve damage, and mental disturbances. The "madness" of King George III may have been due to a form of porphyria. In other manifestations of the disease, cutaneous porphyrias cause skin problems on exposure to light. This need, for patients with certain forms of porphyria, to avoid light, coupled with the fact that porphyrias can be treated by blood tranfusions, may have led to the legend of vampires.

YouTube Lectures by Kevin HERE & HERE

Breakdown of heme

Catabolism of heme (Figure 6.133) begins in macrophages within the spleen . Targets for degradation are hemes within damaged red blood cells, which get removed from the blood supply due to their appearance. It is because of this system, for example, that sickle cell anemia is classified as an anemia (decrease in red blood cells or hemoglobin in the blood). After cells have sickled, they lose their shape and are more likely to be removed from the blood by this process, leaving the patient weakened from low blood cell counts.

The first biochemical step in catabolism is conversion of heme to biliverdin. This reaction is catalyzed by heme oxygenase and requires electrons from NADPH. In the process, Fe^{++} is released. Interestingly, carbon monoxide is also produced and it acts as a vasodilator.

Next, biliverdin is converted to bilirubin by biliverdin reductase and is secreted from the liver into bile. Bacteria in the

intestine convert bilirubin to urobilinogens, some of which is absorbed intestinal cells and transported into kidneys and excreted. The yellow color of urine arises from the compound known as urobilin, which is an oxidation product of urobilinogen. The remainder of the urobilinogens are converted in the intestinal tract to stercobilinogen whose oxidation product is stercobilin and it gives the color associated with feces.

To Make a Cholesterol

To the tune of "*When Johnny Comes Marching Home*"

Metabolic Melodies Website HERE

Some things that you can build with acetyl-CoAs
Are joined together partly thanks to thiolase
They come together 1-2-3
Six carbons known as H-M-G
And you're on your way
To make a cholesterol

To synthesize a mevalonate in the cell
Requires reducing HMG-CoA, as well
The enzyme is a RE-ductase
Controlled in allosteric ways
When the cell's impelled
To make a cholesterol

The mevalonate made in metabolic schemes
Gets decarboxylated down to isoprenes
They're linked together willy-nil
To build a PP-geranyl
In the cells' routines
To make a cholesterol

A single step links farnesyls but that's not all
The squalene rearranges to lanosterol
From that there's nineteen steps to go
Before the sterol's apropos
Which you must recall
To make a cholesterol

The regulation of the scheme's complex in ways
Inhibited by feedback of the RE-duc-tase
And statins mimic so they say
The look of HMG-CoA
So we sing their praise
And not make cholesterol

Recording by David Simmons
Lyrics by Kevin Ahern

The Dieter's Song

To the tune of "*Story of Love*"

Metabolic Melodies Website HERE

You better lose your middle
Run a little
Get yourself fit as a fiddle
You must break a sweat
You will truly get
Fit

You need to change your diet
Don't deny it
Reducing intake you should try it
Hold off on the cheese
Count the calories,
Love

Bridge
Whenever there is juicy stuff
You need to ponder on the cost
Cuz just a little is enough
Or else your diet's lost

You wanna move your waistline
To the baseline
Give those legs a bit of racetime
It is worth the sweat
When you truly get
Fit

It is worth the sweat
When you truly get
Fit

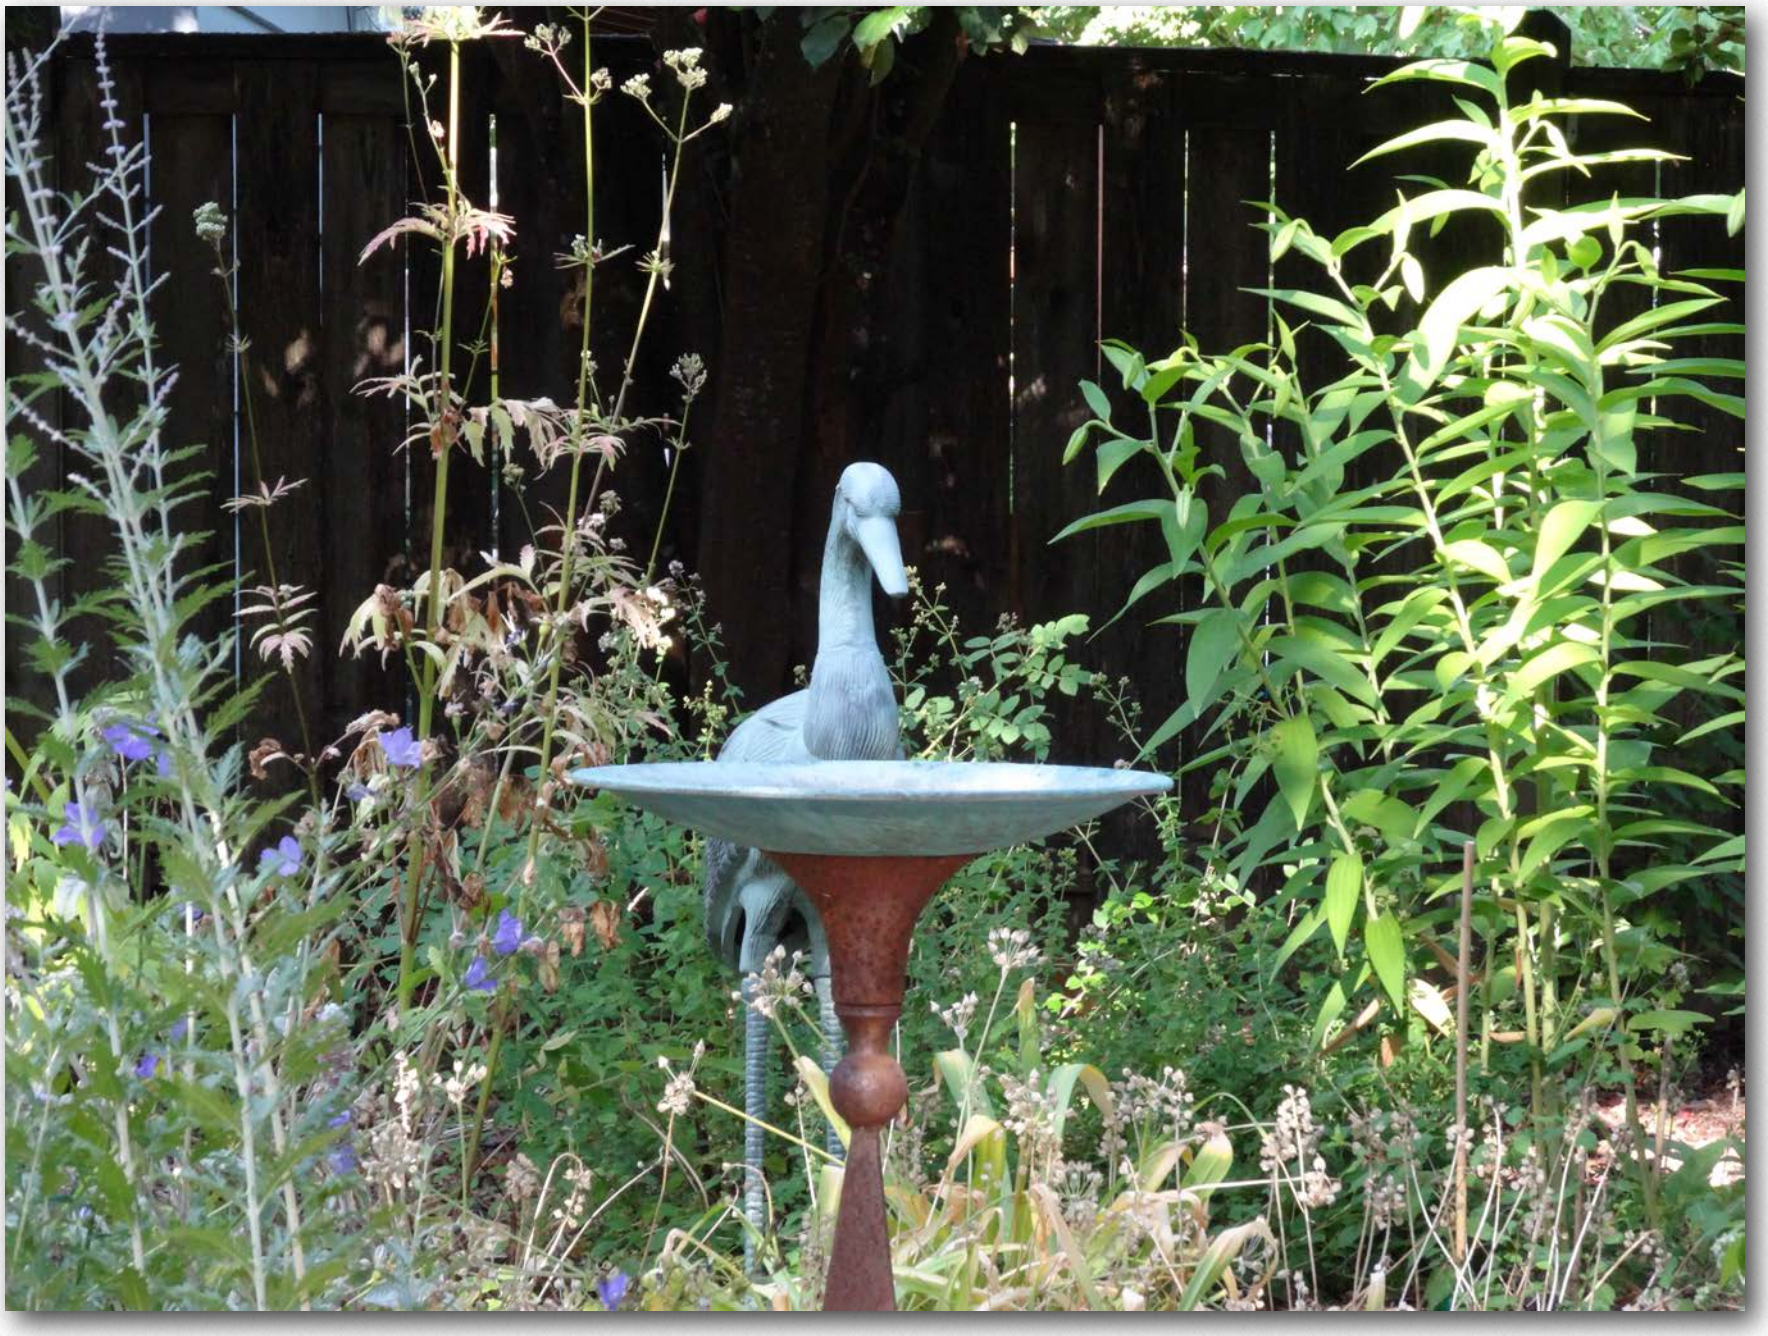
Lyrics by Kevin Ahern

Metabolism: Amino Acids and the Urea Cycle



Amino acid metabolism

In contrast to some of the metabolic pathways described to this point, amino acid metabolism is not a single pathway. The 20 amino acids have some parts of their metabolism that overlap with each other, but others are very different from the rest. In discussing amino acid metabolism, we will group metabolic pathways according to common metabolic features they possess (where possible). First, we shall consider the anabolic pathways.

YouTube Lectures by Kevin
HERE & HERE

Transamination

Before beginning discussion of the pathways, it is worthwhile to discuss a reaction common to the metabolism of most of the amino acids and other nitrogen-containing compounds and that is transamination.

In cells, nitrogen is a nutrient that moves from one molecule to another in a sort of hand-off process. A common transamination reaction is shown on the next page.

α-ketoacid + **Glutamate**

⇅

Amino acid + **α-ketoglutarate**

A specific reaction of this type is shown in Figure 6.134.

Glutamate and glutamine play central roles in transamination, each containing one more amine group than **α**-ketoglutarate and glutamate, respectively. Transamination reactions, as noted earlier, occur by a ping-pong mechanism and involve swaps of amines and oxygens in Schiff base reactions. Two amino acids, glutamine and asparagine are the products of gaining an amine in their respective R-groups in reactions involving ammonium ion.

Synthesis varies

It is also important to recognize that organisms differ considerably in the amino acids that they can synthesize. Humans, for example, cannot make 9 of the 20 amino acids needed to make proteins, and the number of these that can be synthesized in needed amounts varies between adults and children.

Amino acids that cannot be made by an organism must be in the diet and are called essential amino acids. Non-essential amino acids are those an organism can make in sufficient quantities (Figure 6.135). Though amino acids do not have a common pathway of metabolism, they are often organized in "families" of amino acids with overlapping metabolic reactions common to members of each group. To designate amino acid families in the text we will use a blue font for headings to distinguish them.

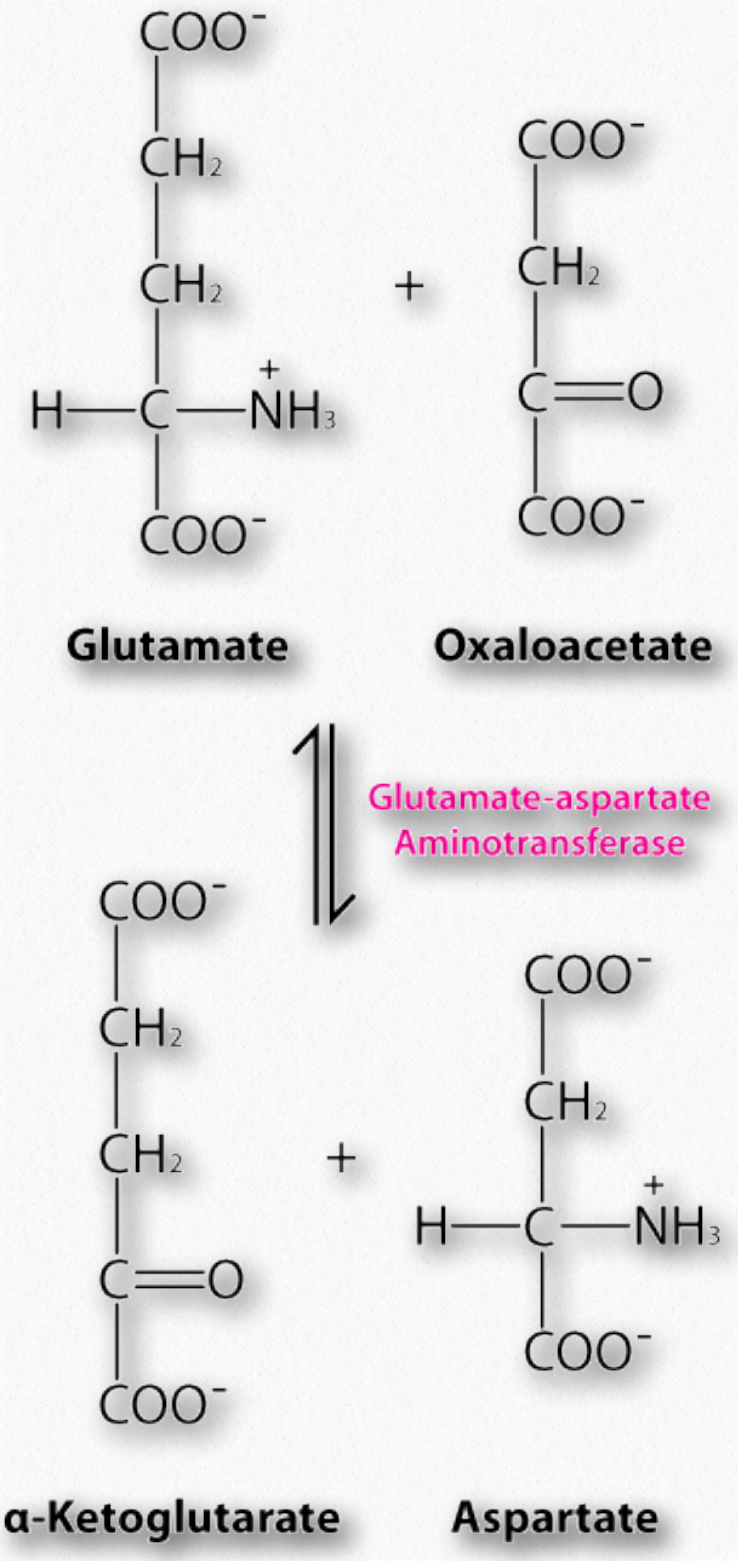


Figure 6.134 - Example of a transaminase (aminotransferase) reaction

Image by Aleia Kim

α-ketoglutarate family

This family of amino acids arises from α-ketoglutarate of the citric acid cycle. It includes the amino acids glutamic acid, glutamine, proline, and arginine. It is also called the glutamate family, since all the amino acids in it derive from glutamate.

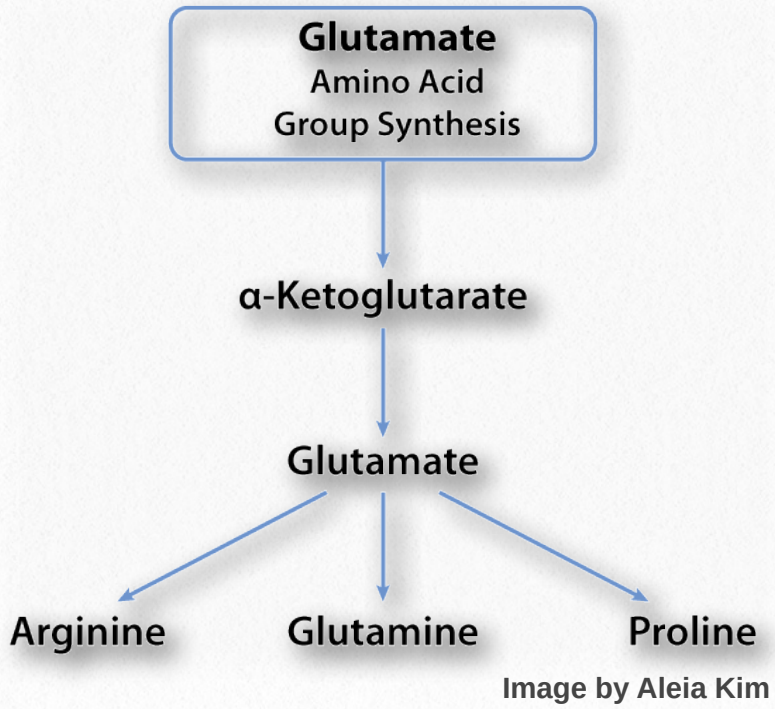

Image by Aleia Kim

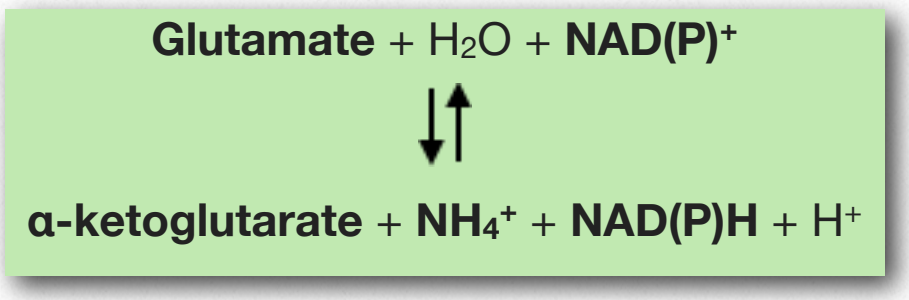
Essential	Non-Essential
Histidine	Alanine
Isoleucine	Arginine
Leucine	Asparagine
Lysine	Aspartic acid
Methionine	Cysteine
Phenylalanine	Glutamic acid
Threonine	Glutamine
Tryptophan	Glycine
Valine	Proline
	Selenocysteine
	Serine
	Tyrosine

Figure 6.135 - Essential and non-essential amino acids

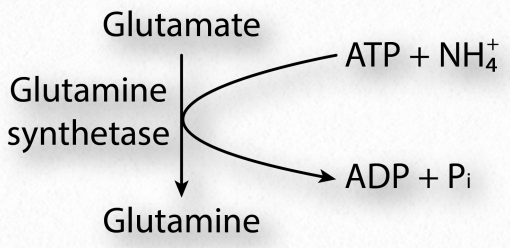
Image by Pehr Jacobson

Glutamate

α-ketoglutarate is readily converted to glutamate in transamination reactions, as noted above. It can also be produced by the enzyme glutamate dehydrogenase, which catalyzes the reaction below (in reverse) to make glutamate.



In the forward direction, the reaction is a source of ammonium ion, which is important both for the urea cycle and for glutamine metabolism. Because it is a byproduct of a citric acid cycle intermediate, glutamate can therefore trace its roots to any of the intermediates of the cycle. Citrate and isocitrate, for example, can be thought of as precursors of glutamate. In addition, glutamate can be made by transamination from α-ketoglutarate in numerous transamination reactions involving other amino acids.



Inhibitors of Glutamine Synthetase		
Amino acids	Nucleotides	Other
Glycine Alanine Serine Histidine Tryptophan	AMP CTP	Carbamoylphosphate Glucosamine-6-phosphate

Figure 6.136 Action and inhibitors of glutamine synthetase

Image by Pehr Jacobson

catalyzed by glutamate synthetase commonly arises from nitrite reduction, amino acid breakdown, or photorespiration. Because it builds ammonia into an amino acid, glutamine synthetase helps reduce the concentration of toxic ammonia - an important consideration in brain tissue. Some inhibitors of glutamine synthetase are, in fact, the products of glutamine metabolism. They include histidine, tryptophan, carbamoyl phosphate, glucosamine-6-phosphate, CTP, and AMP. The glutamine

Glutamine

Synthesis of glutamine proceeds from glutamate *via* catalysis of the enzyme glutamine synthetase, one of the most important regulatory enzymes in all of amino acid metabolism (Figure 6.136).

Regulation of the enzyme is complex, with many allosteric effectors. It can also be controlled by covalent modification by adenylylation of a tyrosine residue in the enzyme (Figure 6.137). In the figure, P_A and P_D are regulatory proteins facilitating conversion of the enzyme.

Ammonia used in the reaction

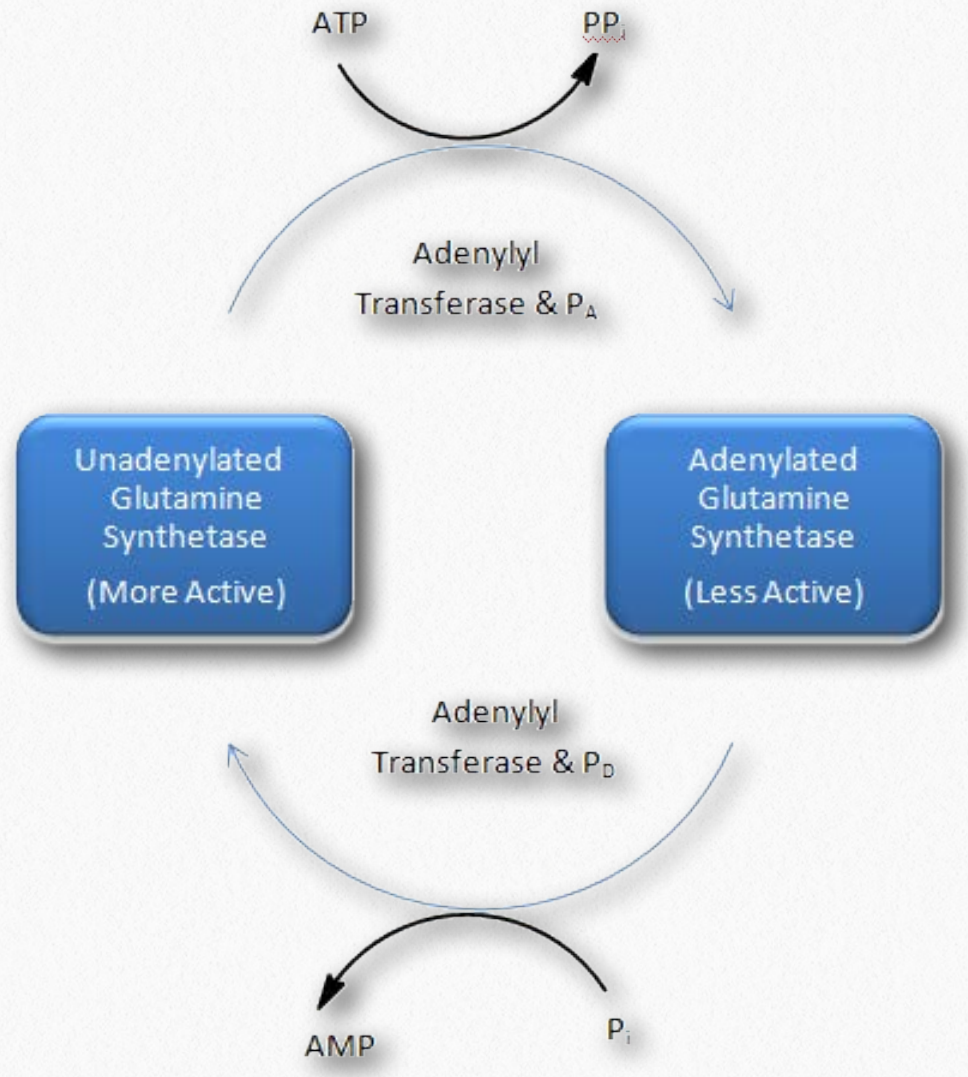


Figure 6.137 - Regulation of glutamine synthetase by adenylylation

mate substrate site is a target for the inhibitors alanine, glycine, and serine. The ATP substrate site is a target for the inhibitors GDP, AMP, and ADP. Complete inhibition of the enzyme is observed when all of the substrate sites of the multi-subunit enzyme are bound by inhibitors. Lower levels of inhibitors results in partial or full activity, depending on the actual amounts.

Proline

Synthesis of proline starts with several reactions acting on glutamate. They are shown below in the green text box.

1. **ATP** + **L-glutamate**
   ⇅ (Glutamate-5-kinase)
   ADP + **L-glutamate 5-phosphate**

2. **L-glutamate 5-phosphate** + **NADPH** + H^+
   ⇅ (Glutamate-5-semialdehyde dehydrogenase)
   L-glutamate 5-semialdehyde + **Pi** + **NADP$^+$**

The L-glutamate-5-semialdehyde, so produced, is a branch point for synthesis of proline or ornithine. In the path to make proline, spontaneous cyclization results in formation of 1-pyrroline-5-carboxylic acid (Figure 6.138).

This, in turn, is reduced to form proline by pyrroline-5-carboxylate reductase.

1-pyrroline-5-carboxylate + **NAD(P)H** + H^+
⇅
L-proline + **NAD(P)$^+$**

Arginine

Arginine is a molecule synthesized in the urea cycle and, thus, all urea cycle molecules can be considered as precursors. Starting with citrulline, synthesis of arginine can proceed as shown on the next page. The urea cycle can be seen HERE.

Figure 6.138 - Spontaneous cyclization of L-glutamate-5-semialdehyde (left) to 1-pyrroline-5-carboxylic acid (right)
Image by Aleia Kim

1. **Citrulline** + **ATP** + **Aspartate**

   Argininosuccinate + **PP_i** + **AMP**

2. **Argininosuccinate**

   ⇅ (**Argininosuccinase**)

   Arginine + **Fumarate**

An alternate biosynthetic pathway for making arginine from citrulline involves reversing the reaction catalyzed by nitric oxide synthase. It catalyzes an unusual five electron reduction reaction that proceeds in the following manner

Citrulline + **Nitric Oxide** + 3/2 **$NADP^+$**

⇅

L-arginine + 3/2 **NADPH** + H^+ + 2 O_2

Yet another way to synthesize arginine biologically is by reversal of the arginase reaction of the urea cycle

Arginine + Water

⇅

Ornithine + **Urea**

Arginine can also be made starting with glutamate. This 5 step pathway leading to ornithing is illustrated at the top of the next page (enzymes in blue). Ornithine, as noted above can readily be converted to arginine.

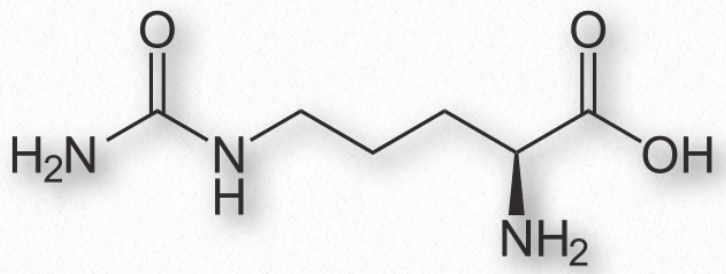

Figure 6.139 - Citrulline

The last means of making arginine is by reversing the methylation of asymmetric dimethylarginine (ADMA - Figure 6.140). ADMA is a metabolic byproduct of protein modification. It interferes with production of nitric oxide and may play a role in cardiovascular disease, diabetes mellitus, erectile dysfunction, and kidney disease.

   ⇅ (**Transaminase**)

   N-acetylornithine + **α-ketoglutarate**

5. **N-acetylornithine** + H_2O

   ⇅ (**N-acetylornithinase**)

   Ornithine + **Acetate**

Serine family

Serine is a non-essential amino acid synthesized from several sources. One starting point is the glycolysis intermediate, 3-phosphoglycerate, (3-PG) in a reaction

3-PG + **NAD$^+$**

⇅

3-phosphohydroxypyruvate + **NADH** + H^+

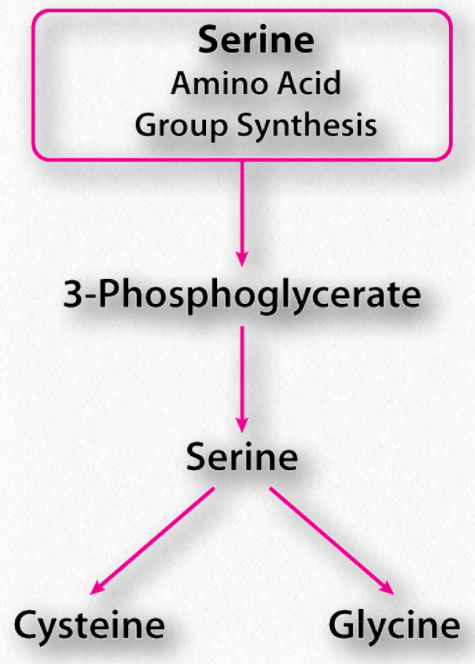

Image by Aleia Kim

catalyzed by 3-PG dehydrogenase.

Transamination by phosphoserine aminotransferase produces O-phosphoserine. The phosphate is then removed by phosphoserine phosphatase, to make serine. These reactions are shown below. Phosphoserine phosphatase is missing in the genetic disease known as Williams-Beuren syndrome.

1. **3-phosphohydroxypyruvate** + **Glutamate**

   ⇅

   O-phosphoserine + **α-ketoglutarate**

2. **O-phosphoserine** + H_2O

   ⇅

   Serine + **P_i**

Serine can also be derived from glycine and *vice versa*. Their metabolic paths are intertwined as will be seen below. Serine is important for metabolism of purines and pyrimidines, and is the precursor for glycine, cysteine, and tryptophan in bacteria, as well as for sphingolipids and folate. Serine in the active site of serine proteases is essential for catalysis. A serine in the active site of acetylcholinesterases is the target of nerve gases and insecticides.

Covalent modification target

Serine in proteins can be the target of glycosylation or phosphorylation. D-serine is the second D-amino acid known to function in humans. It serves as a neuromodulator for NMDA receptors, by serving as a co-agonist, together with glutamate. D-serine is being studied as a schizophrenia treatment in rodents and as a possible biomarker for Alzheimers.

Glycine

As noted, glycine's metabolism is intertwined with that of serine. This is apparent in the reaction catalyzed by serine hydroxymethyltransferase.

Serine + **Tetrahydrofolate**

⇅

Glycine + **N_5,N_{10}-Methylene Tetrahydrofolate** + H_2O

Notably, the previous reaction is also needed for recycling of folate molecules, which are important for single carbon reactions in nucleotide synthesis.

Vertebrates can also synthesize glycine in their livers using the enzyme glycine synthase.

Glycine is a very abundant component of collagen. It is used in the synthesis of purine nucleotides and porphyrins. It is an inhibitory neurotransmitter and is a co-agonist of NMDA receptors with glutamate. Glycine was detected in material from Comet Wild 2.

Cysteine

Cysteine can be synthesized from several sources. One source is the metabolism of the other sulfur-containing amino acid, methionine. This begins with formation of S-Adenosyl-Methionine (SAM), catalyzed by methionine adenosyltransferase.

Methionine + **ATP**

⇅

SAM + **P_i** + **PP_i**

SAM is a methyl donor for methyl transfer reactions and that is the next step in the pathway - donation of a methyl group (catalyzed by transmethylase)

SAM + Acceptor

⇅

SAH + CH_3-Acceptor

SAH (S-Adenosylhomocysteine) is cleaved by S-adenosylhomocysteine hydrolase,

SAH

⇅

Homocysteine + **Adenosine**

Homocysteine can be recycled back to methionine by action of methionine synthase

On the path to making cysteine, homocysteine reacts as follows (catalyzed by cystathionine **β**-synthase).

Homocysteine + **Serine**

⇅

Cystathionine

Last, cystathionase catalyzes release of cysteine

Cystathionine + H_2O

⇅

Cysteine + **β-ketobutyrate** + NH_4^+

β-ketobutyrate can be metabolized to propionyl-CoA and then to succinyl-CoA to be used ultimately in the citric acid cycle.

Another route to making cysteine is a two-step process that begins with serine, catalyzed first by serine-O-acetyltransferase

Serine + **Acetyl-CoA**

Aspartate family

Metabolism of aspartic acid is similar to that of glutamate. Aspartic acid can arise from transamination of a citric acid cycle intermediate (oxaloacetate).

Aspartate can also be generated from asparagine by the enzyme asparaginase.

Asparagine + H_2O

⇅

Aspartate + **NH_4^+**

Further, aspartate can be produced by reversal of a reaction in the urea cycle (see HERE)

Aspartate is also a precursor to four amino acids that are essential in humans. They are methionine, isoleucine, threonine, and lysine. Because oxaloacetate can be produced from aspartate, aspartate is an important intermediate for gluconeogenesis when proteins are the energy source.

YouTube Lectures by Kevin HERE & HERE

Asparagine

Asparagine, too, is an amino acid produced in a simple transamination reaction. In this case, the precursor is aspartate and the amine donor is glutamine (catalyzed by asparagine synthetase)

Aspartate + **Glutamine** + **ATP**

⇅

Asparagine + **Glutamate** + **AMP** + **PP_i**

Methionine

Metabolism of methionine overlaps with metabolism of the other sulfur-containing amino acid, cysteine. Methionine is not made in humans (essential) so the pathway shown in Figure 6.141 is from bacteria.

The process begins with phosphorylation of aspartate. Numbers for each catalytic step in the figure are for the enzymes that follow:

1 - Aspartokinase
2 - Aspartate-semialdehyde dehydrogenase
3 - Homoserine dehydrogenase
4 - Homoserine O-transsuccinylase
5 - Cystathionine-γ-synthase
6 - Cystathionine-β-lyase
7 - Methionine synthase

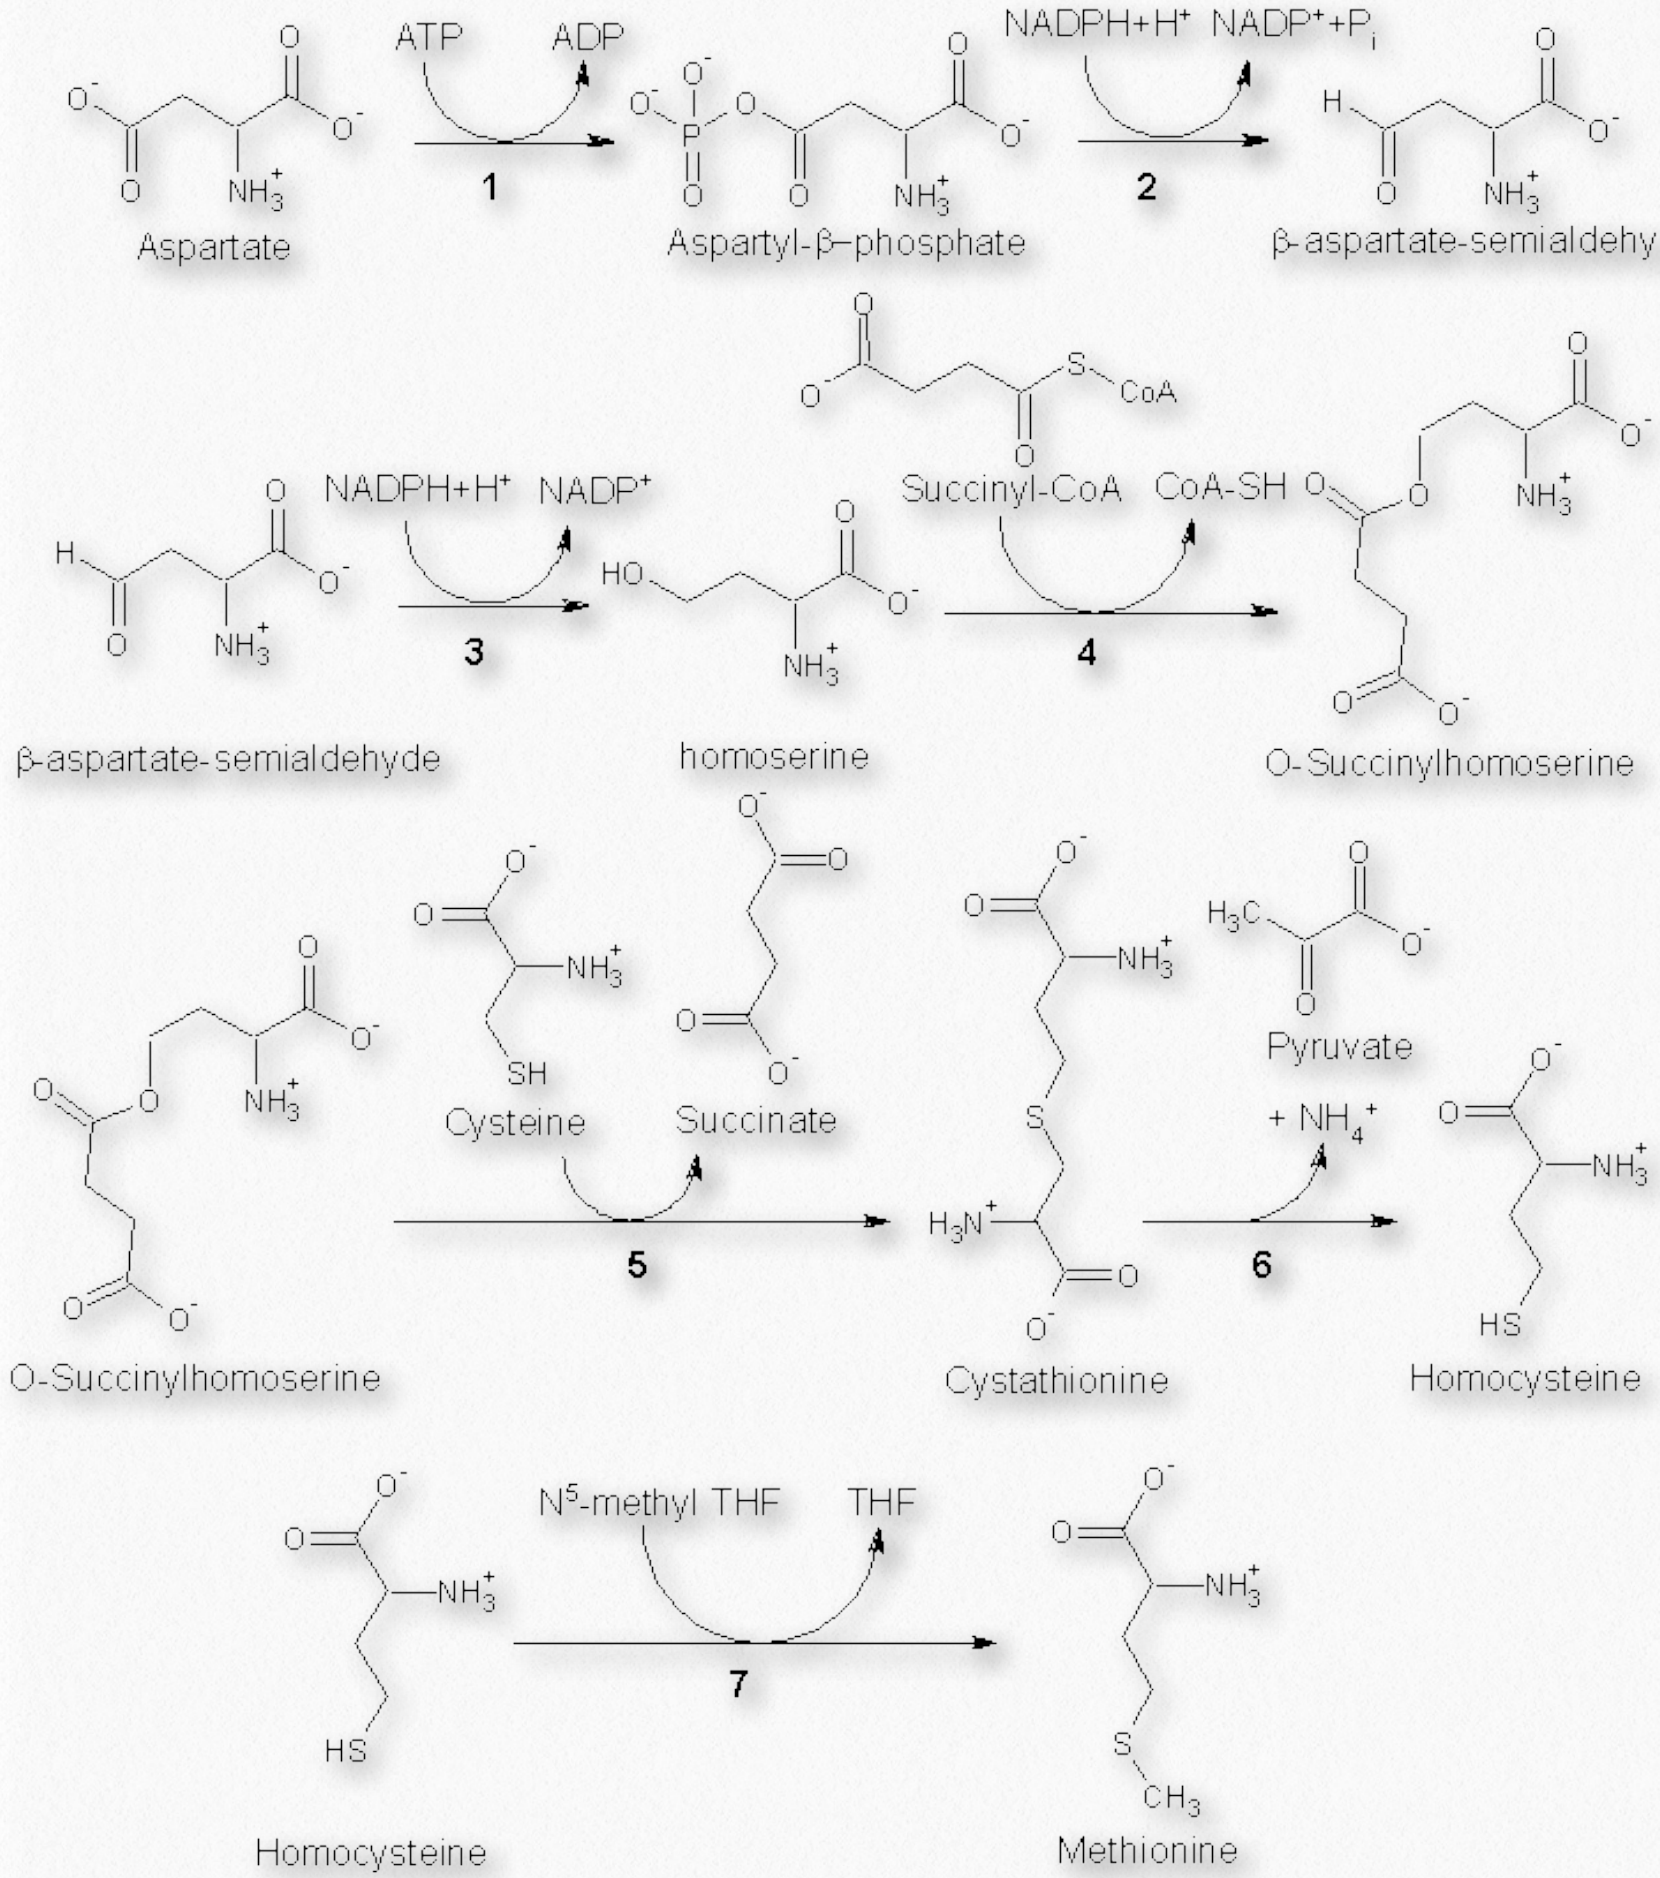

Figure 6.141 - Synthesis of methionine from aspartic acid

Wikipedia

Though humans cannot make methionine by the pathway shown in the figure, they can recycle methionine from homocysteine (a product of S-adenosylmethionine metabolism). This reaction requires the enzyme methionine synthase and Vitamin B_{12} as a co-factor.

An alternative pathway of converting homocysteine to methionine involves a prominent liver enzyme, betaine-homocysteine methyltransferase. This enzyme catalyzes the reaction below.

Glycine Betaine + **Homocysteine**

⇅

Dimethylglycine + **Methionine**

In this reaction, a methyl group is transferred to homocysteine from glycine betaine to make the methionine. Glycine betaine is a trimethylated amine of glycine found in plants. It is a byproduct of choline metabolism.

Bacteria, mitochondria, and chloroplasts use a modified form of methionine, N-formylmethionine (Figure 6.142), as the first amino acid incorporated into their proteins. Formylation of methionine occurs only after methionine has been attached to its tRNA for translation. Addition of the formyl group is catalyzed by the enzyme methionyl-tRNA formyltransferase

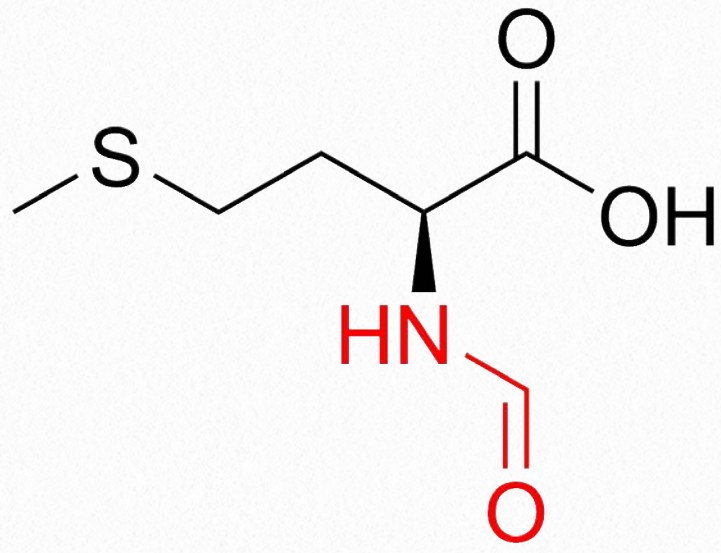

Figure 6.142 - **N-formyl-methionine**

Threonine

Though threonine is chemically similar to serine, the metabolic pathway leading to threonine does not overlap with that of serine. As seen in the figure, aspartate is a starting point for synthesis. Two phosphorylations/dephosphorylations and two reductions with electrons from NADPH result in production of threonine.

Enzymes in Figure 6.143 are as follows:

1 Aspartokinase
2 β-aspartate semialdehyde dehydrogenase
3 Homoserine dehydrogenase
4 Homoserine kinase
5 Threonine synthase

Breakdown of threonine produces acetyl-CoA and glycine. It can also produce α-ketobutyrate, which can be converted to succinyl-CoA for oxidation in the citric acid cycle.

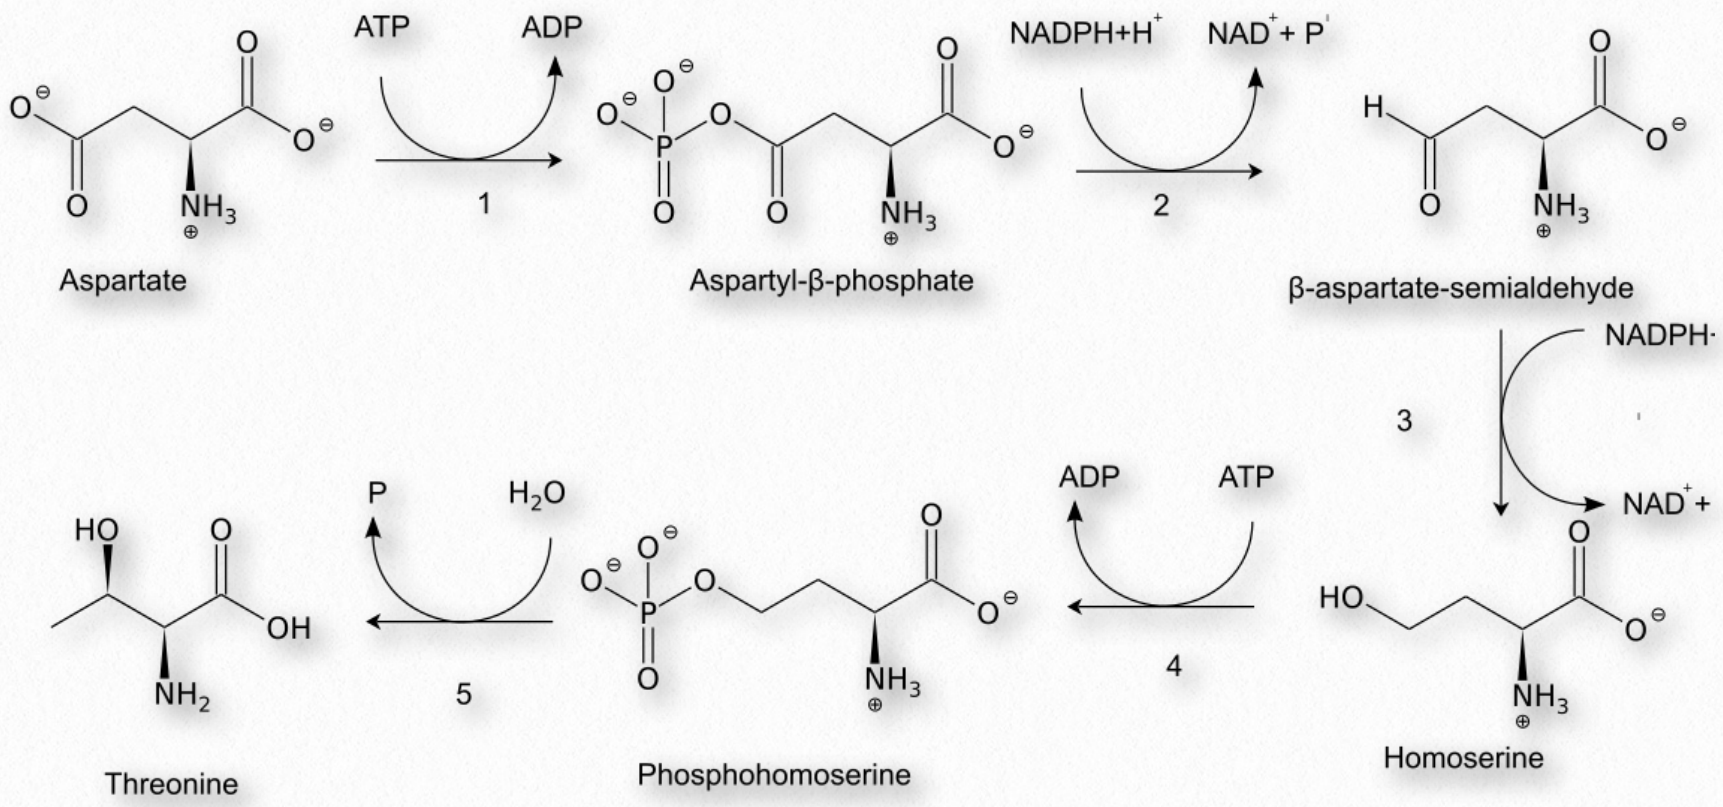

Figure 6.143 - Synthesis of threonine from aspartate

Wikipedia

Lysine

To get from aspartate to lysine, nine reactions and two non-enzymatic steps are involved, as seen in Figure 6.144. Enzymes involved in lysine biosynthesis include (numbers correspond to numbered reactions in Figure 6.144):

1 - Aspartokinase
2 - Aspartate-semialdehyde dehydrogenase
3 - 4-hydroxy-tetrahydrodipicolinate synthase
4 - 4-hydroxy-tetrahydrodipicolinate reductase
5 - 2,3,4,5-tetrahydropyridine-2,6-dicarboxylate N-succinyltransferase
6 - Succinyl-diaminopimelate transaminase
7 - Succinyl-diaminopimelate desuccinylase
8 - Diaminopimelate epimerase
9 - Diaminopimelate decarboxylase

Low in cereal grains

Lysine is the essential amino acid found in the smallest quantity in cereal grains, but is found abundantly in legumes. Besides its synthesis and breakdown, lysine can be methylated, acetylated, hydroxylated, ubiquitinated, sumoylated, neddylated, biotinylated, pupylated, and carboxylated within proteins containing it. Hydroxylation of lysine is important for strengthening collagen and acetylation/methylation of lysine in histone proteins play roles in control of gene expression and epigenetics. Besides being used to make proteins, lysine is impor-

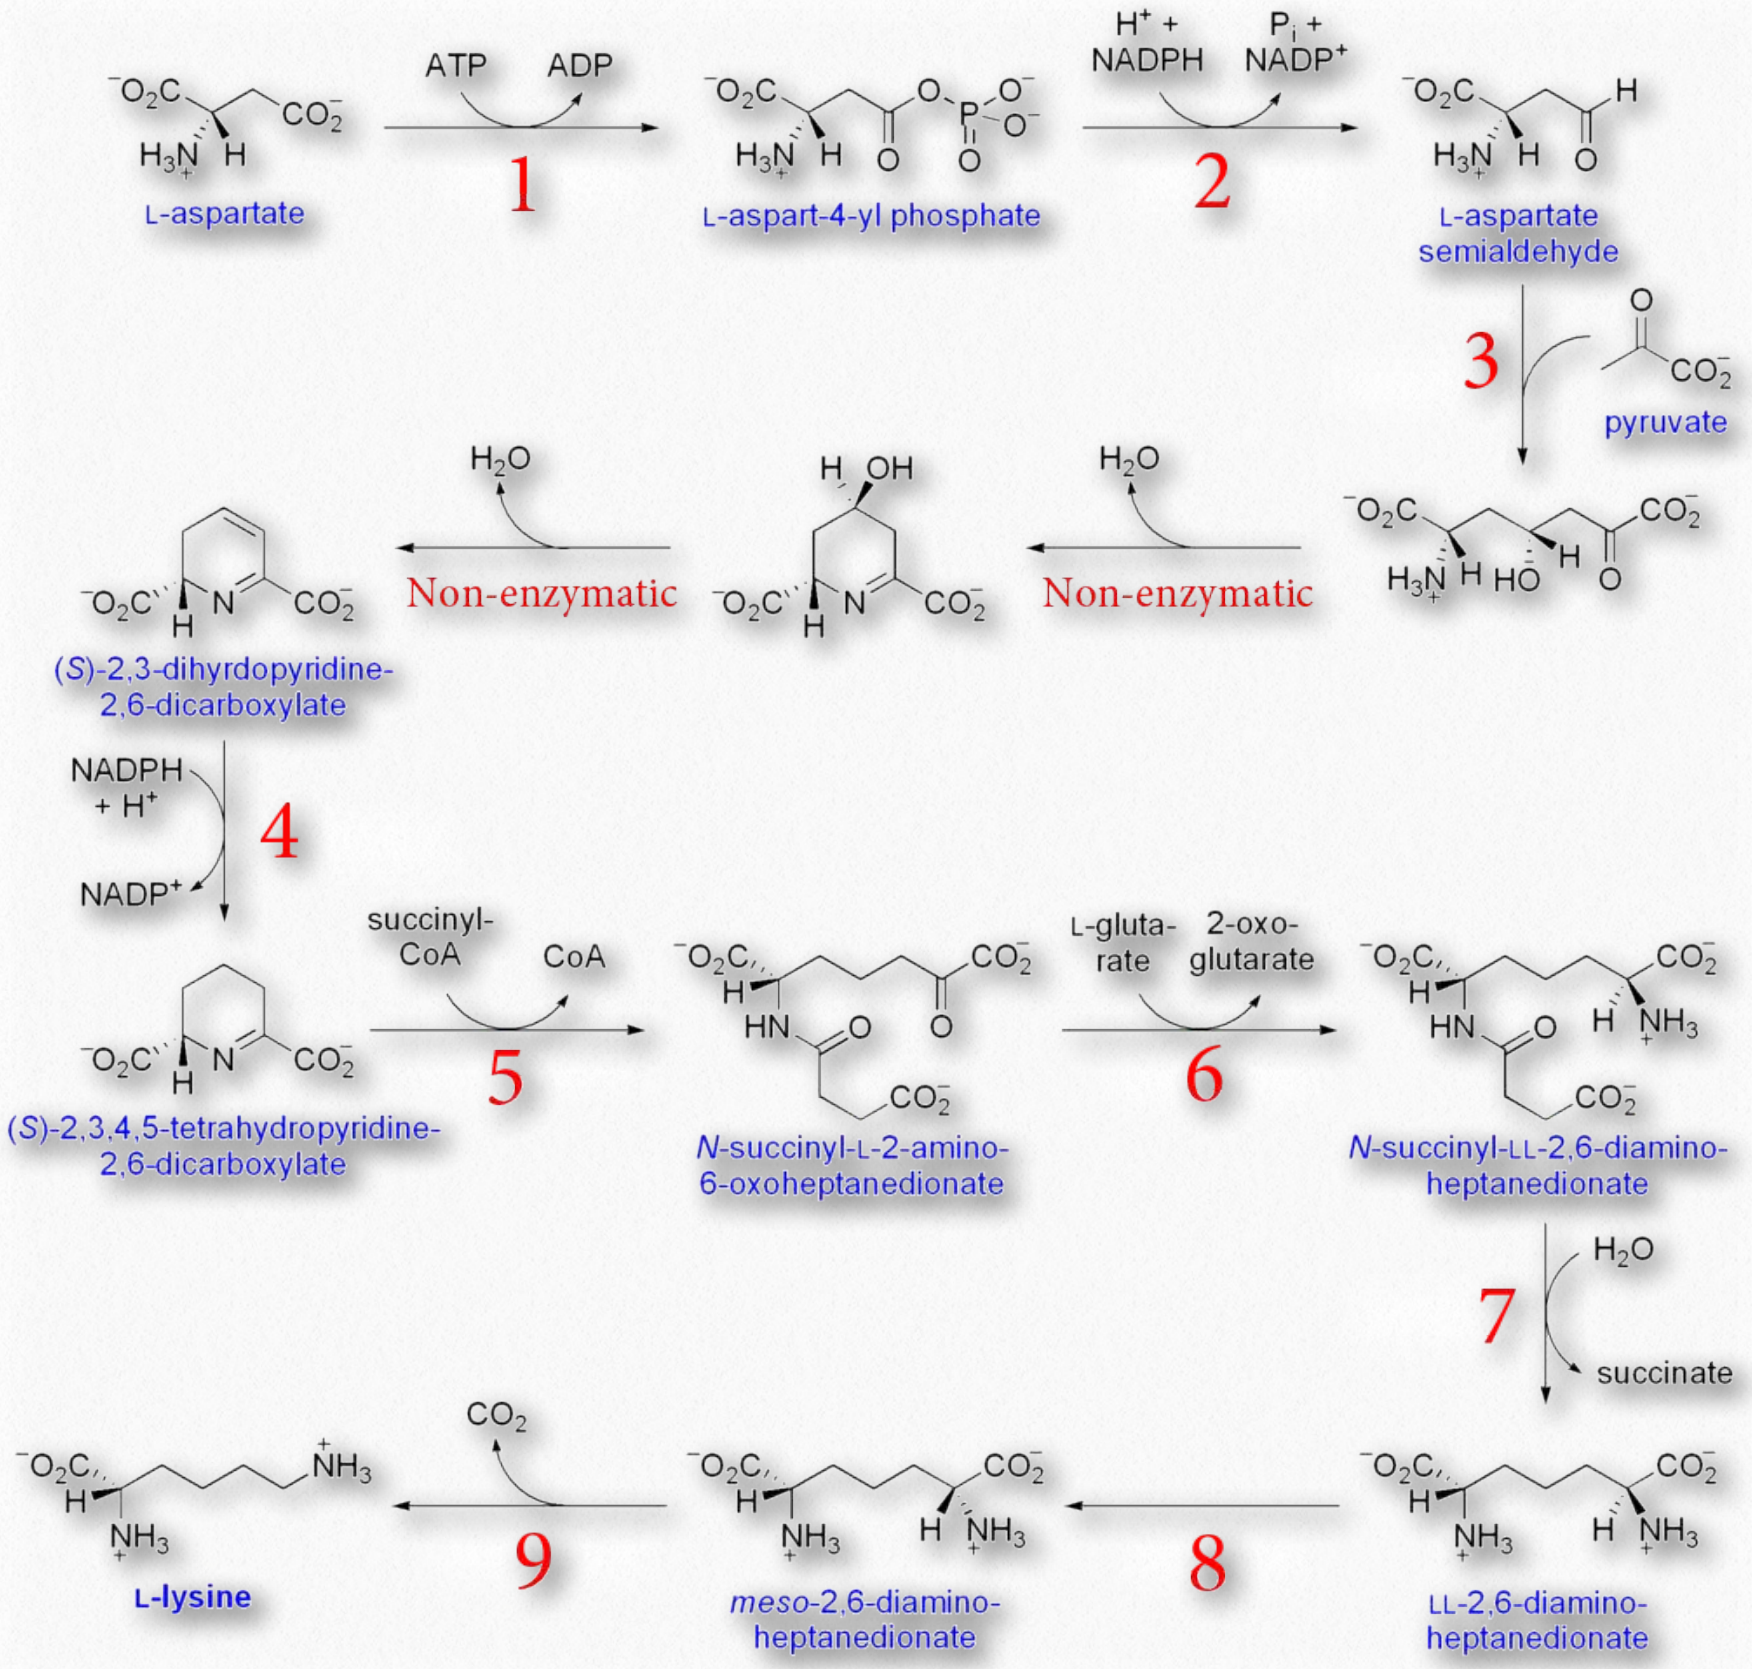

Figure 6.144 - Synthesis of Lysine from Aspartic Acid

tant for calcium absorption, recovery from injuries, and for production of hormones.

Oral lysine has been used as a treatment for herpes infections (cold sores) but its efficacy is not established and it is not clear by what mechanism is would reduce the duration of the infection or reduce the number of outbreaks of viral infection..

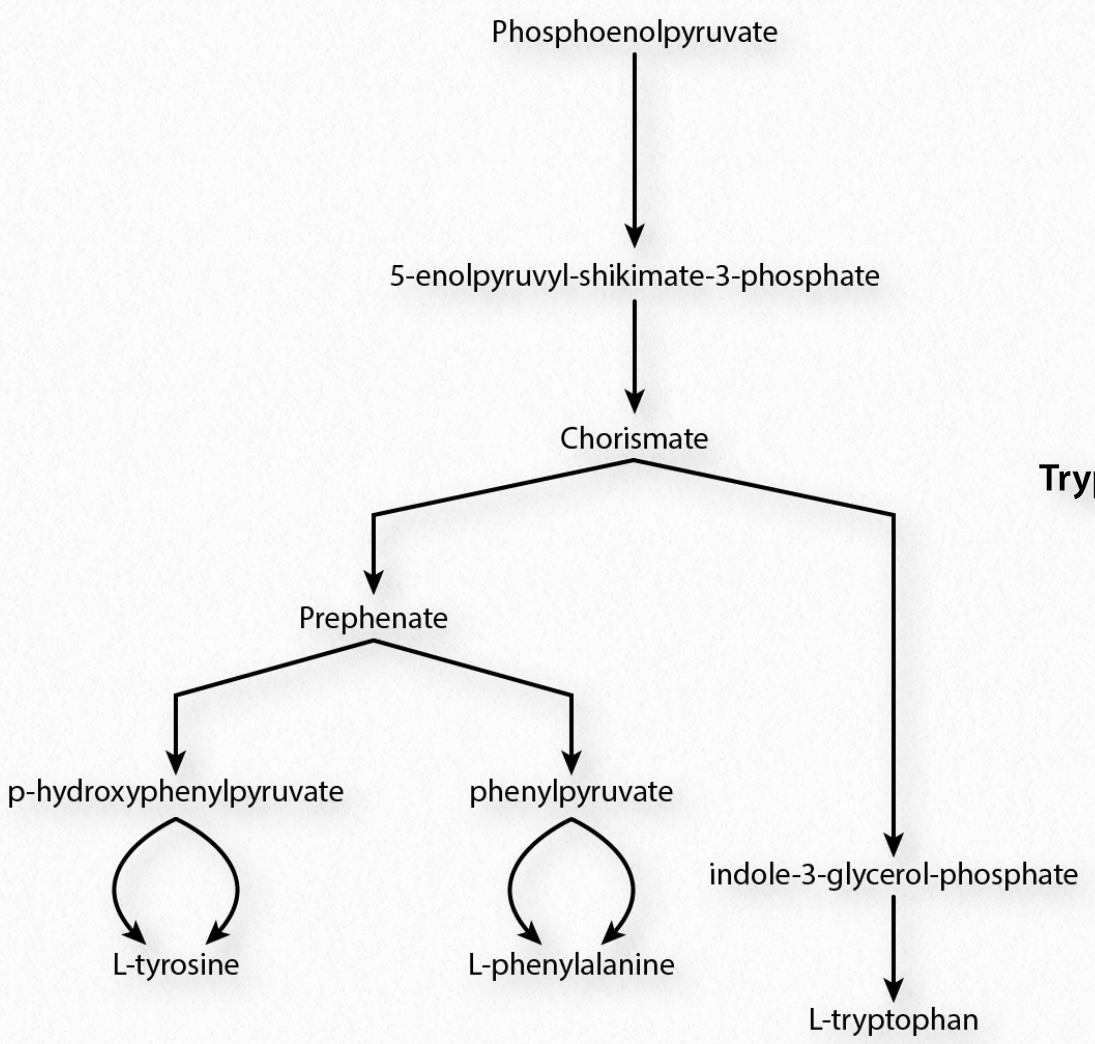

Figure 6.145 - Schematic pathway from PEP to aromatic amino acids

Image by Aleia Kim

Aromatic amino acids

The aromatic amino acids, tryptophan, phenylalanine, and tyrosine can all be made starting with two simple molecules - PEP and erythrose-4-phosphate (Figure 6.145). All three aromatic amino acids are also important sources of hormones, neurotransmitters, and even the skin pigment melanin.

YouTube Lectures by Kevin HERE & HERE

Tryptophan synthesis

The proteogenic amino acid with the largest R-group, tryptophan is an essential amino acid distinguished structurally by its indole group. The amino acid is made in bacteria and plants from shikimic acid or anthranilate and serine is used in its synthesis.

Erythrose-4-phosphate and phosphenolpyruvate (PEP) also serve as building blocks of tryptophan. The pathway of its synthesis is shown in Figures 6.146 to 6.148.

Erythrose-4-phosphate and phosphoenolpyruvate (PEP) are joined and then, after one hydrolysis, one dehydration, one oxidation and one reduction, the product is shikimic acid (Figure 6.147).

Shikimic acid is converted to chorismic acid in three steps, as shown in Figure 6.147. Finally, synthesis of tryptophan from chorismic acid is shown in Figure 6.148.

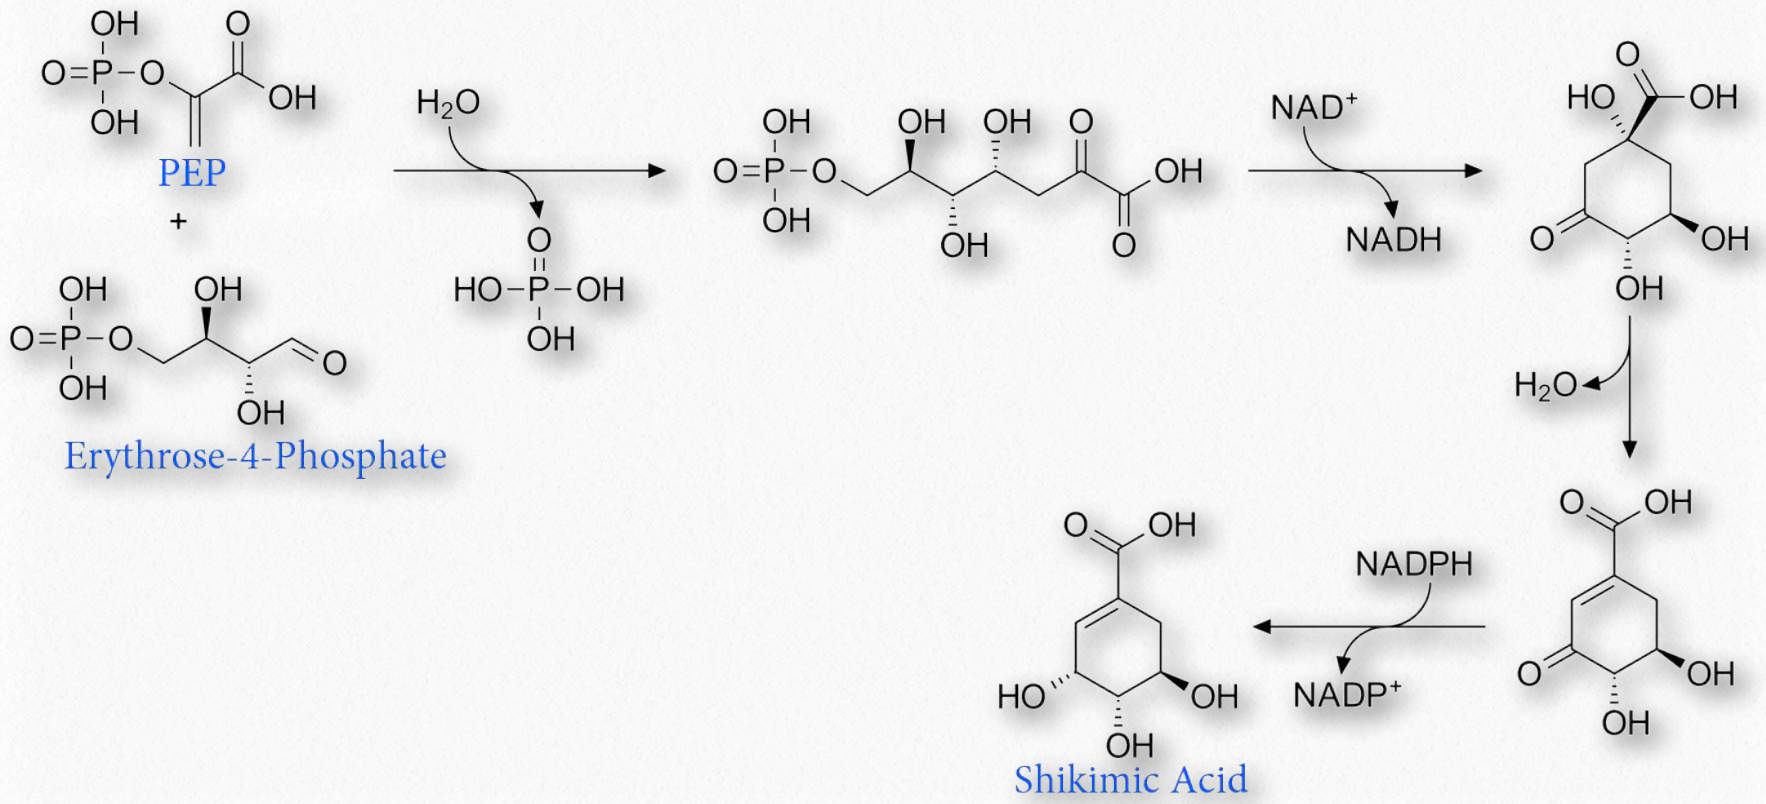

Figure 6.146 - Synthesis of shikimic acid from PEP and erythrose-4-phosphate

Wikipedia

Regulation

Regulation of tryptophan synthesis in bacteria occurs partly *via* a process called attenuation that operates through the trp operon. In this mechanism, low levels of tryptophan slow ribosomal movement (and translation) through the operon. This is particularly important because bacteria can have transcription and translation occurring simultaneously. Slowing translation due to low tryptophan levels allows a tran-

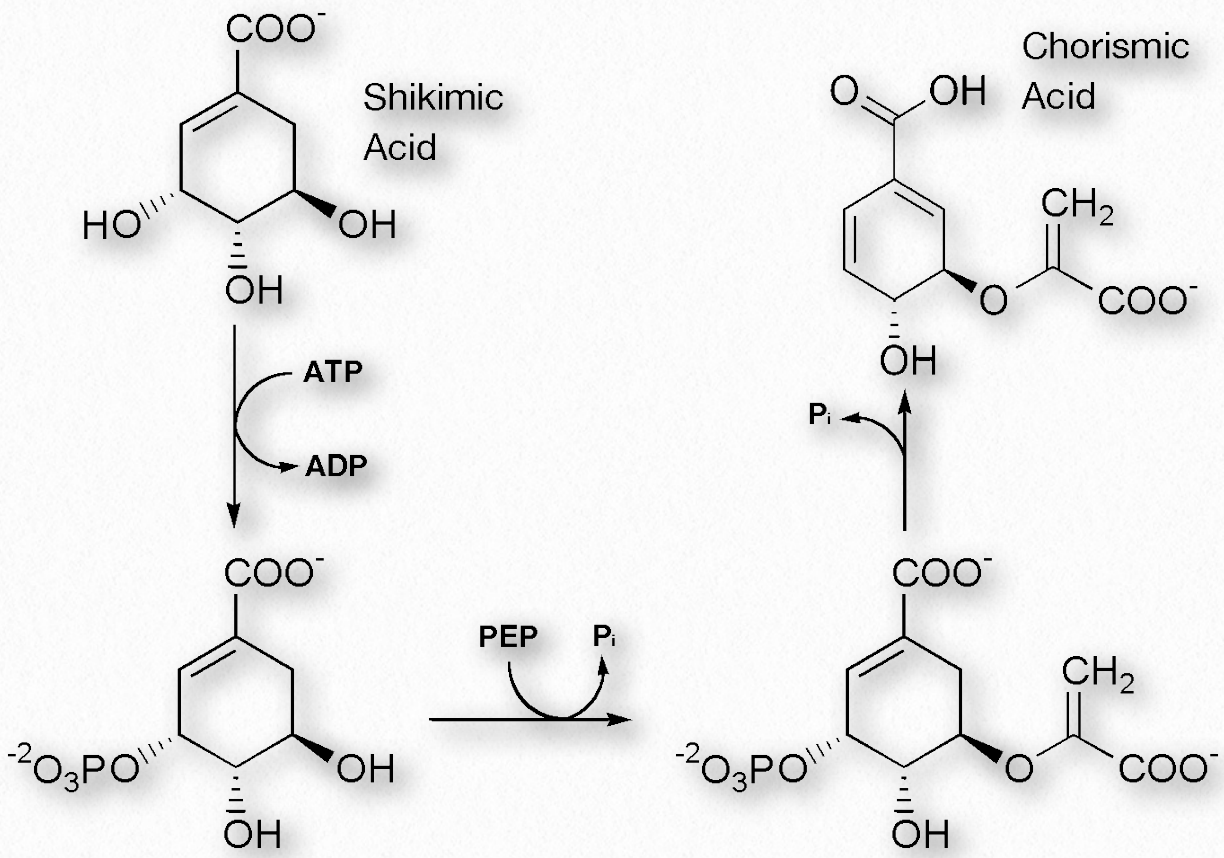

Figure 6.147 - The route to tryptophan - making chorismic acid from shikimic acid

Wikipedia

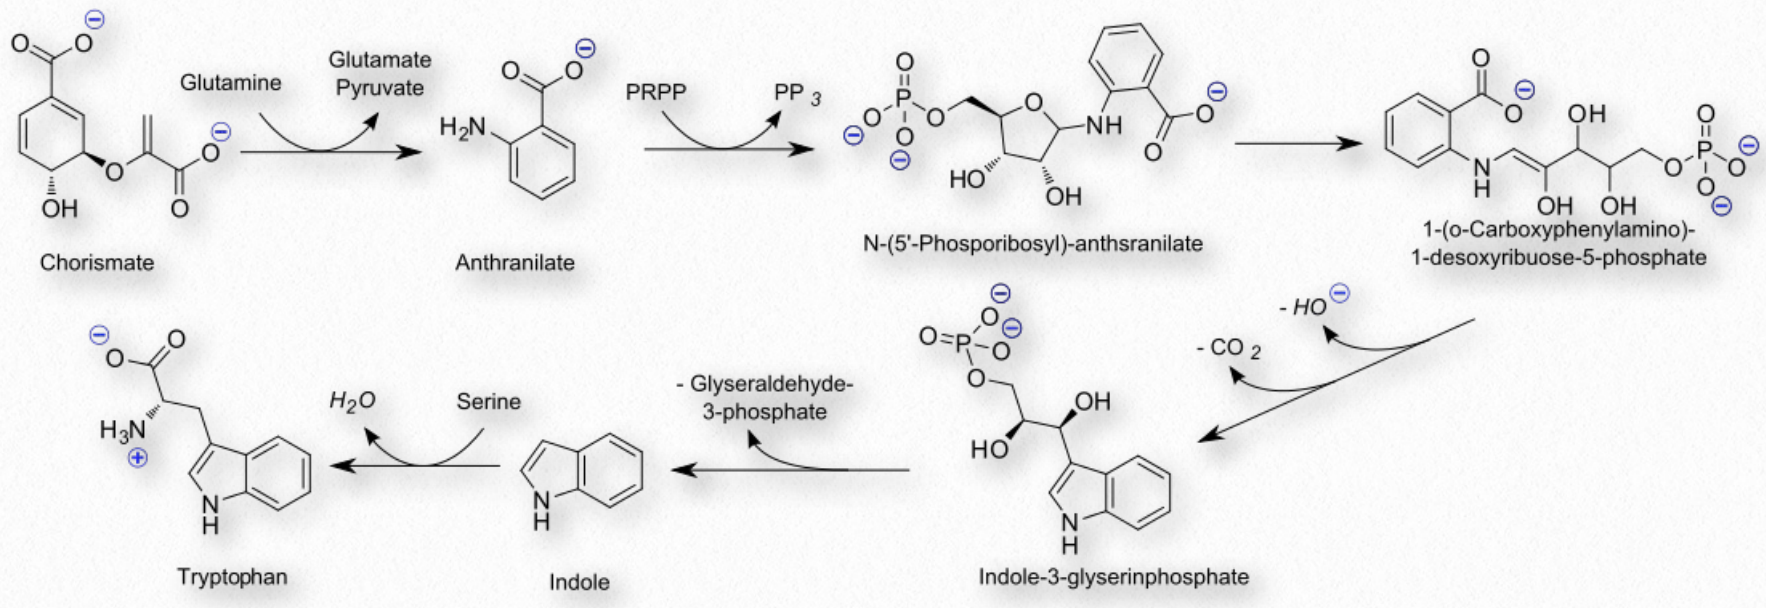

Figure 6.148 - Synthesis of tryptophan from chorismic acid

scription termination mechanism to be inhibited. Since translation only slows when tryptophan is in short supply, premature termination of transcription occurs when tryptophan is abundant (see also HERE).

Besides its importance for making proteins, tryptophan is an important precursor of serotonin (neurotransmitter), melatonin (hormone), niacin (vitamin), and auxin (plant hormone). The two pathways leading from tryptophan to three of these molecules is shown in Figure 6.149.

Melatonin

Melatonin is a compound made from tryptophan that is found in a wide spectrum of biological systems, including plants, animals, fungi, and bacteria. In animals, it acts as a hormone for circadian rhythm synchronization, signaling the onset of darkness each day. It has effects on the timing of sleep, seasonal effects, and can affect blood pressure, among other physiological phenomena. It can cross cell membranes, as well as the blood-brain barrier. Melatonin is a potent anti-oxidant and provides protective functions for nucleic acids. It is used sometimes to help in treatment of sleep disorders. Some reports have indicated that children with autism have abnormal melatonin pathways with low levels of the hormone.

Blue light

Melatonin production is affected by blue light and may be linked to sleep abnormalities for people using computer monitors after dark. To protect against this, some computer programs are available that reduce the screen's blue light output in the evenings. Special eyeglasses that block blue light are also available. Though melatonin is linked to sleep in some animals (including humans), noctur-

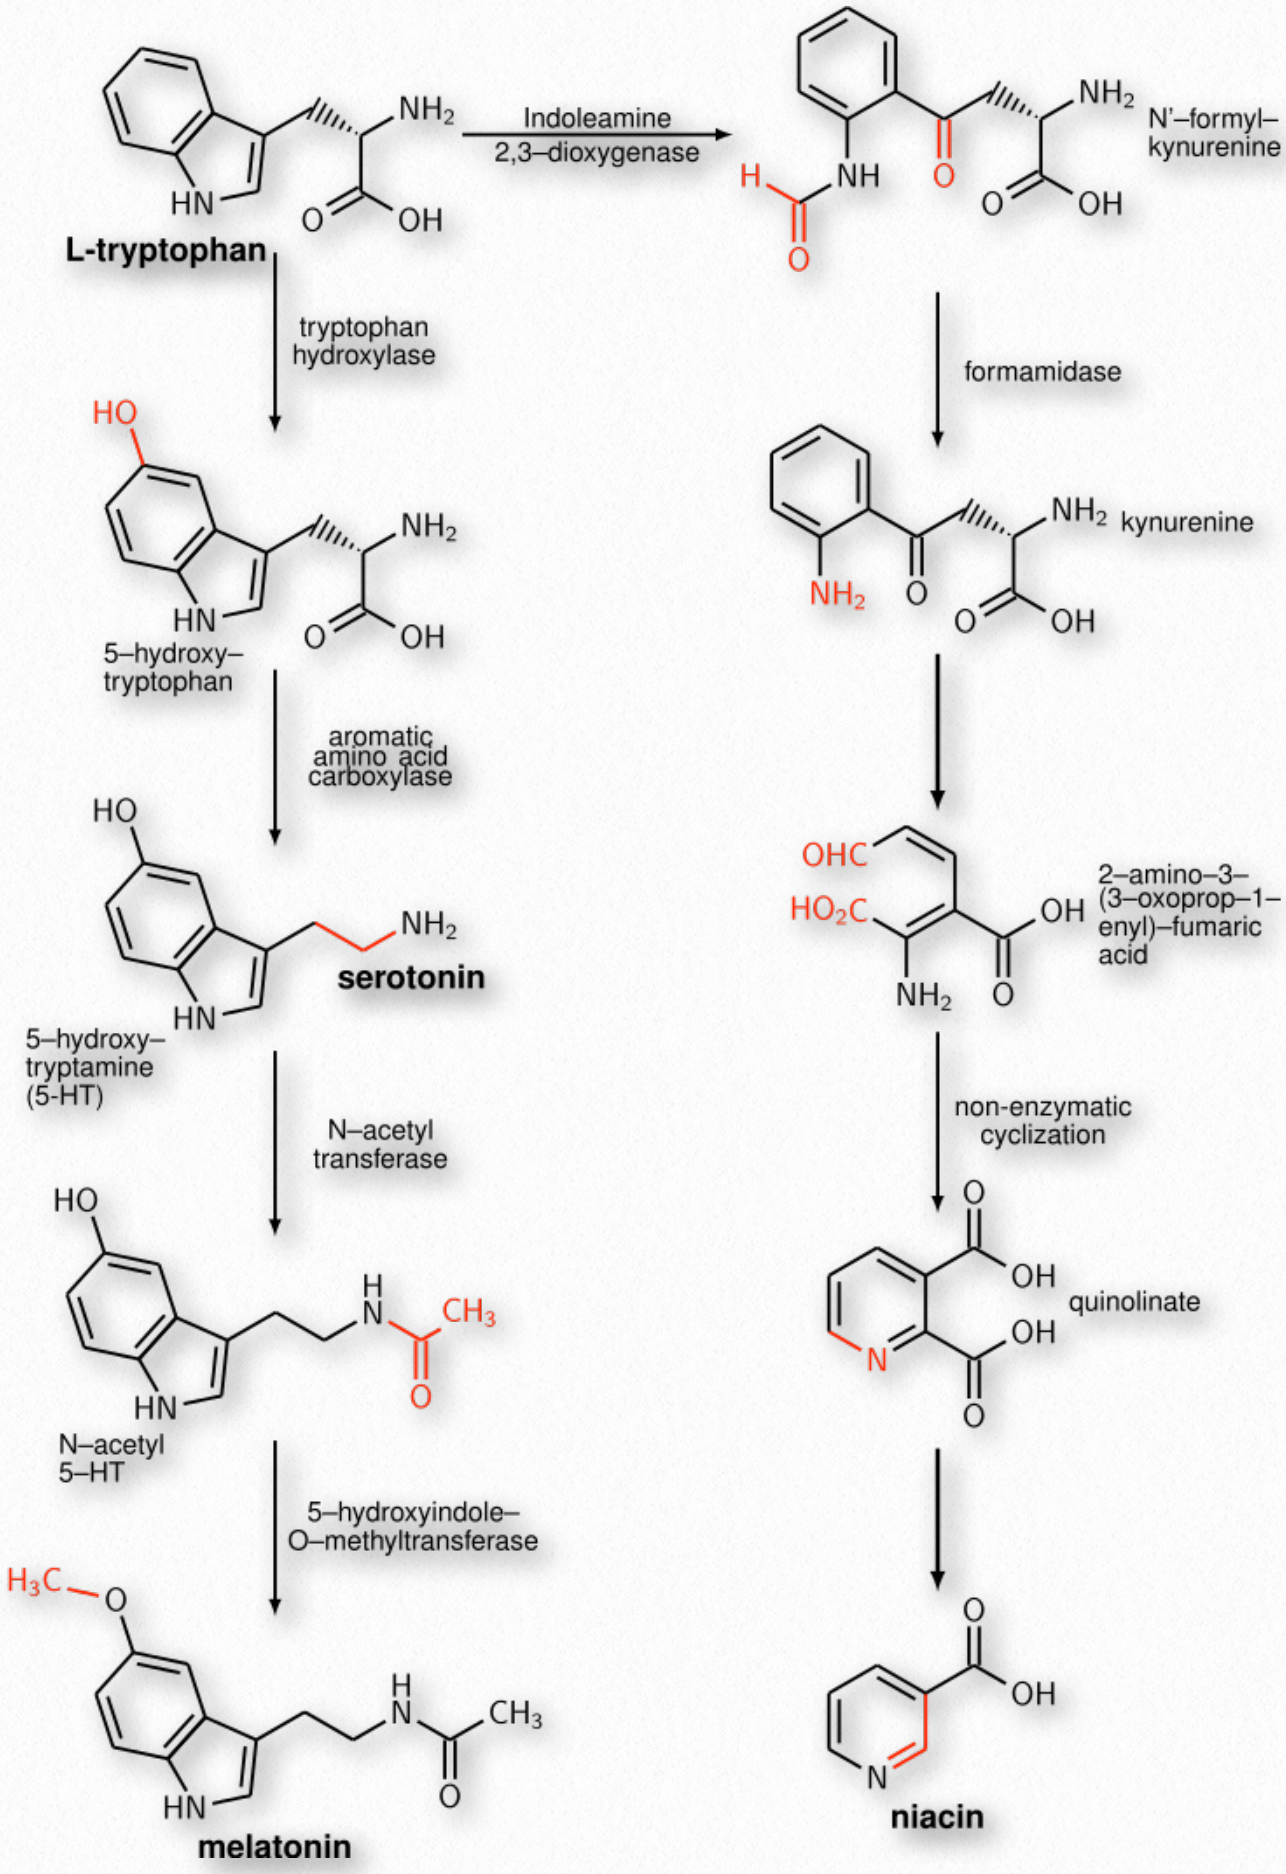

Figure 6.149 - Tryptophan is a precursor of serotonin, melatonin, and niacin

nal animals are activated by increasing melatonin levels. Varying day/night lengths during the year alter melatonin production and provide biological signals of the seasons. These are especially important in the seasonal coloring and breeding habits of some animals. Melatonin is present in cherries, bananas, grapes, rice, cereals, olive oil, wine, and beer.

Serotonin

Serotonin, or 5-hydroxytryptamine, is a monoamine neurotransmitter derived from tryptophan. Blood platelets store serotonin and release it when they bind to a clot, causing vasoconstriction. Serotonin plays a role in cognitive functions and enhances memory and learning. Serotonin is widely thought to be a contributor to feelings of happiness and well-

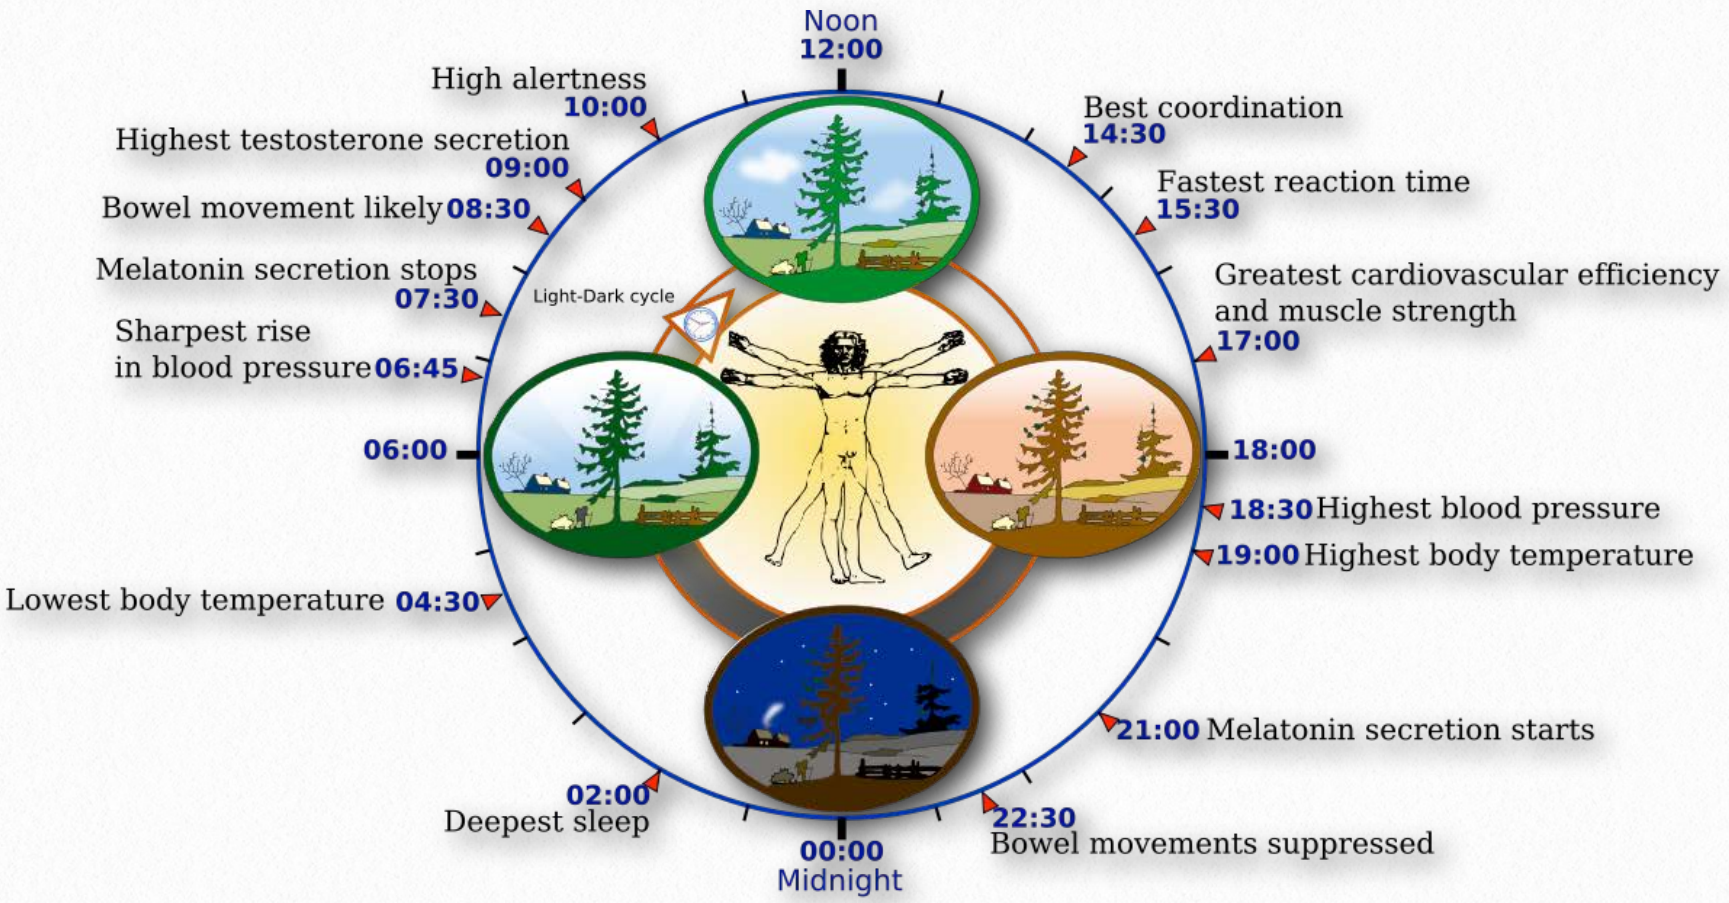

Figure 6.150 - Melatonin and human circadian rhythms

Wikipedia

being. Some common anti-depressant drugs, including Prozac, Paxil and Zoloft, act to modulate action of serotonin at synapses.

Niacin

Niacin is also known as Vitamin B_3 and nicotinic acid. Niacin can be made from tryptophan and people who have the inability to absorb tryptophan in the digestive system exhibit symptoms similar to niacin deficiency.

YouTube Lectures by Kevin HERE & HERE

Extreme deficiency of niacin in the diet leads to the disease known as pellagra, while insufficient amounts of niacin in the diet are linked with nausea, anemia, headaches, and tiredness. A diet that is primarily composed of grains like corn can lead to niacin deficiency, because the niacin in these sources is not readily bioavailable. Treatment of the grain with alkali, as in the traditional Mexican practice of soaking corn in lime, can make the niacin more easily absorbed from food.

Niacin is related to pyridine and the amide form of it is nicotinamide, an important component of NAD^+/NADH and $NADP^+$/NADPH. The last pairs of molecules are essential as electron acceptors/carriers for most cellular oxidation-reduction reactions.

Auxins

Auxins are plant growth hormones derived from tryptophan. The most important of these

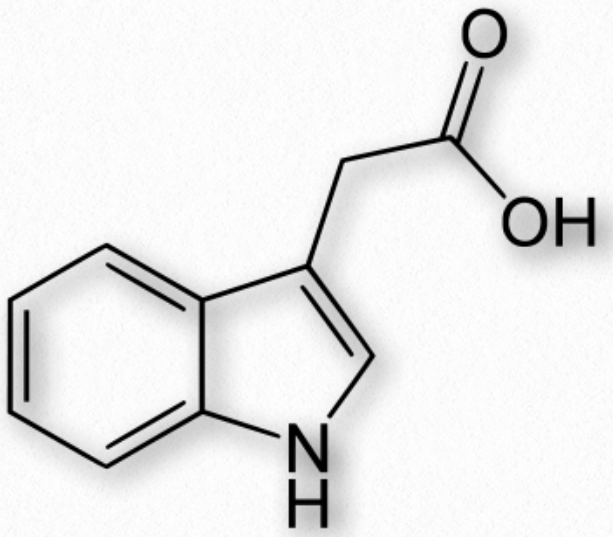

Figure 6.151 - Auxin - indole-3-acetic acid

is indole-3-acetic acid (Figure 6.151). Auxins are involved in almost every aspect of plant growth and development. They activate proteins, such as expansins and various enzymes that modify the structure of cell wall components, to loosen the cell walls of a plant and stimulate elongation of cells. In the presence of cytokinins, auxins stimulate cell division. Auxins are also involved in the maintenance of meristems and in cell patterning and organogenesis. Auxins are crucial for establishing root primordia as well as for elongation of root hairs. Auxins play important roles in organizing the xylem and phloem of plants, and it has long been known that plant callus tissue can be made to differentiate into shoots or roots, depending on the relative concentrations of auxins and cytokinins supplied in the medium.

Figure 6.152 - Wild type *Arabidopsis* (left) and a mutant unable to transmit auxin signals (right)

Wikipedia

Figure 6.153 Crown gall on a rose

Wikipedia

Agrobacterium tumefaciens, a bacterium which infects a wide variety of plants, inserts its own DNA, including genes necessary for the synthesis of plant hormones, into its host's cells. The subsequent overproduction of auxins stimulates the growth of tumors (called crown galls) on the plant (Figure 6.153).

Phenylalanine

Phenylalanine is an essential, hydrophobic amino acid in humans that is a precursor of tyrosine and since tyrosine is a precursor of several important catecholamines, phenylalanine is, thus, a precursor of them as well.

PKU

Phenylalanine is linked to the genetic disease phenylketonuria (PKU) which arises from an inability to metabolize the amino acid in people lacking (or deficient in) the enzyme phenylalanine hydroxylase. If left untreated, the disease can cause brain damage and even death, but if detected early, it can be easily managed by carefully monitoring dietary intake of the amino acid. Because of this, newborns are routinely tested for PKU. Phenylalanine is a component of the artificial sweetener known as aspartame (Nutrasweet - Figure 6.154) and is consequently dangerous for people suffering from this disorder.

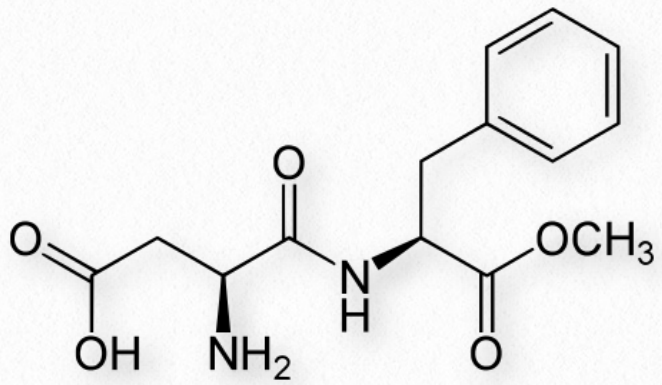

Figure 6.154 - Aspartame - a methyl ester of the aspartic acid-phenylalanine dipeptide

Biosynthesis of phenylalanine in bacteria overlaps with synthesis of tryptophan. The branch occurs at chorismic acid where the enzyme chorismate mutase catalyzes a molecular rearrangement to produce prephenate.

Chorismate ⇅ **Prephenate**

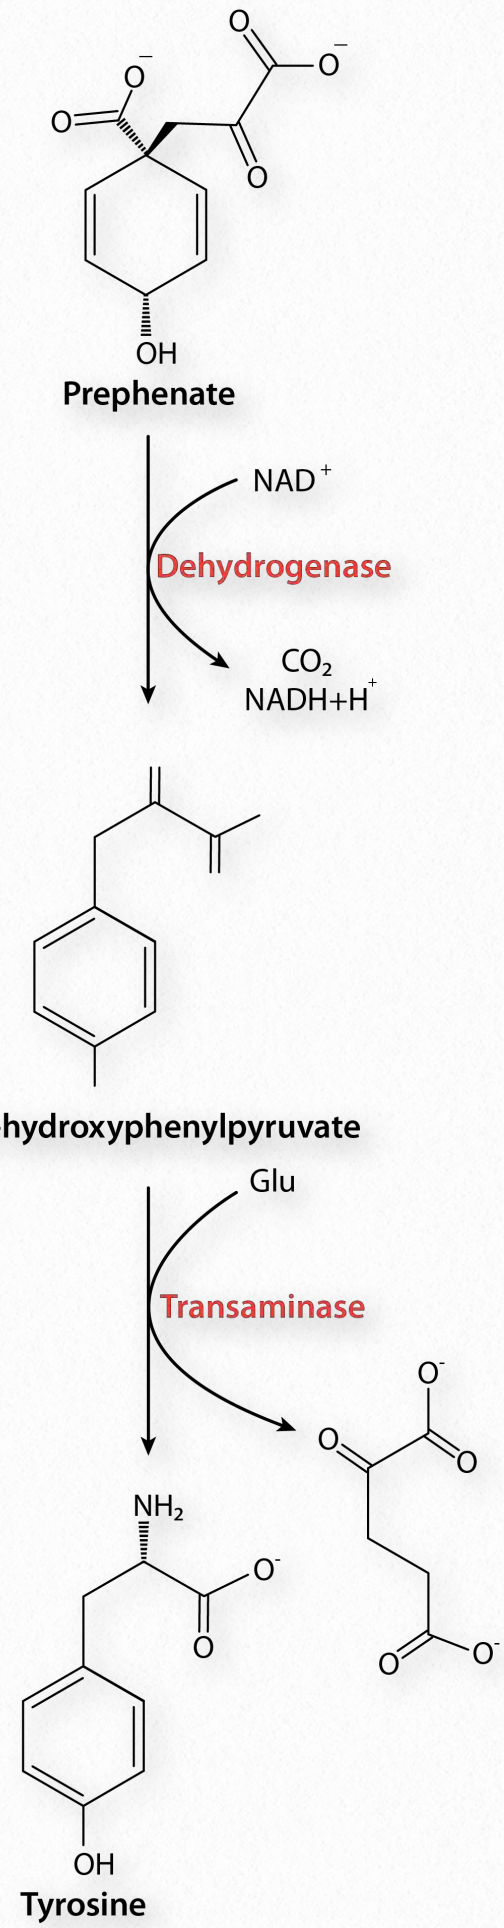

Figure 6.155 - Synthesis of tyrosine from prephenate

Image by Pehr Jacobson

Hydroxylation of phenylalanine by aromatic amino acid hydroxylase (phenylalanine hydroxylase) yields tyrosine.

Tyrosine

Because tyrosine is made from phenylalanine and the latter is an essential amino acid in humans, it is not clear whether to classify tyrosine as essential or non-essential. Some define it as a conditionally essential amino acid. Others simply categorize it as non-essential.

As noted above, tyrosine can arise as a result of hydroxylation of phenylalanine. In addition, plants can synthesize tyrosine by oxidation of prephenate followed by transamination of the resulting 4-hydroxyphenylpyruvate (Figure 6.155).

The hydroxyl group on tyrosine is a target for phosphorylation by protein kinase enzymes involved in signal transduction path-

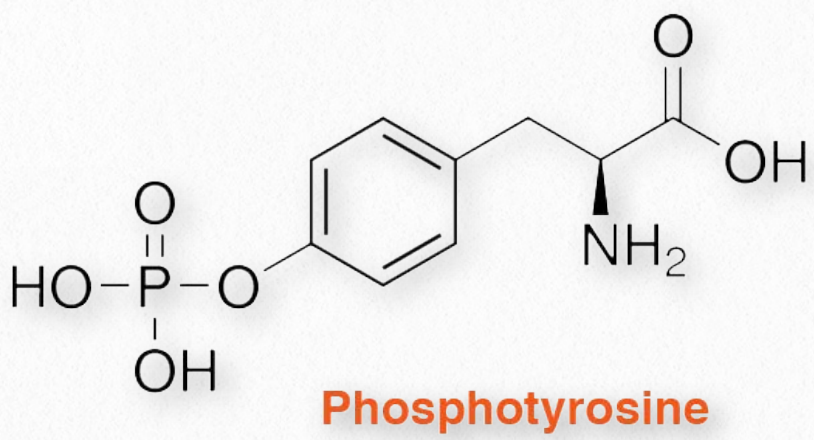

Figure 6.156 - The phosphorylated form of tyrosine

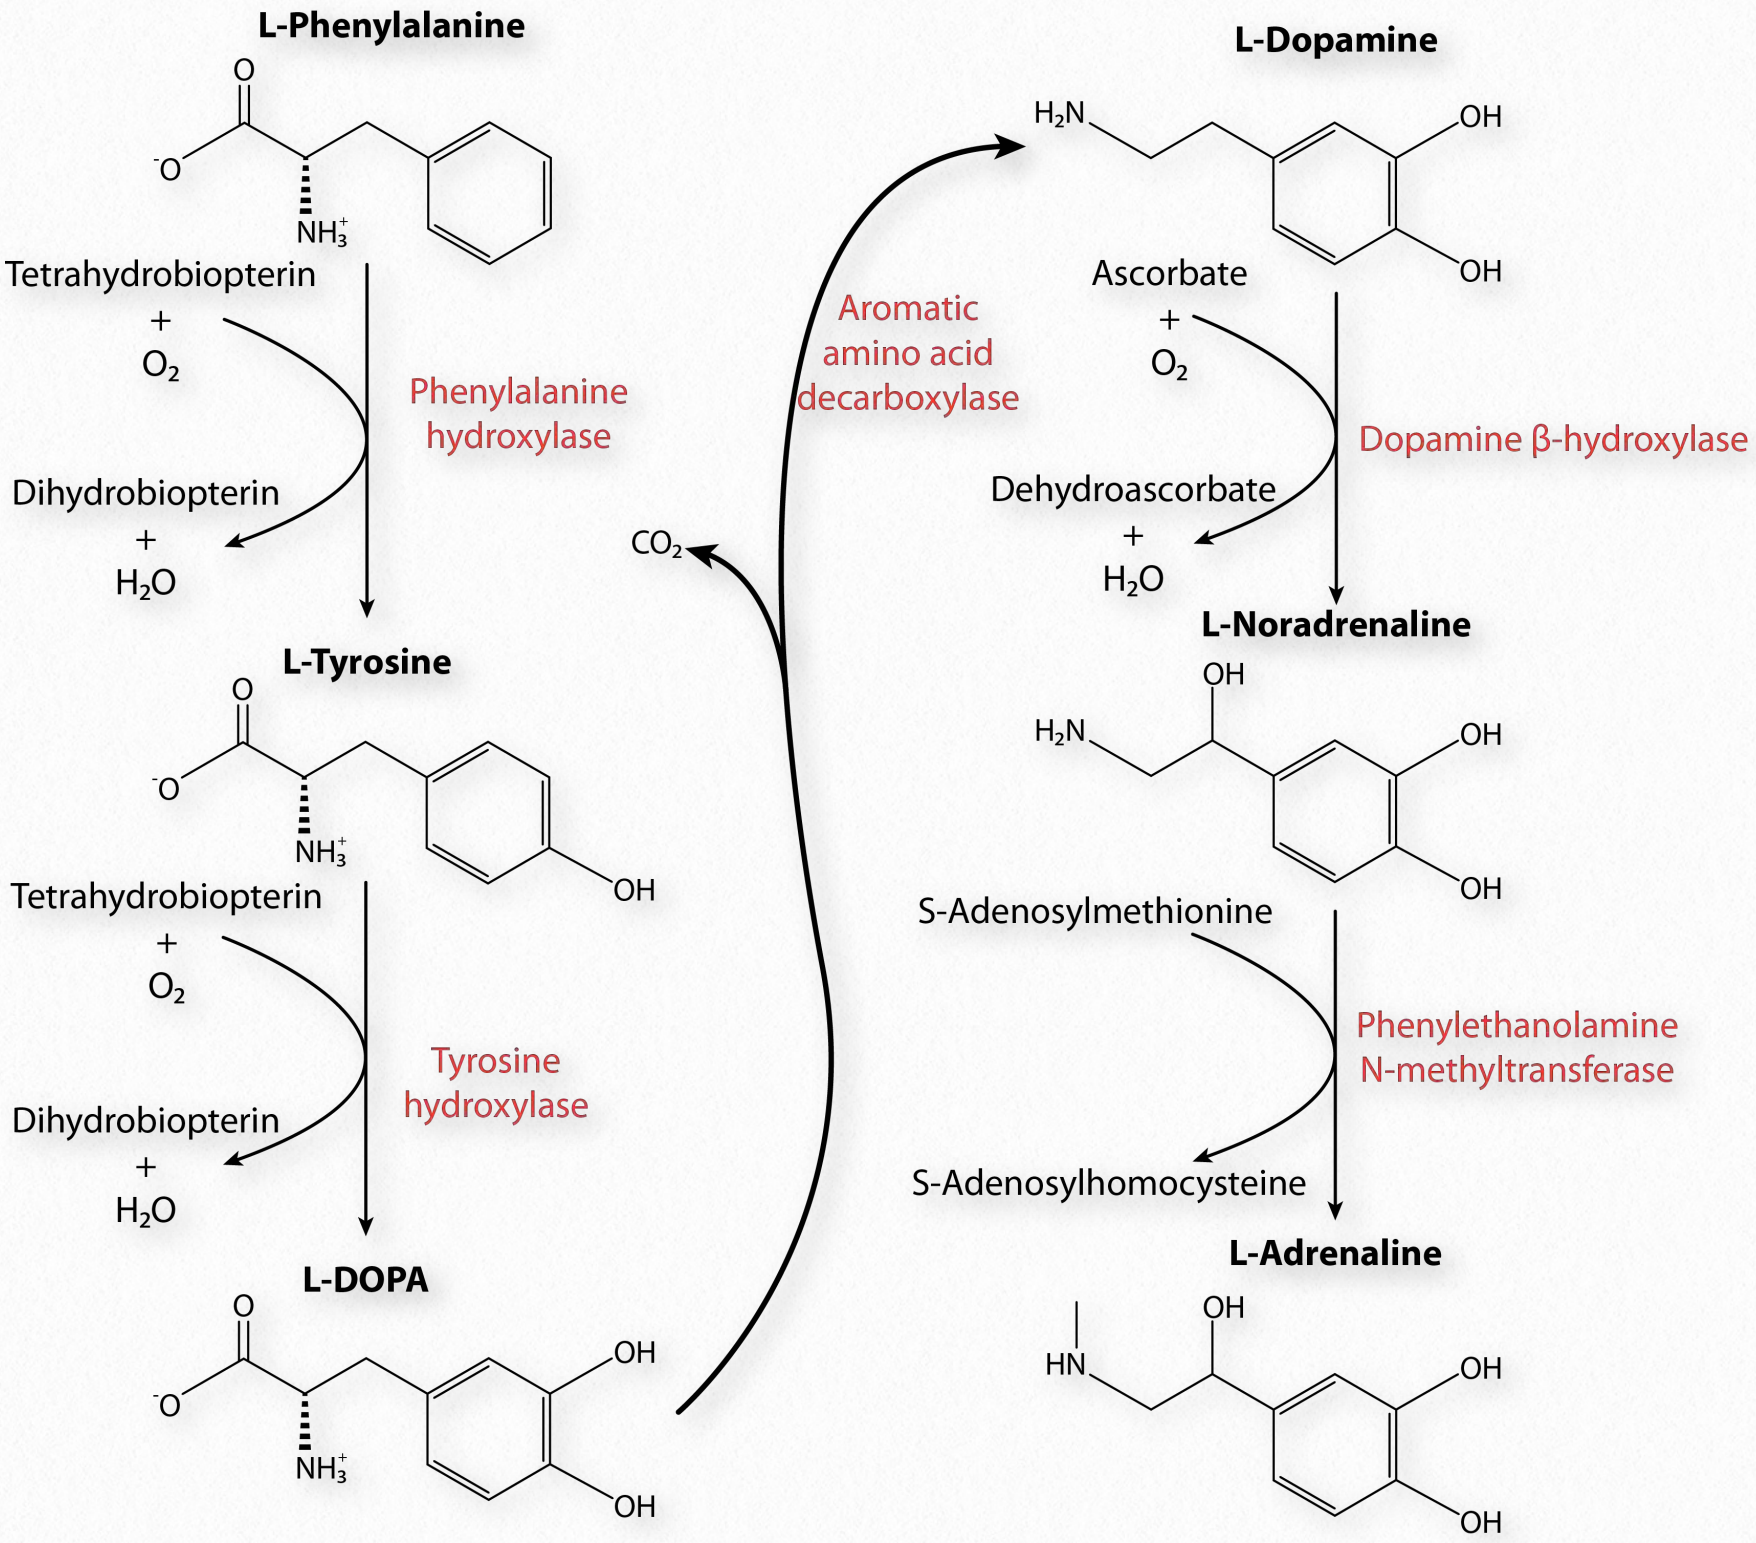

Figure 6.157 - Conversion of phenylalanine and tyrosine to catecholamines

Image by Pehr Jacobson

ways (Figure 6.156). When located in membranes, these enzymes are referred to as receptor tyrosine kinases and they play important roles in controlling cellular behavior/response.

In photosystem II of chloroplasts, tyrosine, at the heart of the system, acts as an electron donor to reduce oxidized chlorophyll. The hydrogen from the hydroxyl group of tyrosine is lost in the process, requiring re-reduction by four core manganese clusters.

Tyrosine is also important in the small subunit of class I ribonucleotide reducta-

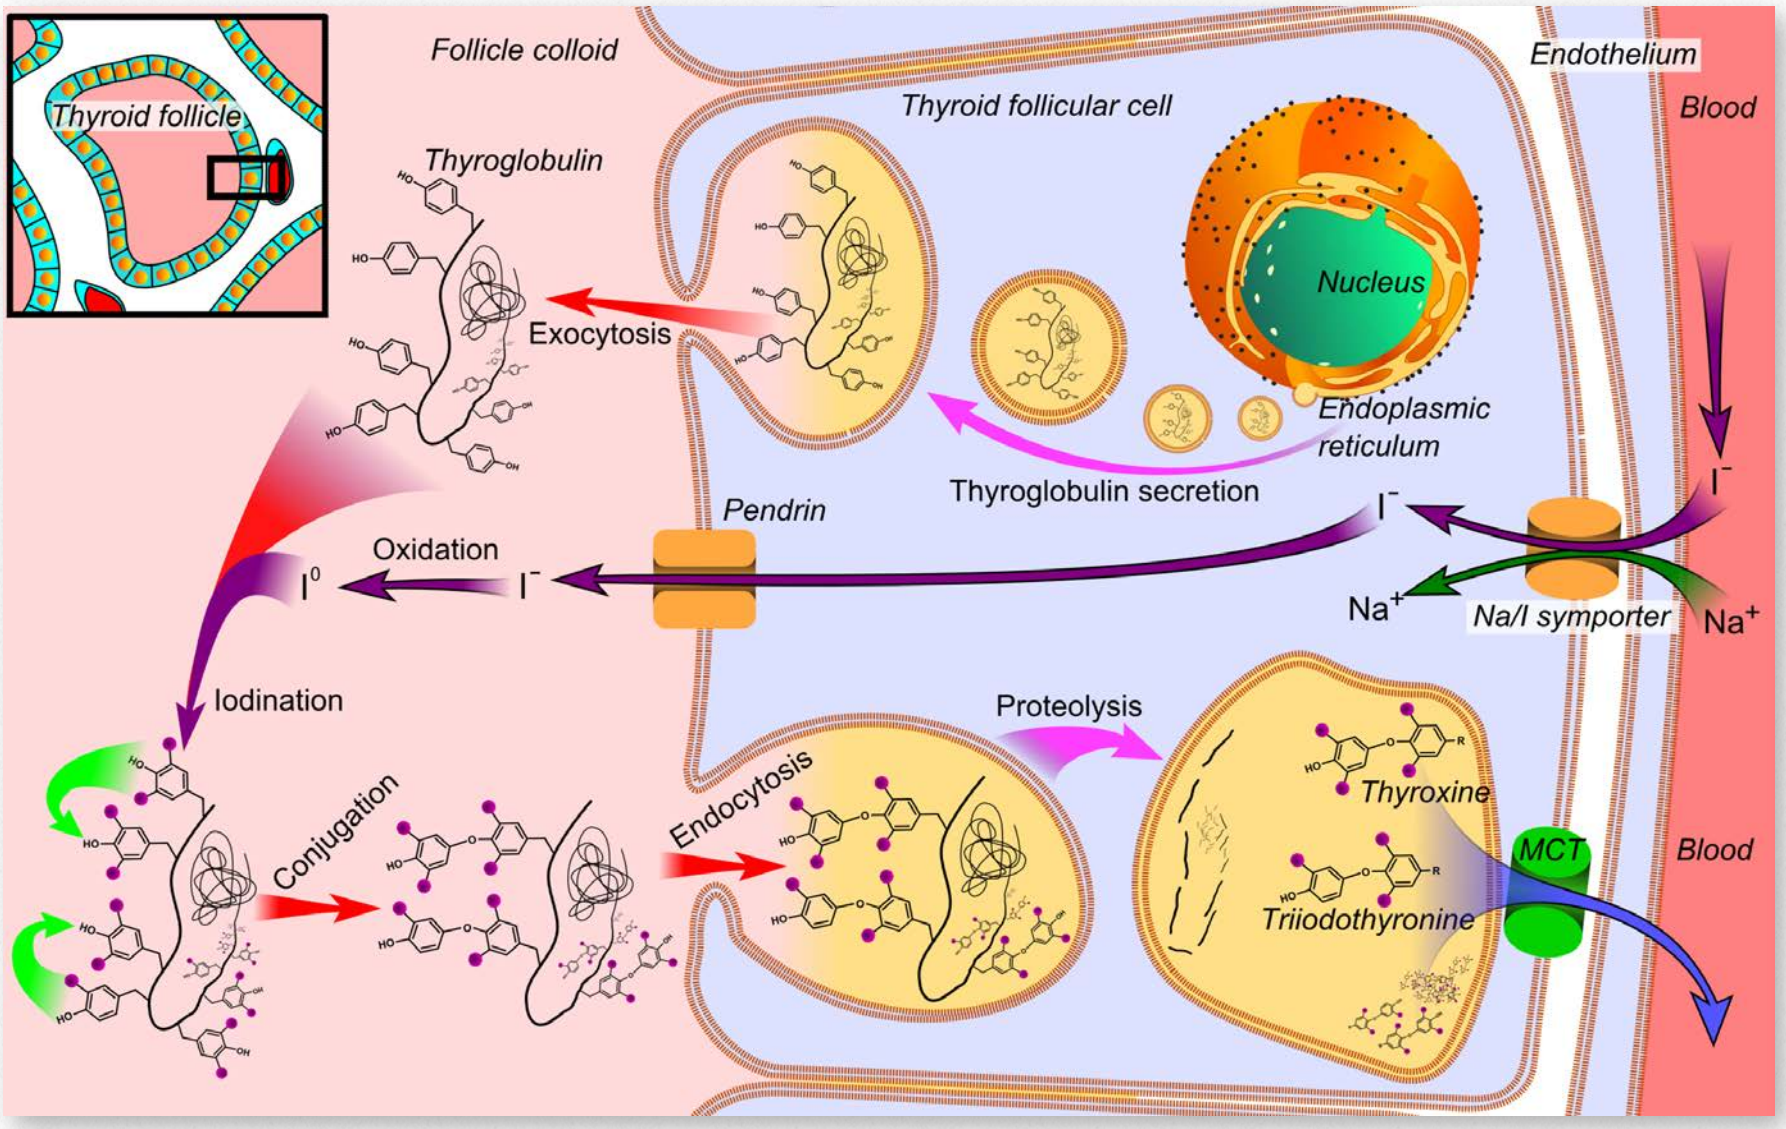

Figure 6.158 - Synthesis of thyroid hormones from tyrosine and movement in the body

Wikipedia

ses where it forms a stable radical in the catalytic action of the enzyme (see HERE).

Tyrosine metabolites

Tyrosine is a precursor of catecholamines, such as L-dopa, dopamine, norepinephrine, and epinephrine (Figure 6.157). The thyroid hormones triiodothyronine (T3) and thyroxine (T4) are also synthesized from tyrosine. As shown in Figure 6.158, this involves a series of iodinations of tyrosines side-chains of a protein known as thyroglobulin. Combinations of iodinated tyrosines give rise to thyroxine and triiodothyronine. These are subsequently cleaved from the protein and released into the bloodstream.

YouTube Lectures by Kevin HERE & HERE

Oxidation and polymerization of tyrosine is involved in synthesis of the family of melanin pigments. Tyrosine is involved in the synthesis of at least two types - eumelanin and pheomelanin (Figure 6.159).

Another molecule derived from tyrosine is the benzoquinone portion of Coenzyme Q (CoQ). This

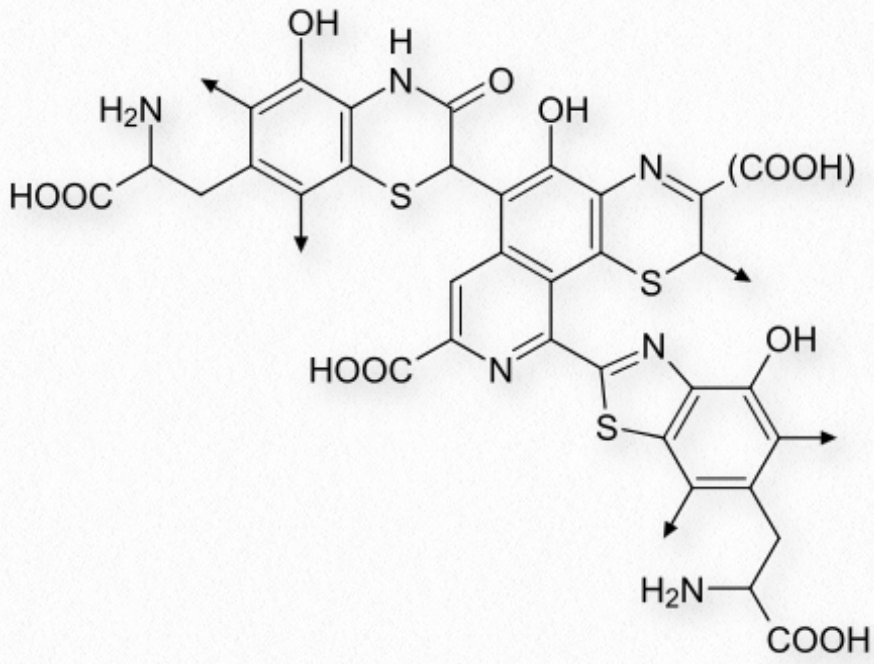

Figure 6.159 - A portion of pheomelanin - Arrows show directions of polymer extension

pathway requires the enzyme HMG-CoA Reductase and since this enzyme is inhibited by cholesterol-lowering statin drugs, CoQ can be limited in people being treated for high cholesterol levels.

Dopamine

Dopamine plays several important roles in the brain and body. A member of the catecholamine and phenethylamine families, its name comes from the fact that it is an amine made by removing a carboxyl group from L-DOPA. Dopamine is synthesized in the brain and kidneys. It is also made in plants, though its function in plants is not clear. Conversion of dopamine to norepinephrine (Figure 6.157) requires vitamin C.

Dopamine is a neurotransmitter, being released by one nerve cell and then traveling across a synapse to signal an adjacent nerve cell. Dopamine plays a major role in the brain's reward-mediated behavior. Rewards, such as food or social interaction, increase dopamine levels in the brain, as do addictive drugs. Other brain dopamine pathways are involved in motor control and in managing the release of various hormones.

Chemical messenger

Outside the nervous system, dopamine is a local chemical messenger. In blood vessels, it inhibits norepinephrine release and causes vasodilation. In the kidneys, it increases sodium excretion and urine output. It reduces gastrointestinal motility and protects intestinal mucosa in the digestive system and in the immune system, it reduces lymphocyte activity. The effect dopamine has on the pancreas is to reduce insulin production. With the exception of the blood vessels, dopamine is synthesized locally and exerts its effects near the cells that release it.

Epinephrine

Epinephrine (also called adrenalin) is a catecholamine chemically related to norepinephrine that is a hormone with medical applications. It is used to treat anaphylaxis, cardiac arrest, croup, and, in some cases, asthma, when other treatments are not working, due to its ability to favor bronchodilation.

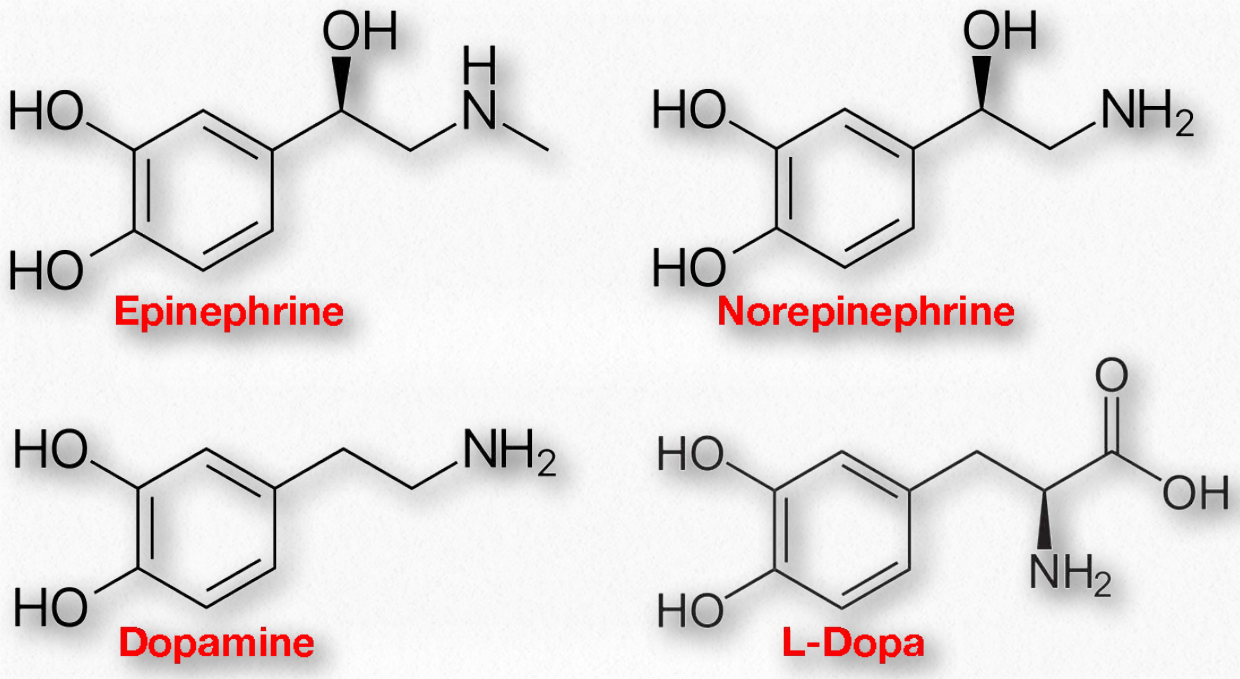

Figure 6.160 - Four catecholamines made from tyrosine

Epinephrine is the drug of choice for treating anaphylaxis. The compound may be given through inhalation, by intravenous injection, or subcutaneous injection and exerts effects through the α- and β-adrenergic receptors. In the body, it is produced and released by adrenal glands and some neurons.

Effects

Physiological effects of epinephrine may include rapid heart beat, increased blood pressure, heart output, pupil dilation, blood sugar concentration and increased sweating. Other physical effects may include shakiness, increased anxiety, and an abnormal heart rhythm.

Norepinephrine

Norepinephrine (also called noradrenalin) is a catecholamine molecule that acts as a hormone and neurotransmitter. It is chemically similar to epinephrine, differing only in the absence of a methyl group on its amine. Norepinephrine is made and released by the central nervous system (*locus coeruleus* of the brain) and the sympathetic nervous system. The compound is released into the blood stream from adrenal glands and affects α- and β-adrenergic receptors.

Norepinephrine is at its lowest levels during sleep and at its highest levels during stress (fight or flight response). The primary function of norepinephrine is to prepare the body for action. It increases alertness, enhances memory functions, and helps to focus attention. Norepinephrine increases heart rate and blood pressure, increases blood glucose and blood flow to skeletal muscle and decreases flow of blood to the gastrointestinal system.

Medical considerations

Norepinephrine may be injected to overcome critically low blood pressure and drugs countering its effects are used to treat heart conditions. α-blockers, for example, are used to battle cardiovascular and psychiatric disor-

ders. β-blockers counter a different set of norepinephrine's effects than α-blockers and are used to treat glaucoma, migraine headaches and other cardiovascular problems.

Pyruvate family

The family of amino acids derived from pyruvate has four members, each with a simple aliphatic side chain no longer than four carbons. The simplest of these is alanine.

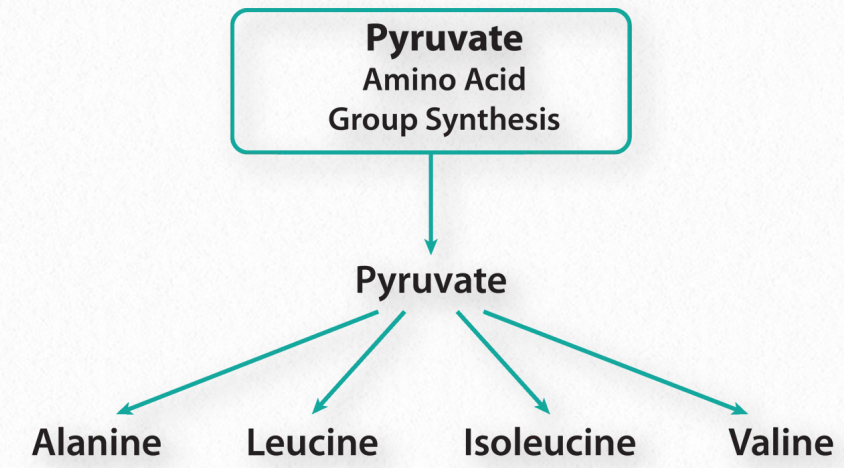

Image by Aleia Kim

Alanine

Alanine is the amino acid that is most easily produced from pyruvate. The simple transamination catalyzed by alanine transaminase produces alanine from pyruvate.

Alternative pathways for synthesis of alanine include catabolism of valine, leucine, and isoleucine.

Glucose-alanine cycle

The glucose-alanine cycle is an important nitrogen cycle related to the Cori cycle that occurs between muscle and liver cells in the body (see HERE). In it, breakdown of glucose in muscles leads to pyruvate. When nitrogen levels are high, pyruvate is transaminated to alanine, which is exported to hepatocytes.

Glutamate + Pyruvate

⇅

Alanine + α-ketoglutarate

In the liver cells, the last transamination of the glucose-alanine cycle occurs. The amine group of alanine is transferred to α-ketoglutarate to produce pyruvate and glutamate. Glucose can then be made by gluconeogenesis from pyruvate. Importantly, breakdown of glutamate yields ammonium ion, which can be made into urea for excretion, thus reducing the body's load of potentially toxic amines. This pathway may be particularly important in the brain.

Another way of removing excess ammonium from a tissue is by attaching it to glutamate to make glutamine. Glutamate is a neurotransmitter, so having an alternative way of removing amines (glucose-alanine cycle) is important, especially in the brain.

YouTube Lectures by Kevin
HERE & HERE

Leucine

Like valine and isoleucine, leucine is an essential amino acid in humans. In adipose tissue and muscle, leucine is used in sterol synthesis. It is the only amino acid to stimulate muscle protein synthesis, and as a dietary supple-

ment in aged rats, it slows muscle degradation. Leucine is an activator of mTOR, a protein which, when inhibited, has been shown to increase life span in *Saccharomyces cerevisiae*, *C. elegans*, and *Drosophila melanogaster*.

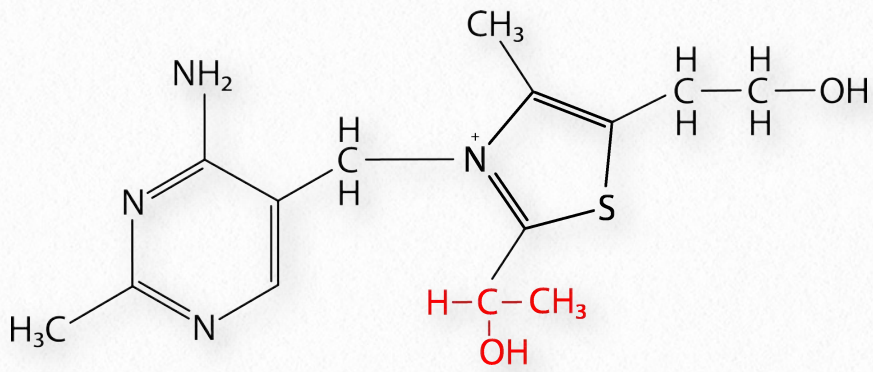

Figure 6.161 - Hydroxyethyl fragment (in red) attached to thiamine pyrophosphate

Image by Pehr Jacobson

Metabolism of leucine, valine, and isoleucine (also called Branched Chain Amino Acids - BCAAs) starts with decarboxylation of pyruvate and attachment of the two-carbon hydroxyethyl fragment to thiamine pyrophosphate (Figure 6.161). Metabolism of isoleucine proceeds with attachment of the hydroxylated two carbon piece (hydroxyethyl-TPP) to α-ketobutyrate and is covered in the section describing that amino acid (see HERE).

Metabolism of valine and leucine proceeds with attachment of the hydroxyethyl piece from TPP to another pyruvate to create α-acetolactate. Rearrangement of α-acetolactate by acetolactate mutase makes 3-hydroxy-3-methyl-2-oxobutanoate.

Valine

An essential amino acid in humans, valine is derived in plants from pyruvate and shares part of its metabolic synthesis pathway with leucine and a small slice of it with isoleucine. Metabolism of all three amino acids starts with decarboxylation of pyruvate and attachment of the two-carbon hydroxyethyl fragment to thiamine pyrophosphate (Figure 6.161), as noted above.

As seen earlier, **α**-ketoisovalerate is the molecule at the point in the metabolic pathway where synthesis of valine branches from that of leucine. In fact, α-ketoisovalerate is only one step away from valine. Transamination of α-ketoisovalerate catalyzed by valine isoleucine aminotransferase gives valine.

α-ketoisovalerate + Glutamate

⇅

Valine + α-ketoglutarate

Isoleucine

Synthesis of isoeleucine (an essential amino acid in humans) begins in plants and microorganisms with pyruvate and **α**-ketobutyrate (a byproduct of threonine metabolism - threonine deaminase - Figure 6.162).

Metabolism of isoleucine proceeds with attachment to α-ketobutyrate of the hydroxyethyl-TPP product of pyruvate decarboxylation to form **α**-aceto-**α**-hydroxybutyrate. The reaction is catalyzed by acetolactate synthase. Rearrangement and reduction by acetohydroxy acid isomeroreductase and NAD(P)H yields **α**,**β**-dihydroxy-**β**-methylvalerate. Shown on next page.

α,β-dihydroxy-β-methylvalerate

⇅

α-keto-β-methylvalerate + H_2O

Transamination (using glutamate and valine isoleucine transaminase) yields isoleucine.

Interestingly, several of the enzymes of valine metabolism catalyze reactions in the isoleucine pathway. Though the substrates are slightly different, they are enough like the valine intermediates that they are recognized as substrates.

Isoleucine has a second asymmetric center within it, but only one isomeric form of the four possible ones from the two centers is found biologically.

Regulation of synthesis

Regulation of synthesis of the branched chain amino acids (BCAAs - valine, leucine, and isoleucine) is complex. The key molecule in the regulation is α-ketobutyrate, which is synthesized in cells as a breakdown product of threonine. The enzyme catalyzing its synthesis is threonine deaminase (Figure 6.162), which is allosterically regulated. The enzyme is inhibited by its own product (isoleucine) and activated by valine, a product of a parallel pathway.

Thus, when valine concentration is high, the balances shifts in favor of production of isoleucine and since isoleucine competes with valine and leucine for hydroxyethyl-TPP, synthesis of these two amino acids goes down. When isoleucine concentration increases, threonine deaminase is inhibited, shifting the balance back to production of valine and leucine.

Attenuation

Another control mechanism for regulation of leucine synthesis occurs in bacteria and is known as attenuation. In this method, accumulation of leucine speeds the process of translation of a portion of the mRNA copy of the leucine operon (coding sequences for enzymes necessary to make leucine). This, in turn, causes transcription of the genes of the leucine operon to terminate prematurely, thus stopping production of the enzymes necessary to make leucine.

When leucine levels fall, translation slows, preventing transcription from terminating prematurely and allowing leucine metabolic enzymes to be made. Thus, leucine levels in the cell control the synthesis of enzymes necessary to make it.

Histidine is a feedback inhibitor of ATP-phosphoribosyltransferase and thus helps to regulate its own synthesis. Histidine is the only amino acid to contain an imidazole ring. It is ionizable and has a pKa of about 6. As a result, histidine's R-group can gain/lose a proton at pH values close to cellular conditions.

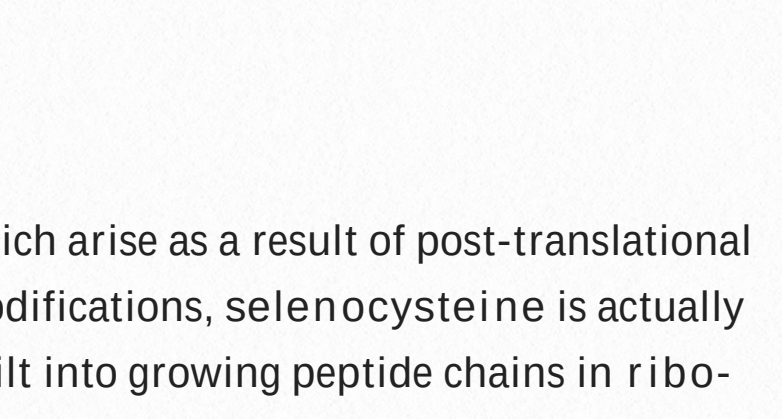
Selenocysteine

A cysteine analog commonly referred to as the 21st amino acid, selenocysteine (Figure 6.163) is an unusual amino acid occasionally found in proteins. Although it is rare, selenocysteine has been found in proteins in bacteria, archaea and eukaryotes.

In contrast to amino acids such as phosphoserine, hydroxyproline, or acetyl-lysine, which arise as a result of post-translational modifications, selenocysteine is actually built into growing peptide chains in ribosomes during the process of translation.

No codon specifies selenocysteine, so to incorporate it into a protein, a tRNA carrying it must bind to a codon that normally specifies STOP (UGA). This alternative reading of the UGA is dependent on formation of a special hairpin loop structure in the mRNA encoding selenoproteins.

Selenium is rather toxic, so cellular and dietary concentrations are typically exceedingly



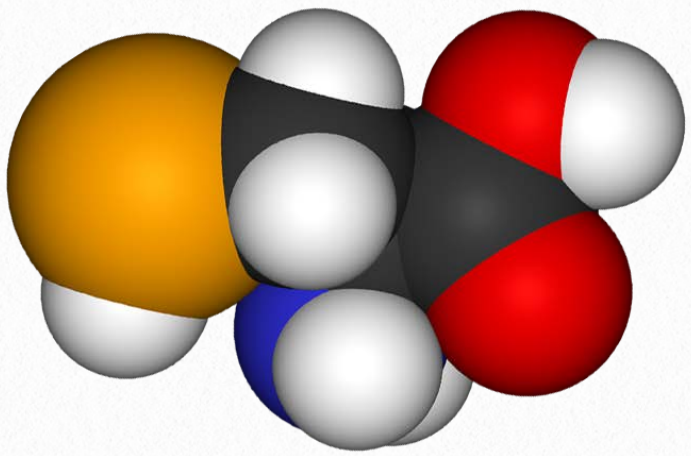


Figure 6.163 - Selenocysteine

low. About 25 human proteins are known to contain the amino acid. These include five glutathione peroxidases, and three thioredoxin reductases. Iodothyronine deiodinase, a key enzyme that converts thyroxine to the active T3 form, also contains selenocysteine in its active site. All of these proteins contain a single selenocysteine.

A eukaryotic protein known as selenoprotein P, found in the blood plasma of animals, contains ten selenocysteine residues and is thought to function as an antioxidant and/or in heavy metal detoxification. Besides selenocysteine, at least two other biological forms of a seleno-amino acid are known. These include 1) selenomethionine (Figure 6.164), a naturally occurring amino acid in Brazil nuts, cereal grains, soybeans, and grassland legumes and 2) methylated forms of selenocysteine, such as Se-methylselenocysteine, are found in *Astragalus*, *Allium*, and *Brassica* species.

Stop codon

The specifics of the process of translation will be described elsewhere in the book, but to get selenocysteine into a protein, the tRNA carrying selenocysteine pairs with a stop codon (UGA) in the mRNA in the ribosome. Thus, instead of stopping translation, selenocysteine can incorporated into a growing protein and translation continues instead of stopping.

Four genes are involved in preparation of selenocysteine for incorporation into proteins. They are known as sel A, sel B, sel C, and sel D. Sel C codes for the special tRNA that carries selenocysteine. The amino acid initially put onto the selenocysteine tRNA is not selenocysteine, but rather serine. Action of sel A and sel D are necessary to convert the serine to a selenocysteine.

An intermediate in the process is selenophosphate, which is the selenium donor. It is derived from H_2Se, the form in which selenium is found in the cell. The tRNA carrying selenocysteine has a slightly different structure than other tRNAs, so it requires assistance in translation. The sel B gene encodes for an EF-Tu-like protein that helps incorporate the selenocysteine into the protein during translation.

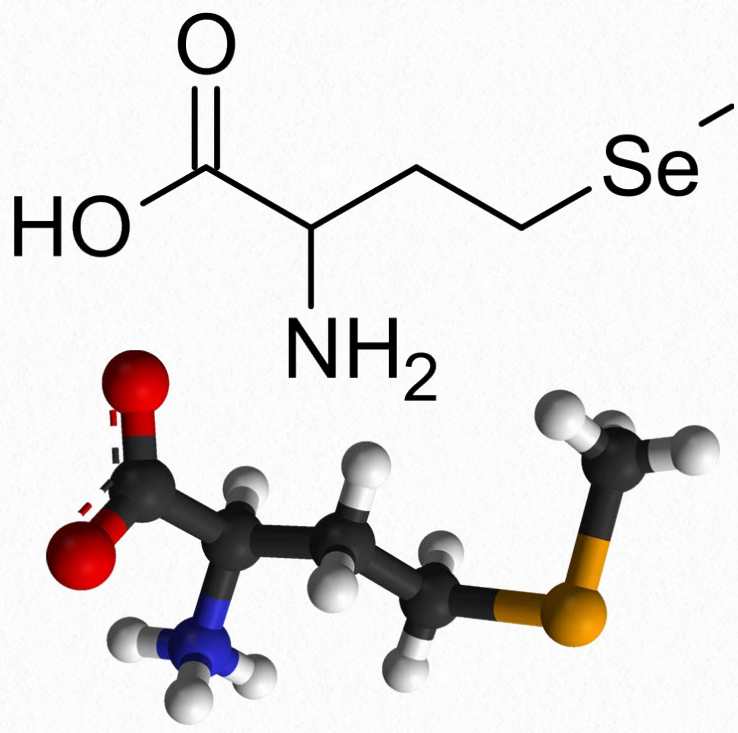

Figure 6.164 - Selenomethionine

Recoding the UGA

Using UGA codons to incorporate selenocysteine into proteins could wreak havoc if done routinely, as UGA, in fact, almost always functions as a stop codon and is only rarely used to code for selenocysteine. Fortunately, there is a mechanism to ensure that the reading of a UGA codon as selenocysteine occurs only when the mRNA encodes a selenoprotein.

Unusual structures in mRNAs

The mRNAs for selenocysteine-containing proteins form unusual mRNA structures around the UGA codon that make the ribosome "miss" it as a stop codon and permit the tRNA with selenocysteine to be incorporated instead.

Pyrrolysine

Like selenocysteine, pyrrolysine is a rare, unusual, genetically encoded amino acid found in some cells. Proteins containing it are enzymes involved in methane metabolism and so far have been found only methanogenic archaeans and one species of bacterium. The amino acid is found in the active site of the enzymes containing it. It is sometimes referred to as the 22nd amino acid.

Synthesis of the amino acid biologically begins with two lysines. One is converted to (3R)-3-Methyl-D-ornithine, which is attached to the second lysine. After elimination of an amine group, cyclization, and dehydration, L-pyrrolysine is produced. Pyrrolysine is attached to an unusual tRNA (pylT gene product) by action of the aminoacyl tRNA synthetase encoded by the pylS gene. This unusual tRNA can pair with the UAG stop codon during translation and allow for incorporation of pyrrolysine into the growing polypeptide chain during translation in a manner similar to incorporation of selenocysteine.

Urea cycle

The urea cycle holds the distinction of being the first metabolic cycle discovered - in 1932, five years before the citric acid cycle. It is an important metabolic pathway for balancing nitrogen in the bodies of animals and it takes place primarily in the liver and kidney.

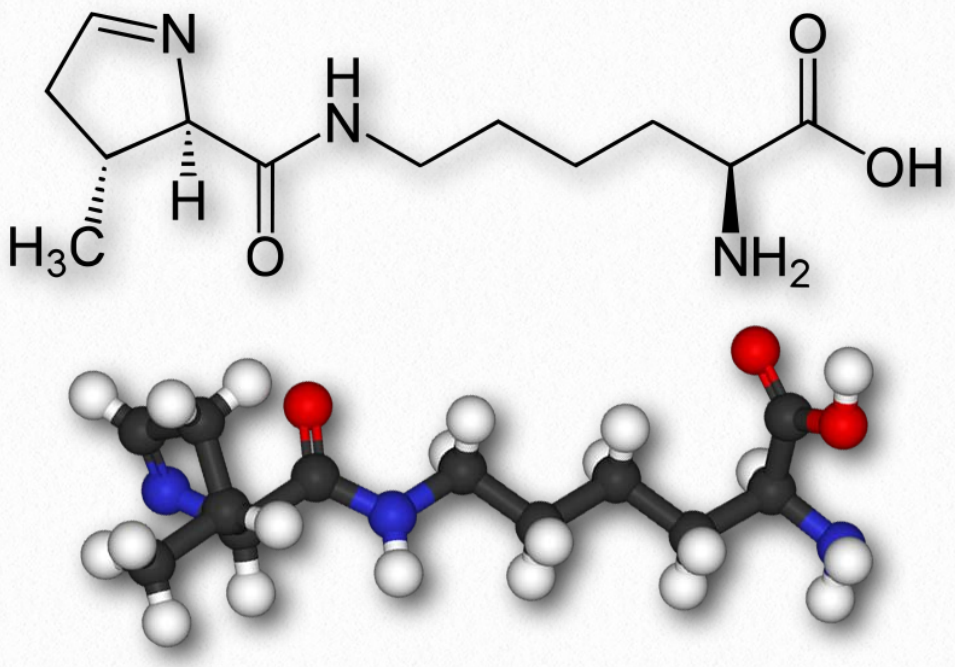

Figure 6.165 - Pyrrolysine

Organisms, like humans, that excrete urea are called ureotelic. Those that excrete uric acid (birds, for example) are called uricotelic and those that excrete ammonia (fish) are ammonotelic. Ammonia, of course, is generated by metabolism of amines and is toxic, so managing levels of it is critical for any organism. Excretion of ammonia by fish is one reason that an aquarium periodically requires cleaning and replacement of water.

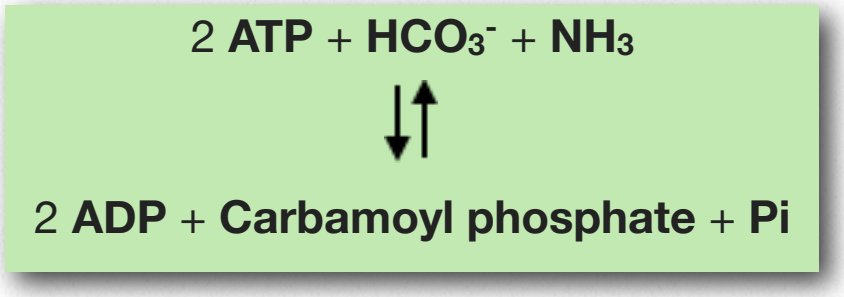
YouTube Lectures by Kevin HERE & HERE

Liver failure can lead to accumulation of nitrogenous waste and exacerbates the problem. As shown in Figure 1.166, the cycle contains five reactions, with each turn of the cycle producing a molecule of urea. Of the five reactions, three occur in the cytoplasm and two take place in the mitochondrion. (The reaction making carbamoyl phosphate, catalyzed by carbamoyl phosphate synthetase is not shown in the figure.)

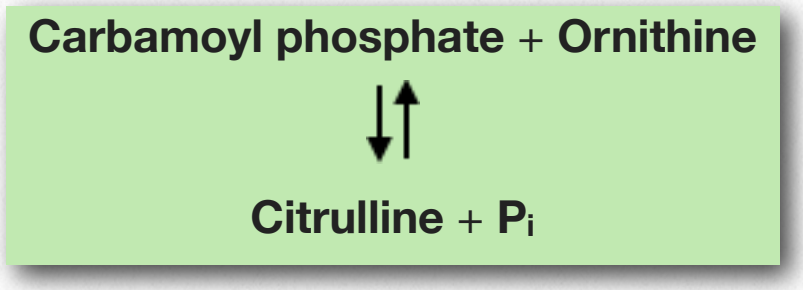
Ornithine synthesis

Though the cycle doesn't really have a starting point, a common place to begin discussion is with the molecule of ornithine. As discussed elsewhere in this book, ornithine intersects the metabolic pathways of arginine and proline.

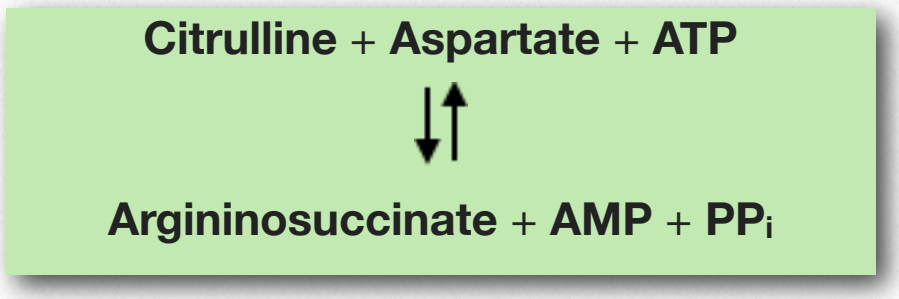
Ornithine is found in the cytoplasm and is transported into the mitochondrion by the ornithine-citrulline antiport of the inner mitochonrial membrane. In the matrix of the mitochondrion, two reactions occur relevant to the cycle. The first is formation of carbamoyl phosphate from bicarbonate, ammonia, and ATP catalyzed by carbamoyl phosphate synthetase I.



Carbamoyl phosphate then combines with ornithine in a reaction catalyzed by ornithine transcarbamoylase to make citrulline.



The citrulline is transported out to the cytoplasm by the ornithine-citrulline antiport mentioned above. In the cytoplasm, citrulline combines with L-aspartate using energy of ATP to make citrullyl-AMP (an intermediate) followed by argininosuccinate. The reaction is catalyzed by argininosuccinate synthase.



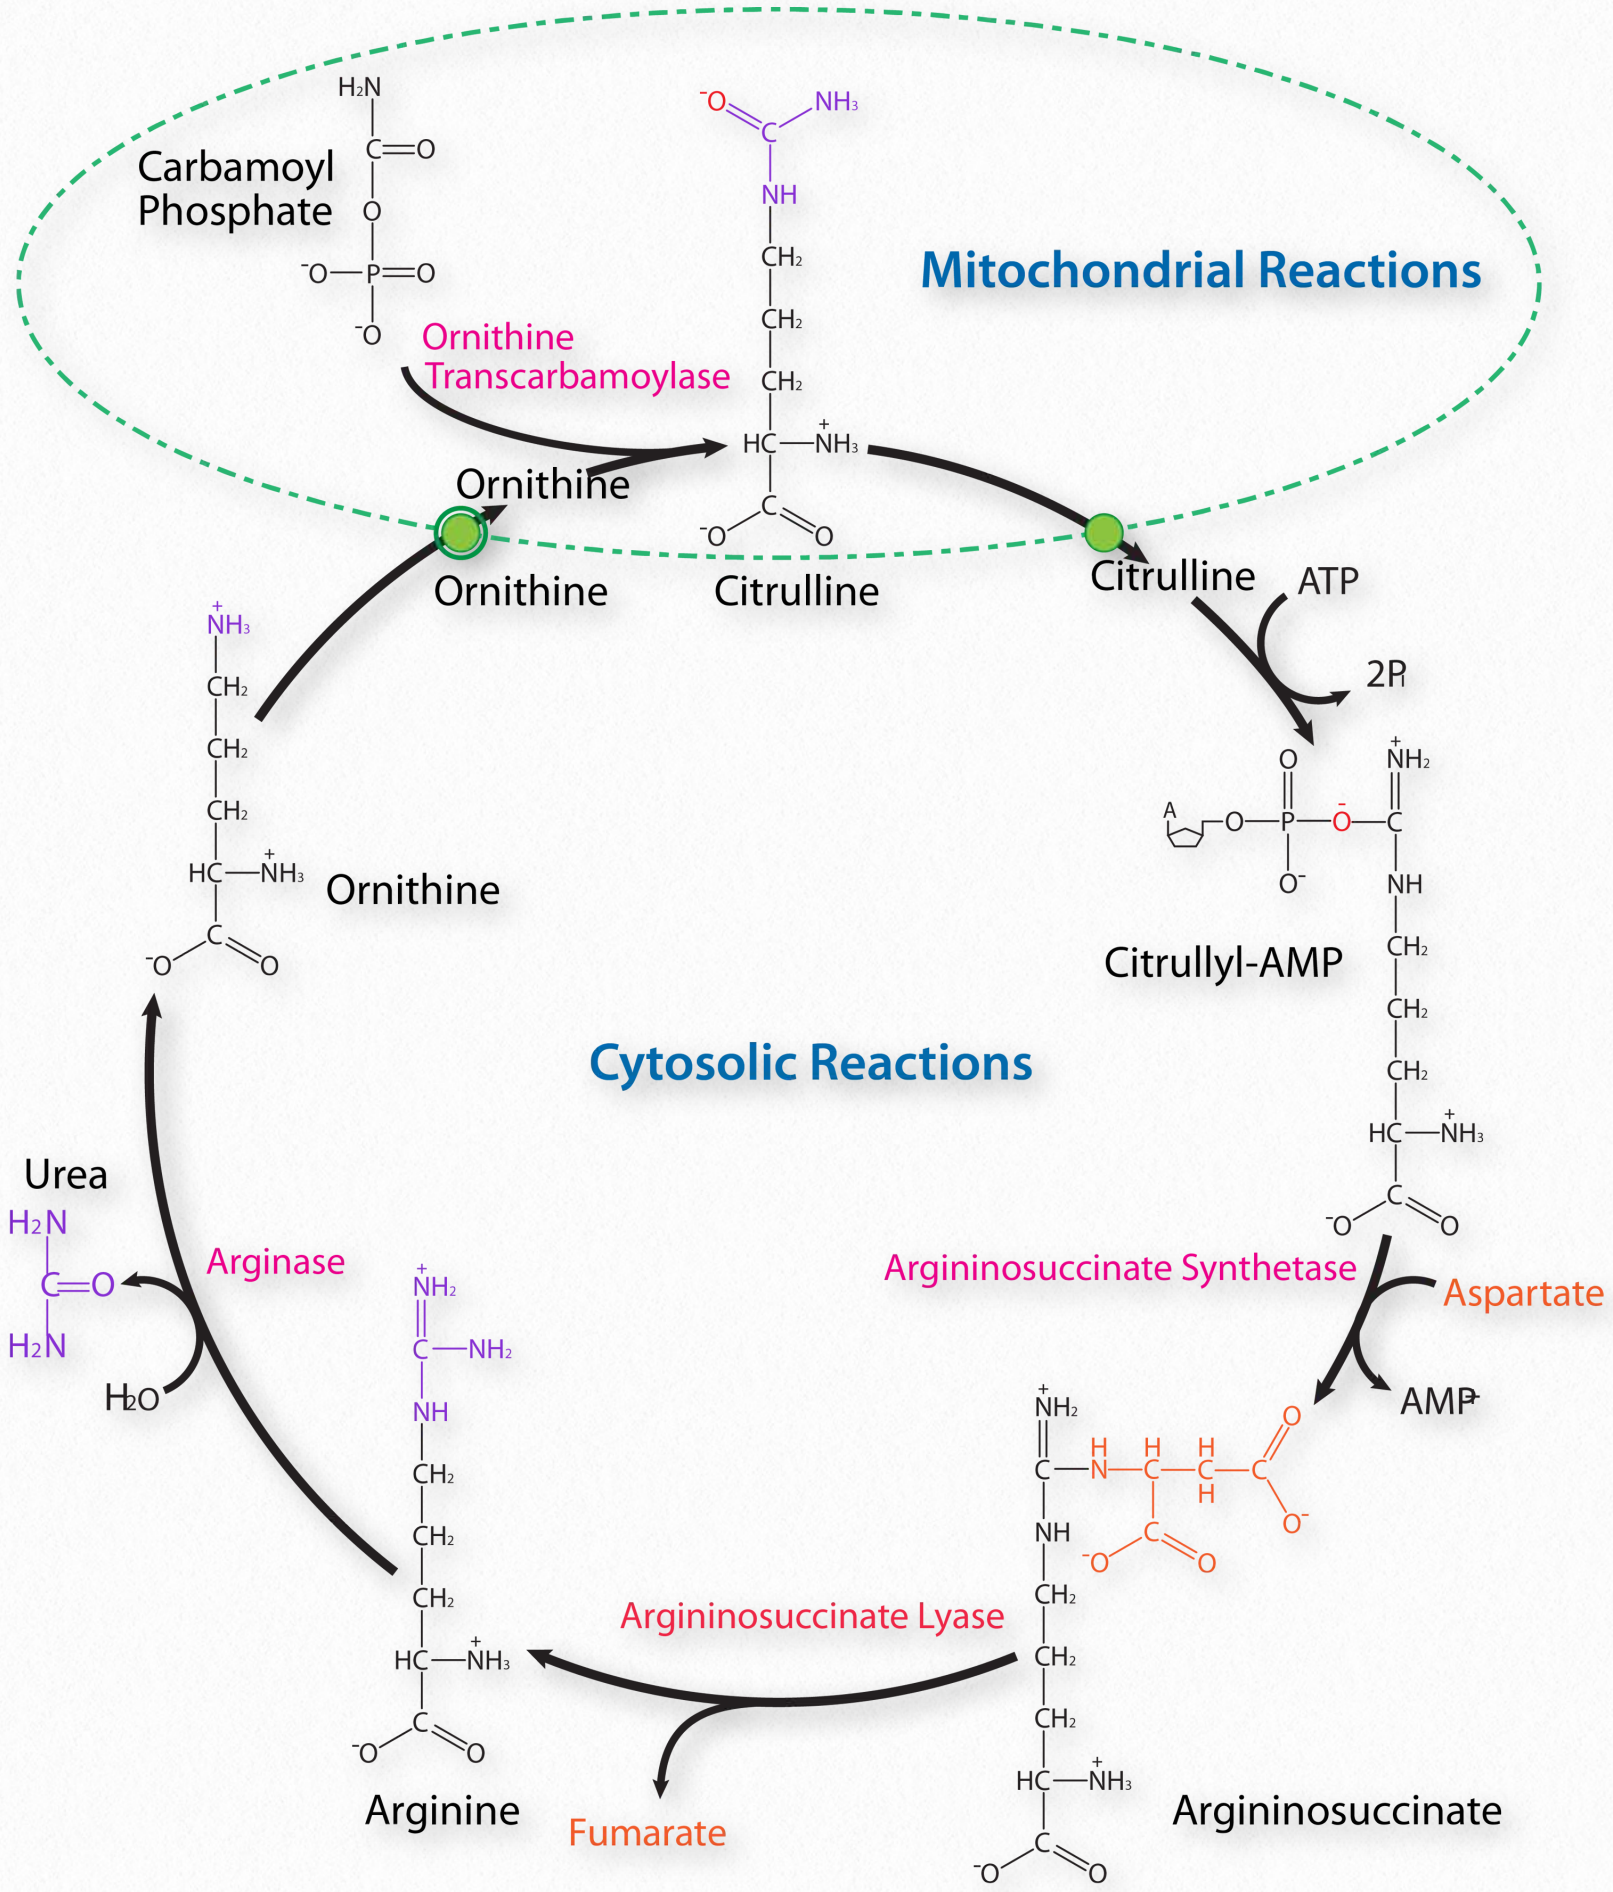


Figure 6.166 - The urea cycle

Image by Aleia Kim

Next, fumarate is split from argininosuccinate by argininosuccinate lyase to form arginine.

Argininosuccinate

⇅

Arginine + **Fumarate**

Water is used by arginase to cleave arginine into urea and ornithine, completing the cycle.

Arginine + H_2O

⇅

Ornithine + **Urea**

Urea is less toxic than ammonia and is released in the urine. Some organisms make uric acid for the same reason.

It is worth noting that aspartic acid, ammonia, and bicarbonate enter the cycle and fumarate and urea are produced by it. Points to take away include 1) ammonia is converted to urea using bicarbonate and the amine from aspartate; 2) aspartate is converted to fumarate which releases more energy than if aspartate were converted to oxaloacetate, since conversion of fumarate to malate to oxaloacetate in the citric acid cycle generates an NADH, but direct conversion of aspartate to oxaloacetate does not; and 3) glutamate and aspartate are acting as shuttles to funnel ammonia into the cycle. Glutamate, as will be seen below, is a scavenger of ammonia.

Urea cycle regulation

The urea cycle is controlled both allosterically and by substrate concentration. The cycle requires N-acetylglutamate (NAG) for allosteric activation of carbamoyl phosphate synthetase I. The enzyme that catalyzes synthesis of NAG, NAG synthetase, is activated by arginine and glutamate. Thus, an indicator of high amine levels, arginine, and an important shuttler of amine groups, glutamate, stimulates the enzyme that activates the cycle.

The reaction catalyzed by NAG synthetase is

Acetyl-CoA + **L-glutamate**

⇅

CoA-SH + **N-acetyl-L-glutamate**

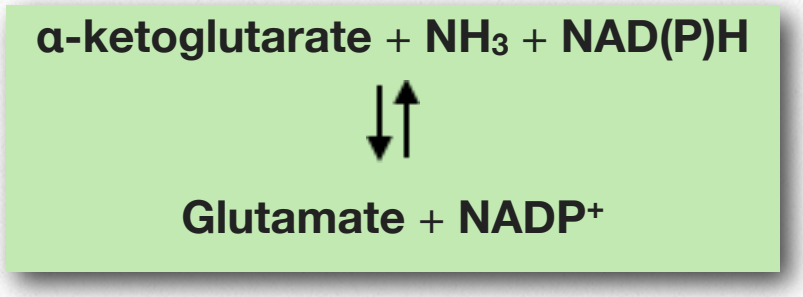
At the substrate level, all of the other enzymes of the urea cycle are controlled by the concentrations of substrates they act upon. Only at high concentrations are the enzymes fully utilized.

Complete deficiency of any urea cycle enzyme is fatal at birth, but mutations resulting in reduced expression of enzymes can have mixed effects. Since the enzymes are usually not limiting for these reactions, increasing substrate can often overcome reduced enzyme

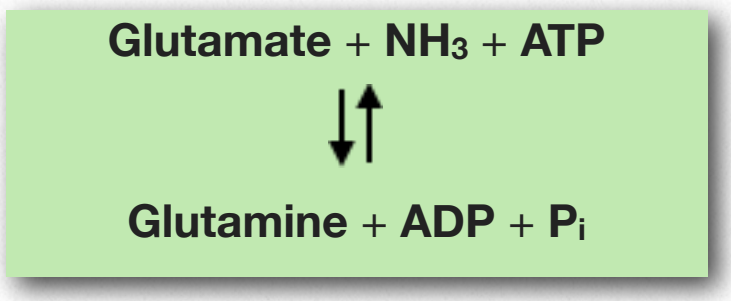
amounts to a point by simply fully activating enzymes present in reduced quantities.

Ammonia accumulation

However, if the deficiencies are sufficient, ammonium can accumulate and this can be quite problematic, especially in the brain, where mental deficiencies or lethargy can result. Reduction of ammonium concentration relies on the glutamate dehydrogenase reaction (named for the reverse reaction).



Additional ammonia can be taken up by glutamate in the glutamine synthetase reaction.



The result of these reactions is that α-ketoglutarate and glutamate concentrations will be reduced and the concentration of glutamine will increase. For the brain, this is a yin/yang situation. Removal of ammonia is good, but reduction of α-ketoglutarate concentration means less energy can be generated by the citric acid cycle. Further, glutamate is, itself, an important neurotransmitter and a precursor of another neurotransmitter - γ-aminobutyric acid (GABA).

Energy generation

From an energy perspective, the urea cycle can be said to break even or generate a small amount of energy, if one includes the energy produced in releasing ammonia from glutamate (one NADH). There are two NADHs produced (including the one for converting fumarate to oxaloacetate), which give 4-6 ATPs, depending on how efficiently the cell performs electron transport and oxidative phosphorylation.

The cycle takes in 3 ATPs and produces 2 ADPs and one AMP. Since AMP is equivalent to 2 ATP, the cycle uses 4 ATP. Thus, the cycle either breaks even in the worst case or generates 2 ATPs in the best case.

Amino acid catabolism

Amino acids are divided according to the pathways involved in their degradation. There are three general categories. Ones that yield intermediates in the glycolysis pathway are called glucogenic and those that yield intermediates of acetyl-CoA or acetoacetate are called ketogenic. Those that involve both are called glucogenic and ketogenic. These are shown in Figures 6.167 and 6.168.

As seen in the two figures, amino acids largely produce breakdown products related to intermediates of the citric acid cycle or glycolysis, but this isn't the complete picture. Some amino acids, like tryptophan,

Glucogenic and Ketogenic Amino Acids

Glucogenic	Ketogenic	Both Glucogenic and Ketogenic
Aspartate	Leucine	Isoleucine
Asparagine	Lysine	Phenylalanine
Alanine		Tryptophan
Glycine		Tyrosine
Serine		
Threonine		
Cysteine		
Glutamate		
Glutamine		
Arginine		
Proline		
Histidine		
Valine		
Methionine		

Figure 6.167 - Results of amino acid catabolism

Image by Aleia Kim

phenylalanine, and tyrosine yield hormones or neurotransmitters on further metabolism (as noted earlier). Others like cysteine and methionine must dispose of their sulfur and all of the amino acids must rid themselves of nitrogen, which can happen *via* the urea cycle, transamination, or both.

Tyrosine catabolism

Breakdown of tyrosine (Figure 6.169) is a five step process that yields acetoacetate and fumarate. Enzymes involved include 1) tyrosine transaminase; 2) p-hydroxylphenylpyruvate dioxygenase; 3) homogentisate dioxygenase; 4) maleylacetoacetate *cis*-*trans*-isomerase; and 5) 4-fumaryl acetoacetate hydrolase.

Breakdown of leucine is a multi-step process ultimately yielding the ketone body acetoacetate and acetyl-CoA. Branched chain amino acids (BCAAs - valine, leucine,

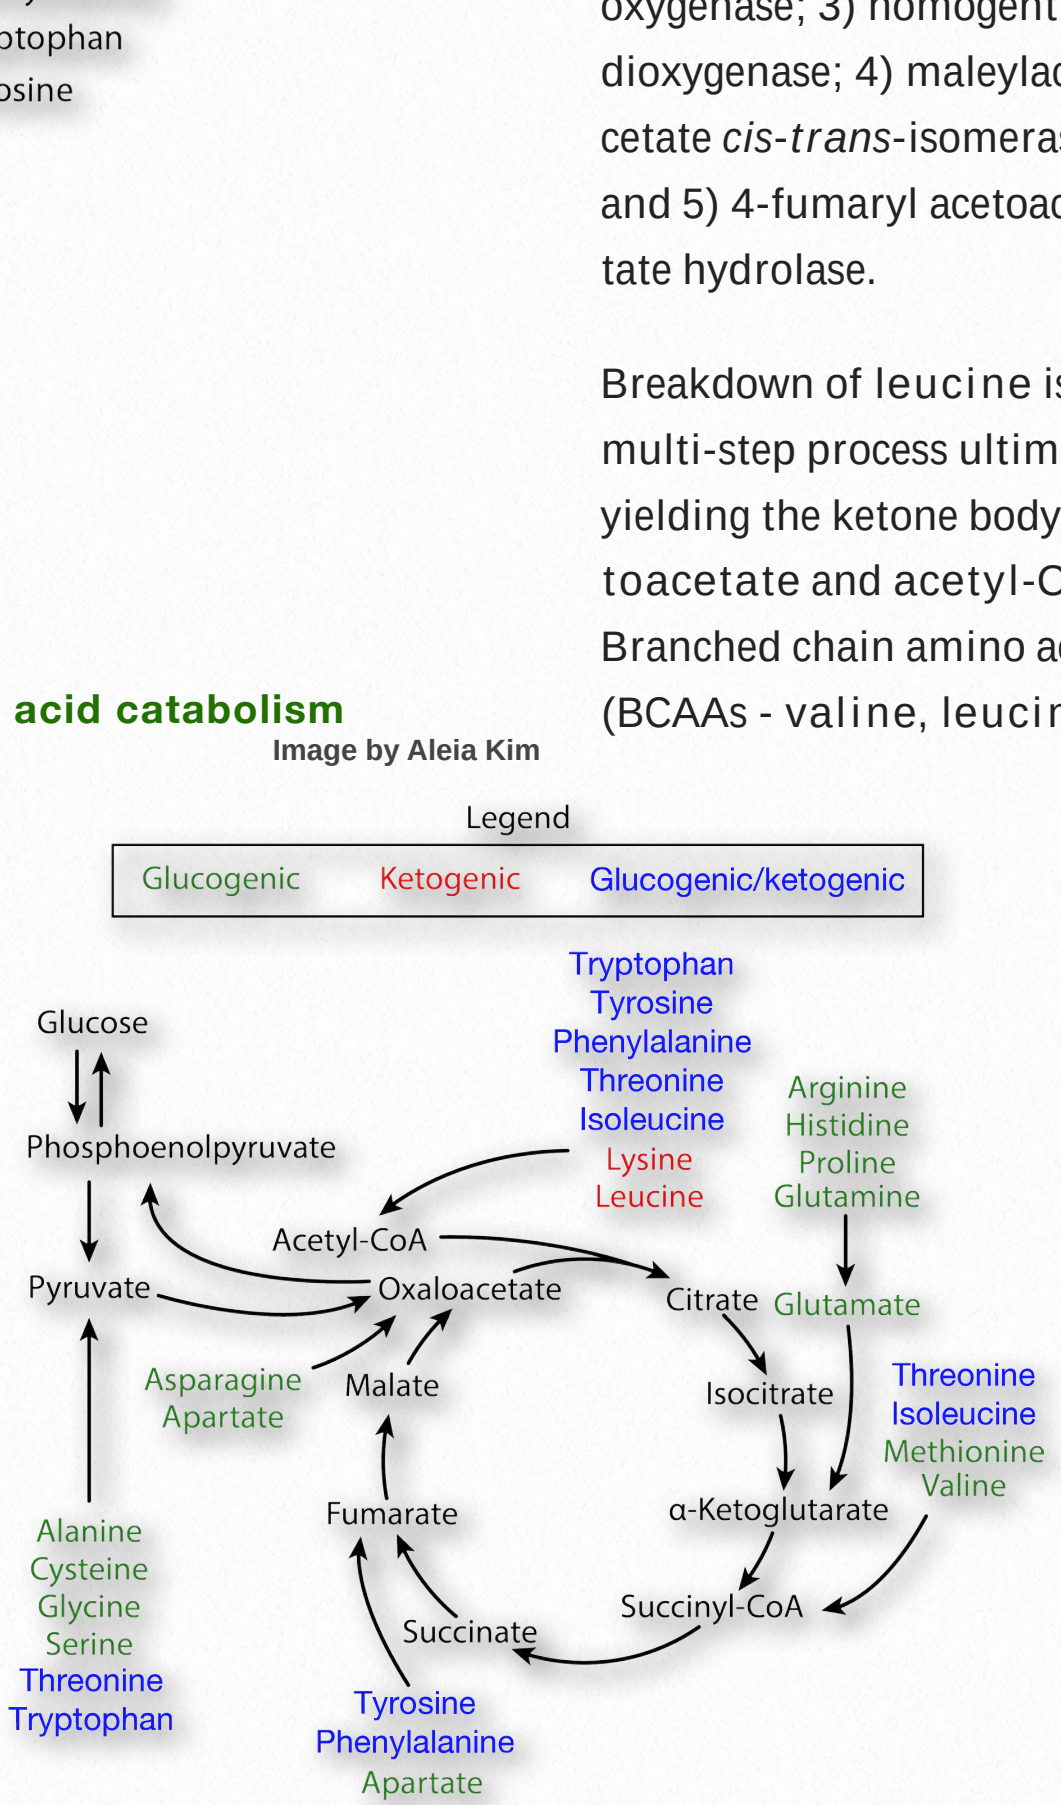


Figure 6.168 - Breakdown pathways for amino acids. Some yield more than one intermediate.

Image by Pehr Jacobson

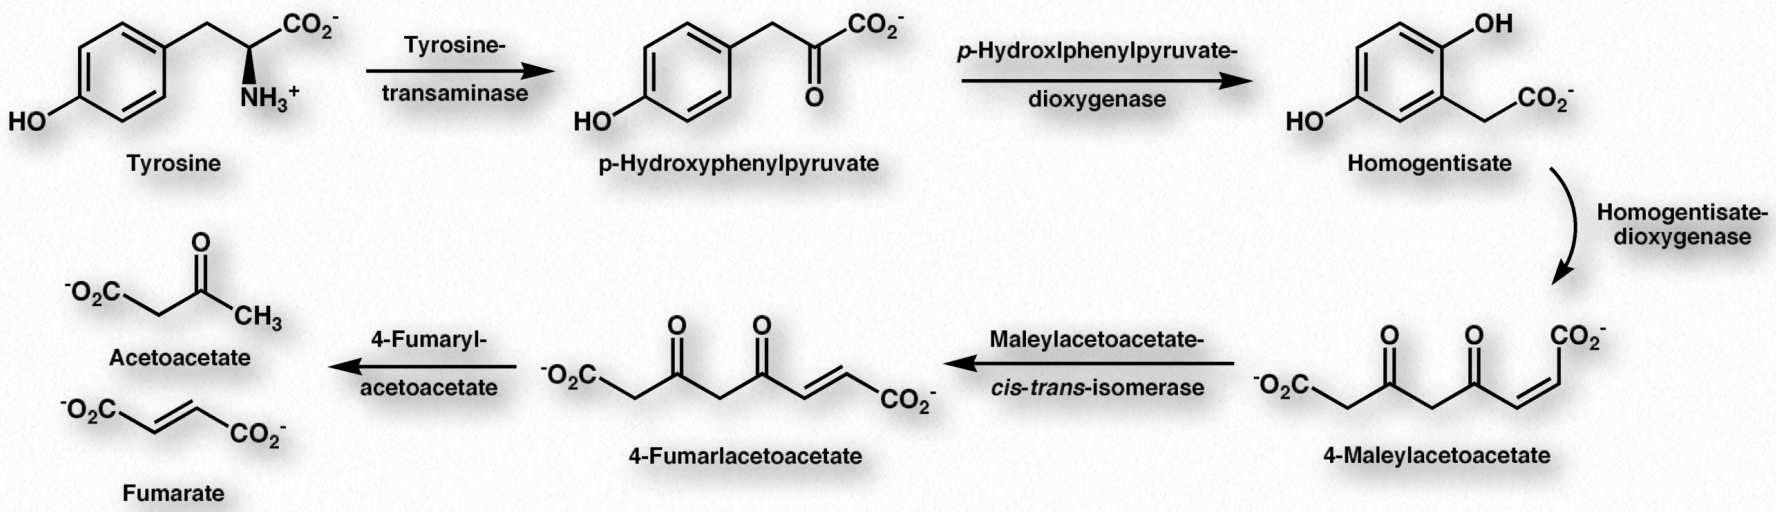

Figure 6.169 - Catabolism of tyrosine to fumarate and acetoacetate.

and isoleucine) rely on Branched Chain AminoTransferase (BCAT) followed by Branched Chain α-ketoacid dehydrogenase (BCKD) for catabolism.

Breakdown of isoleucine yields intermediates that are both ketogenic and glucogenic. These include acetyl-CoA and propionyl-CoA.

Breakdown of valine is a multi-step process ultimately yielding propionyl-CoA.

I Studied So Hard Last Night

To the tune of "*I Saw Her Again Last Night*"

Metabolic Melodies Website HERE

I studied so hard last night
But you know that I couldn't
Get all the reactions down right
Oh my brain simply wouldn't

I made lots of tries
To memorize
But it seemed the more I read the book
I never learned

'Twas much too complex in my head
And so truly confusing
Like most of the things Ahern said
Awfully tough but amusing

I got so upset
That I would forget
Oh I had to find another way
Or I'd never learn

Bridge
Metabolic Melodies
The pathways I could sing in time
They all put my mind at ease
Using just the power of rhyme
My grades began to climb

I studied so hard last night
Now I'll never forget it
The Melodies helped get it right
Just the way Kevin said it

I won't get it wrong
If I sing along
And it makes me feel so good to know
I've truly learned

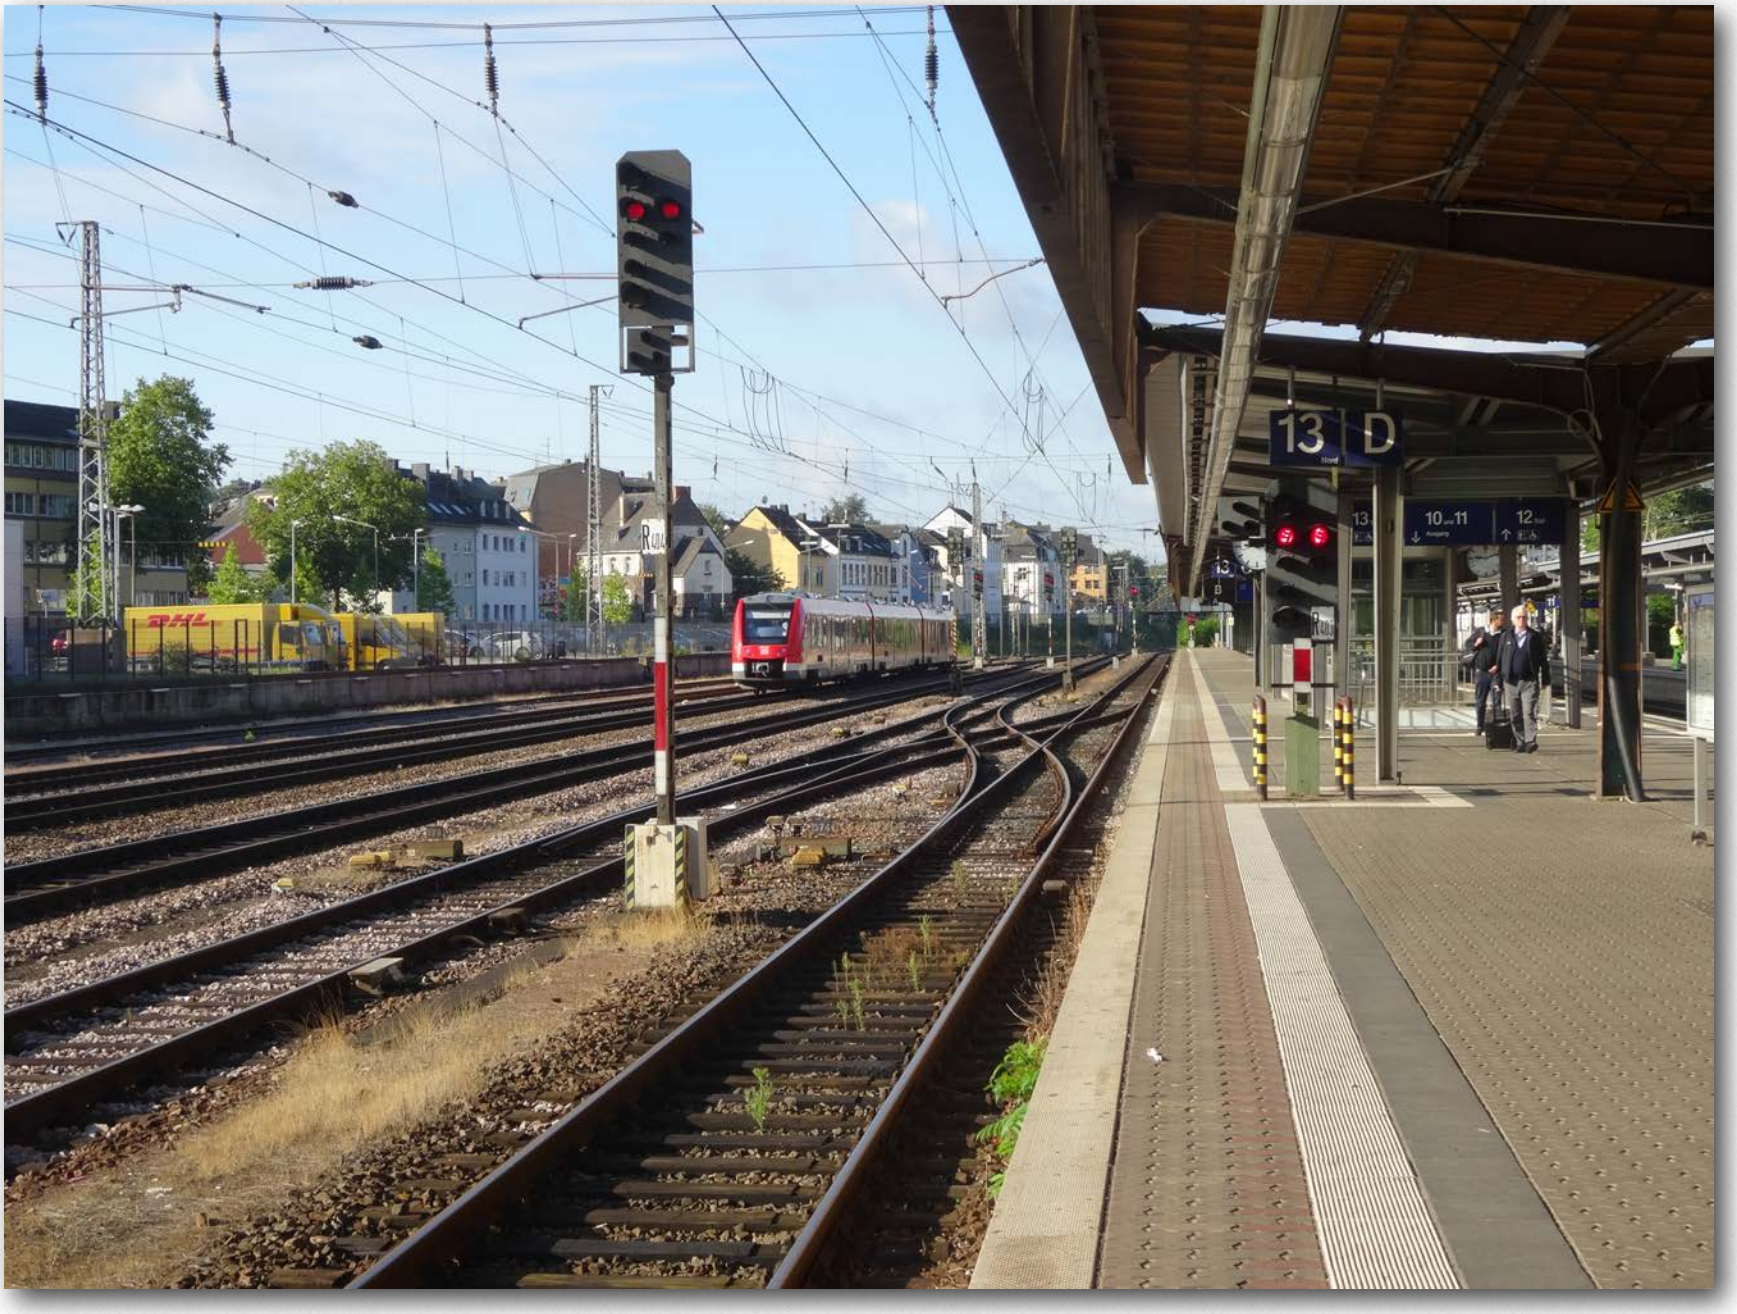
Metabolism: Nucleotides



Diverse functions of nucleotides

Nucleotides are most often thought of as the building blocks of the nucleic acids, DNA and RNA. While this, is, of course, a vital function, nucleotides also play other important roles in cells. Ribonucleoside triphosphates like ATP, CTP, GTP and UTP are necessary, not just for the synthesis of RNA, but as part of activated intermediates like UDP-glucose in biosynthetic pathways. ATP is also the universal “energy currency” of cells, and coupling of energetically unfavorable reactions with the hydrolysis of ATP makes possible the many reactions in our cells that require an input of energy. Adenine nucleotides serve as components of $NAD(P)^+$ and FAD. Nucleotides can also serve as allosteric and metabolic regulators. The synthesis and breakdown pathways for nucleotides and the molecules derived from them are thus, of vital importance to cells. Regulation of nucleotide synthesis, especially for deoxyribonucleotides, is important to ensure that the four nucleotides are made in the

YouTube Lectures by Kevin
HERE & HERE

right proportions, as imbalances in nucleotide concentrations can lead to increases in mutation rates.

Pathways of nucleotide metabolism are organized in two major groups and one minor one. These include, respectively, metabolism of 1) purines; 2) pyrimidines; and 3) deoxyribonucleotides. Each group can be further subdivided into pathways that make nucleotides from simple precursors (*de novo* pathways) and others that use pieces of nucleotides to reassemble full ones (salvage pathways). Notably, *de novo* synthesis pathways for all of the nucleotides begin with synthesis of ribonucleotides. Deoxyribonucleotides are made from the ribonucleotides.

Purine nucleotide metabolism

Synthesis of purine nucleotides by the *de novo* pathway begins with addition of a pyrophosphate to carbon 1 of ribose-5-phosphate, creating phosphoribosylpyrophosphate (PRPP). The reaction is catalyzed by PRPP synthetase. Some number the purine metabolic pathway starting with the next reaction. We have therefore given this reaction the number of zero in Figure 6.172.

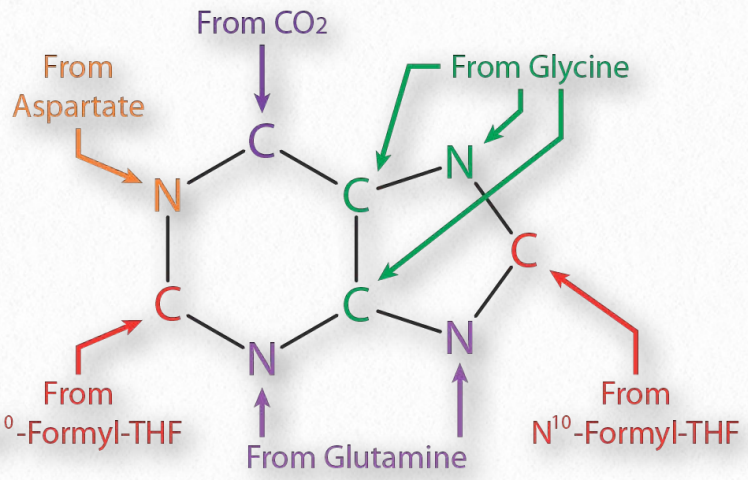


Figure 6.170 - Origin of atoms in purines

Image by Aleia Kim

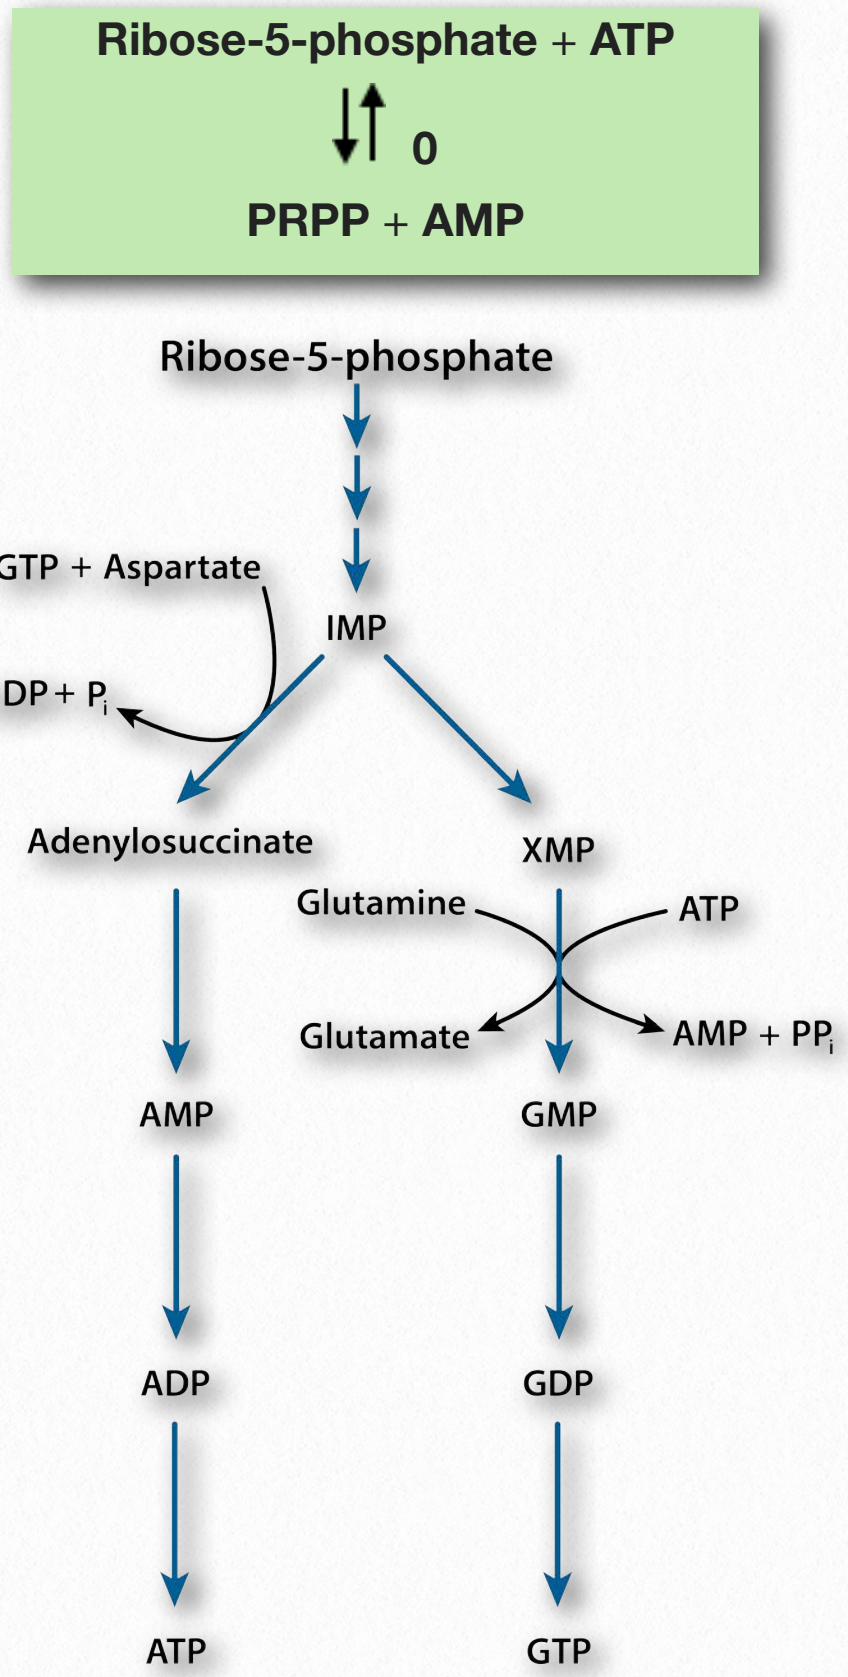

Figure 6.171 - Purine metabolism overview

Image by Pehr Jacobson

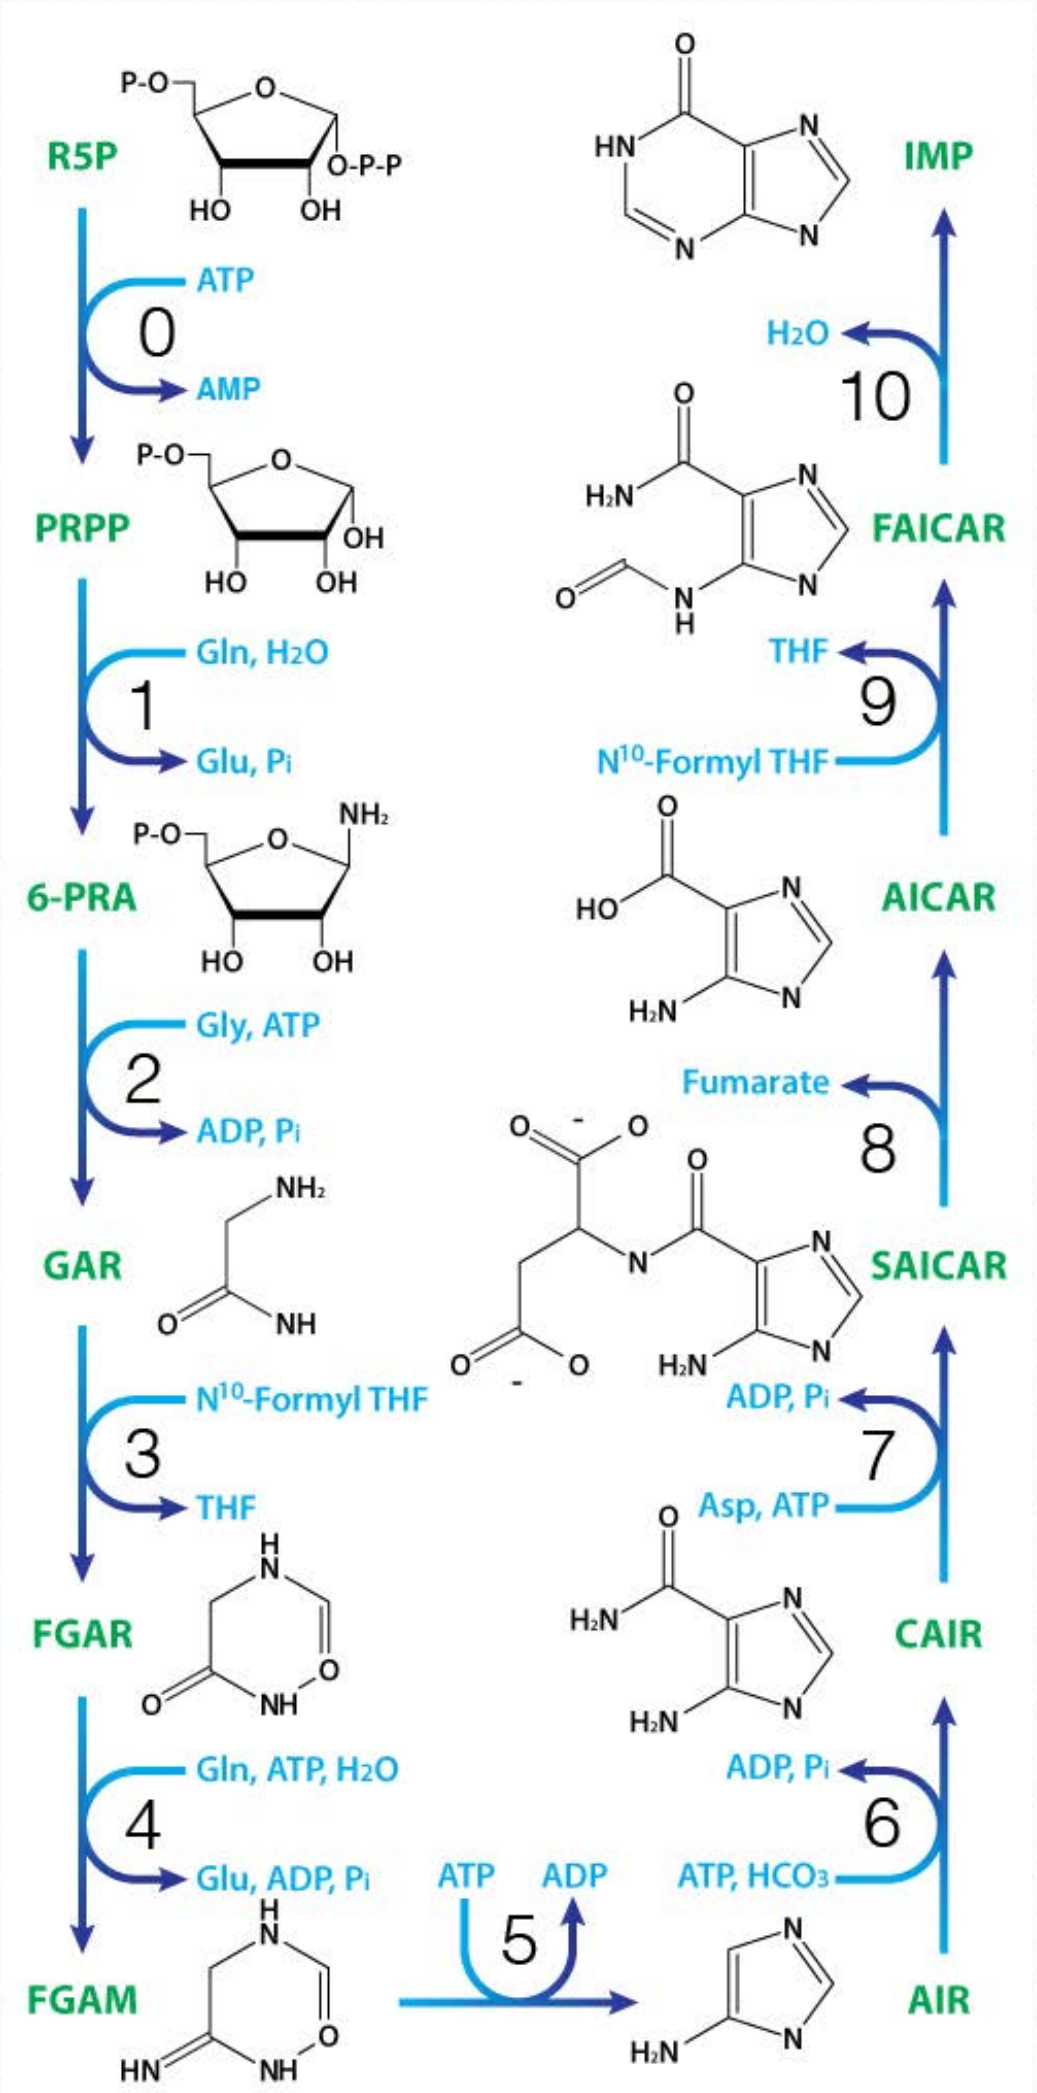

Figure 6.172 - Purine *de novo* synthesis

Image by Aleia Kim

In the next step (reaction 1 in Figure 6.172), the pyrophosphate is replaced by an amine from glutamine in a reaction catalyzed by PRPP amidotransferase (PPAT). The product is 5-phosphoribosylamine (5-PRA).

PRPP + **Glutamine** + H_2O

⇅ 1

5-PRA + **Glutamate** + **PP_i**

PPAT is an important regulatory enzyme for purine biosynthesis. The end products of the pathway, AMP and GMP both inhibit the enzyme and PRPP activates it. Interestingly, full inhibition of the enzyme requires binding of both AMP and GMP.

Binding of only one of the two nucleotides allows the enzyme to remain partially active so that the missing nucleotide can be synthesized. Through this enzyme, the relative amounts of ATP and GTP are controlled.

5-PRA is very unstable chemically (half-life of 38 seconds at

37°C), so it has been proposed that it is shuttled directly from PRPP amidotransferase to GAR synthetase for the next reaction.

In this reaction (#2), glycine is added to the growing structure above the ribose-5-phosphate to create glycineamide ribonucleotide (GAR). This reaction, which requires ATP, is catalyzed, as noted, by the enzyme GAR synthetase.

5-PRA + Glycine + ATP
⇅ 2
GAR + ADP + Pi

In reaction #3, a formyl group is transferred onto the GAR from N^{10}-formyl-tetrahydrofolate (N^{10}-formyl-THF or fTHF) by phosphoribosylglycinamide formyltransferase (GART).

GAR + fTHF
⇅ 3
fGAR + THF

Next, the double bonded oxygen in the ring is replaced with an amine in a reaction catalyzed by phosphoribosylformylglycinamidine synthase (PFAS) that uses glutamine and produces glutamate. The reaction requires energy from ATP (top of next column).

fGAR + L-Glutamine + ATP
⇅ 4
fGAM + L-Glutamate + ADP + P_i

In humans the GAR synthetase, phosphoribosylglycinamide formyltransferase, and the enzyme catalyzing the next reaction (#5), AIR synthetase activities are all on the same protein known as trifunctional purine biosynthetic protein adenosine-3.

fGAM + ATP
⇅ 5
AIR + ADP + P_i + H_2O

In reaction #6, carboxylation of AIR occurs, catalyzed by phosphoribosylaminoimidazole carboxylase (PAIC)

AIR + HCO_3^-
⇅ 6
CAIR + $2H^+$

Aspartic acid is then added to donate its amine group and fumarate will be lost in the reaction that follows this one. The enzyme involved here is phosphoribosyl-

CAIR + L-Aspartate + ATP
⇅ 7
SAICAR + ADP + P_i

aminoimidazole-succinocarboxamide synthase (PAICS)

In the next reaction, the carbon shell of aspartate is released (as fumarate) and the amine is left behind. The reaction is catalyzed by adenylosuccinate lyase (ADSL).

SAICAR

⇅ 8

AICAR + **Fumarate**

Reaction #9 involves another formylation reaction, catalyzed by phosphoribosylaminoimidazolecarboxamide formyltransferase (ATIC-E1).

AICAR + **fTHF**

⇅ 9

FAICAR + **THF**

Next, inosine monophosphate synthase (ATIC-E2) catalyzes release of water to form the first molecule classified as a purine - inosine monophosphate or IMP).

FAICAR

⇅ 10

IMP + H_2O

Though it doesn't appear in DNA, IMP does, in fact, occur in the anticodon of many tRNAs where its ability to pair with numerous bases is valuable in reading the genetic code.

IMP is a branch point between pathways that lead to GMP or AMP. The pathway to GMP proceeds via catalysis by IMP dehydrogenase as follows:

IMP + **NAD^+** + H_2O

⇅

Xanthosine 5'-phosphate + **NADH** + H+

In the last step of GMP synthesis, GMP synthase catalyzes a transamination to form GMP using energy from ATP.

ATP + **Xanthosine 5'-P** + **Glutamine** + H_2O

⇅

AMP + **PP_i** + **GMP** + **Glutamate**

The energy source being ATP makes sense, since the cell is presumably making GMP because it needs guanine nucleotides. If the cell is low on guanine nucleotides, GTP would be in short supply.

Adenine nucleotide synthesis

Synthesis of AMP from IMP follows. First, adenylosuccinate synthetase catalyzes the addition of aspartate to IMP, using energy from GTP.

IMP + Aspartate + GTP

⇅

Adenylosuccinate + GDP + P_i

Then, adenylosuccinate lyase splits fumarate off to yield AMP.

Adenylosuccinate

⇅

AMP + Fumarate

In humans, the bifunctional purine biosynthesis protein known as PURH contains activities of the last two enzymes above.

Abbreviations used above

PRPP = Phosphoribosyl Pyrophosphate
5-PRA = 5-phosphoribosylamine
GAR = glycineamide ribonucleotide
fGAR = Phosphoribosyl-N-formylglycineamide
THF = Tetrahydrofolate
fTHF = N^{10}-formyl-Tetrahydrofolate
fGAM = 5'-Phosphoribosylformylglycinamidine
AIR = 5-Aminoimidazole ribotide
CAIR = 5'-Phosphoribosyl-4-carboxy-5-aminoimidazole
SAICAR = Phosphoribosylamino-imidazolesuccinocarboxamide
AICAR = 5-Aminoimidazole-4-carboxamide ribonucleotide
FAICAR = 5-Formamidoimidazole-4-carboxamide ribotide
IMP = inosine monophosphate

Regulation

It is worth repeating that synthesis of GMP from IMP requires energy from ATP and that synthesis of AMP from IMP requires energy from GTP. In addition, the enzymes converting IMP into intermediates in the AMP and GMP pathways are each feedback inhibited by the respective monophosphate nucleotide. Thus, IMP dehydrogenase is inhibited by GMP (end product of pathway branch) and adenylosuccinate synthetase is inhibited by AMP, the end product of that pathway branch.

Purine nucleotide levels are balanced by the combined regulation of PRPP amidotransferase , IMP dehydrogenase, adenylosuccinate synthetase and the nucleotides AMP and GMP. The importance of the regu-

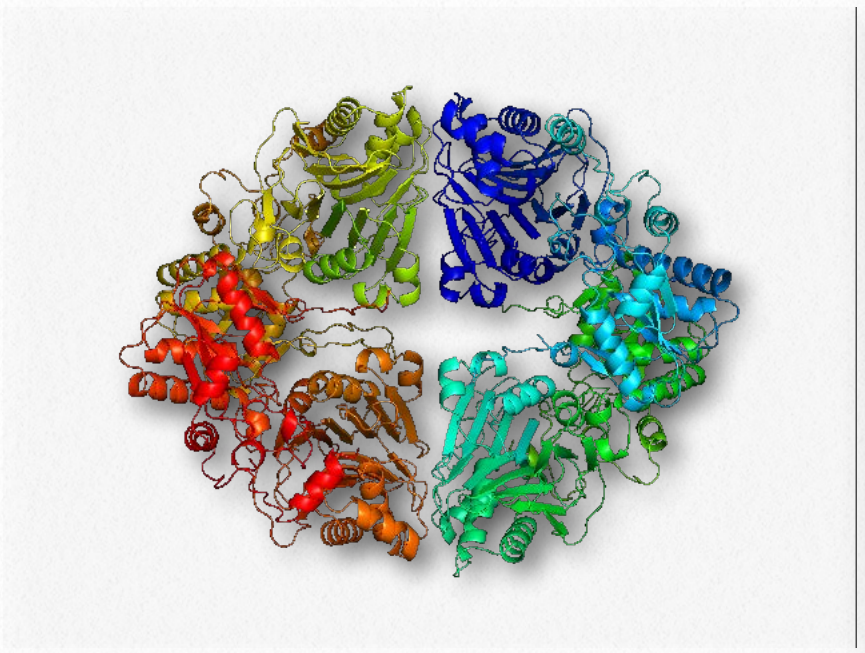

Figure 6.173 - PRPP amidotransferase
Wikipedia

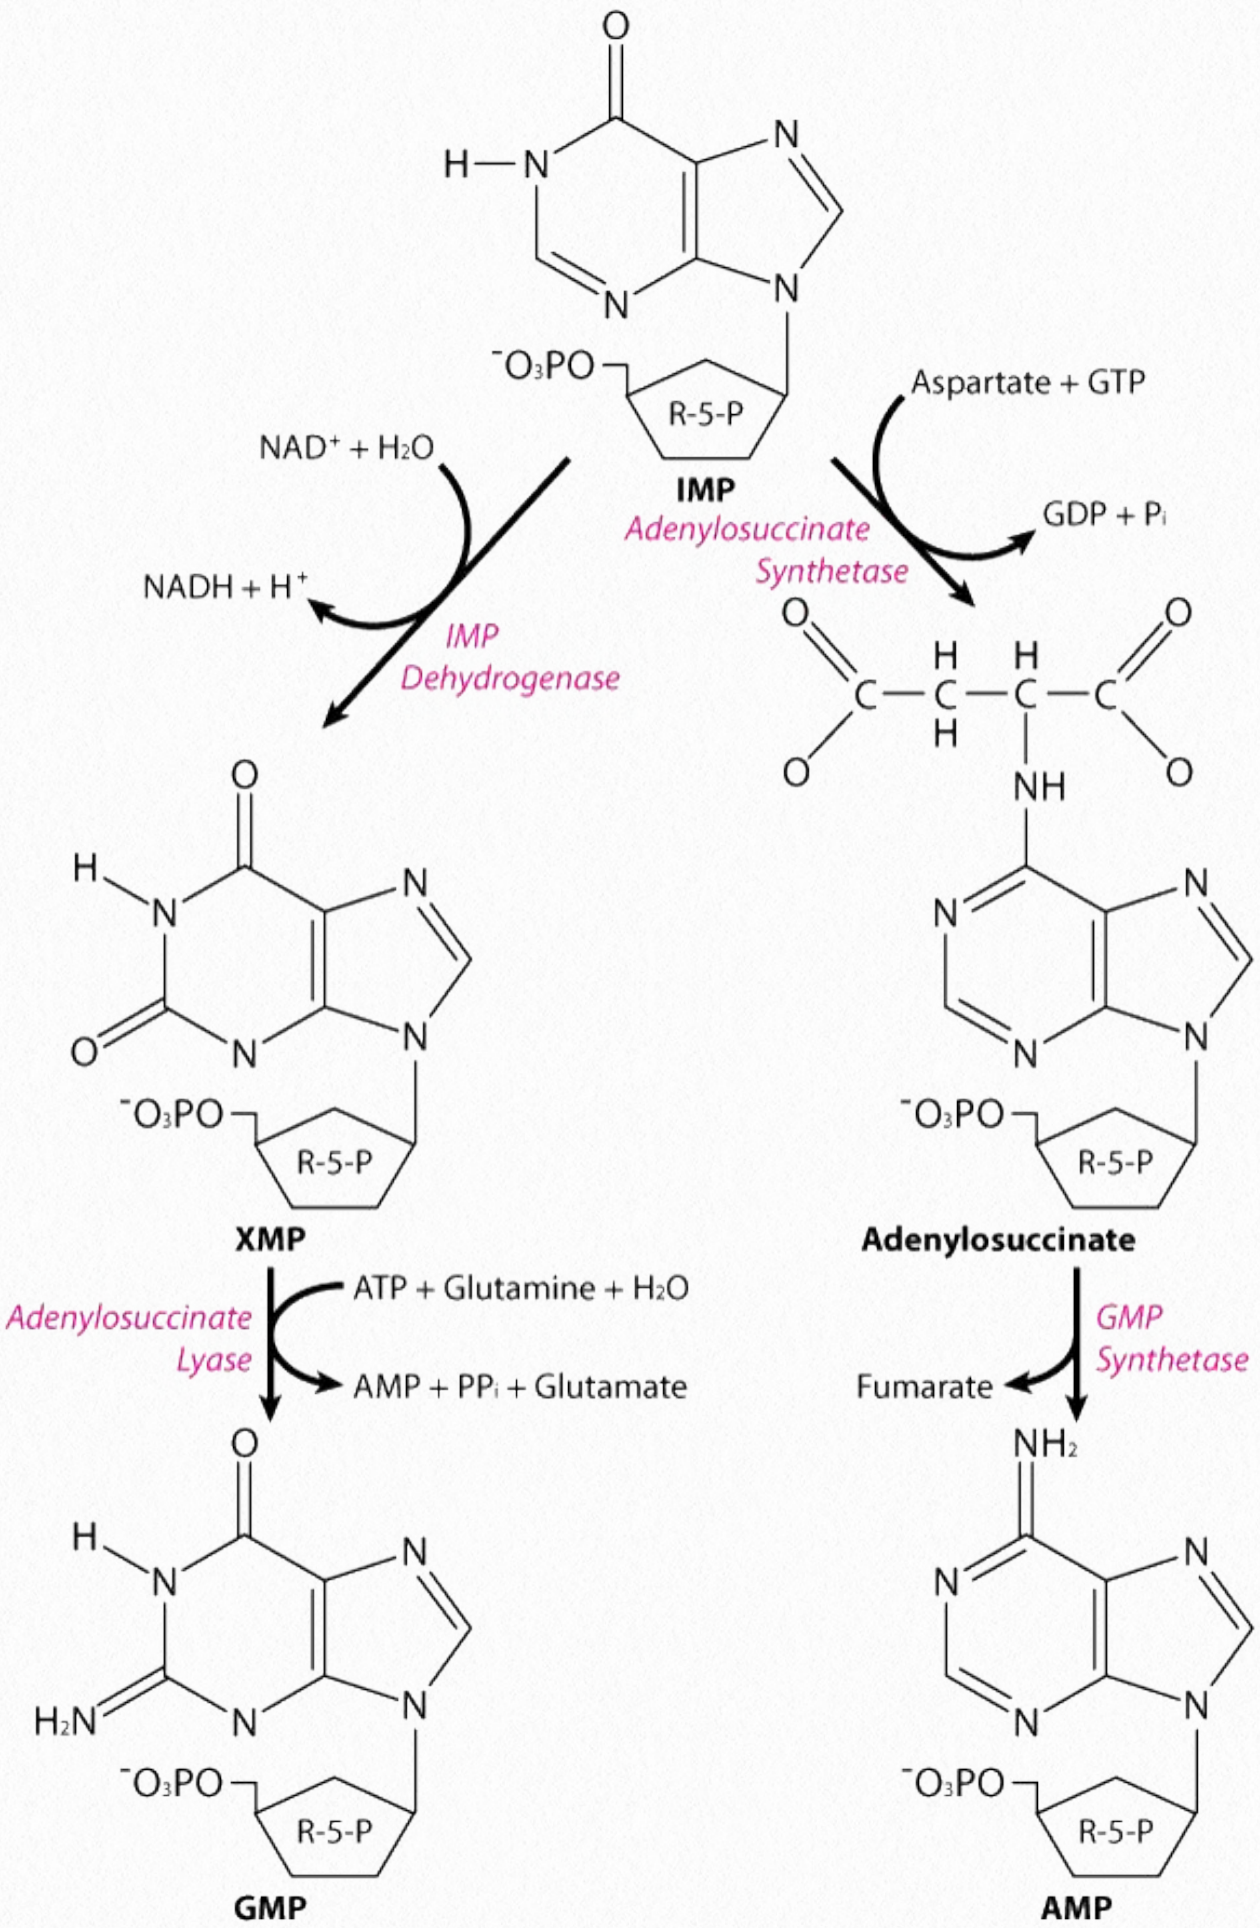

Figure 6.174 - The path from IMP (top) to AMP and GMP

Image by Aleia Kim

latory scheme of purines is illustrated by two examples. First imagine both AMP and GMP are abundant. When this occurs, PRPP amidotransferase will be completely inhibited and no purine synthesis will occur.

Partial activity

High levels of GMP and low levels of AMP would result in PRPP amidotransferase being slightly active, due to the fact GMP will fill one allosteric site, but low AMP levels will mean second allosteric site will likely be unfilled. This lowered (but not completely inhibited) activity of PRPP amidotransferase will allow for limited production of 5-PRA and the rest of the pathway intermediates, so it will remain active.

At the IMP branch, however, the high levels of GMP will inhibit

IMP dehydrogenase, thus shutting off that branch and allowing all of the intermediates to be funneled into making AMP. When the AMP level rises high enough, AMP binds to PRPP amidotransferase and along with GMP, shuts off the enzyme. A reversal will occur if AMP levels are high, but GMP levels are low.

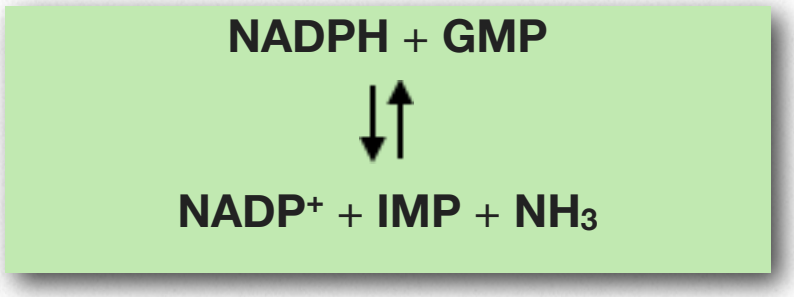
Proper balance

Regulated in this way, AMP and GMP levels can be maintained in a fairly narrow concentration range. Properly balancing nucleotide levels in cells is critical. It is likely for this reason that cells have numerous controls on the amount of each nucleotide made.

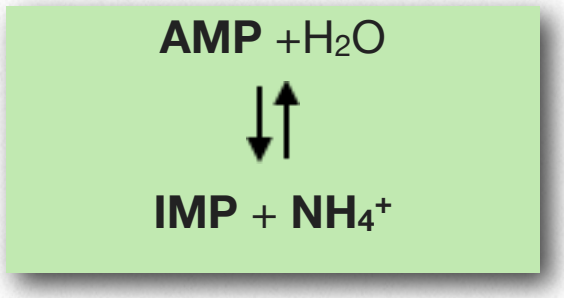
YouTube Lectures by Kevin HERE & HERE

Other mechanisms

Cells have two other ways of balancing GMP and AMP nucleotides. First, the enzyme GMP reductase will convert GMP back to IMP using electrons from NADPH.

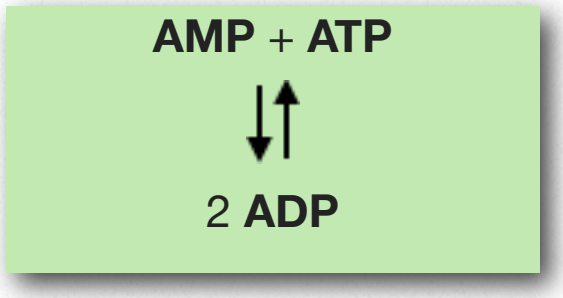


The IMP, in turn, can then be made into AMP if its concentration is low. Second, AMP can be converted back to IMP by the enzyme AMP deaminase. In this case, the IMP can then be made into GMP.



It is important to maintain appropriate proportions of the different nucleotides. Excess or scarcity of any nucleotide of any nucleotide can result in an increased tendency to mutation.

To convert AMP to ATP and GMP to GTP requires action of kinase enzymes. Each monophosphate nucleotide form has its own specific nucleoside monophosphate kinase. For adenine-containing nucleotides (ribose forms and deoxyribose forms), adenylate kinase catalyzes the relevant reaction.



The adenylate kinase reaction is reversible and is used to generate ATP when the cell's ATP concentration is low. When ATP is made from 2 ADPs in this way, AMP levels increase and this is one way the cell senses that it is low on energy.

Guanosine monophosphates also have their own kinase and it catalyzes the reaction at the top of the next page.

GMP + ATP

⇅

GDP + ADP

Other monophosphate kinases for UMP and CMP use ATP in a similar fashion.

In going from the diphosphate form to the triphosphate form, the picture is simple - one enzyme catalyzes the reaction for all diphosphates (ribose and deoxyribose forms). It is known as nucleoside diphosphate kinase or (more commonly) NDK or NDPK and it catalyzes reactions of the form

(d)XTP + (d)YDP

⇅

(d)XDP + (d)YTP

where X and Y refer to any base.

Purine salvage reactions

Not all nucleotides in a cell are made from scratch. The alternatives to *de novo* syntheses are salvage pathways. Salvage reactions to make purine nucleotides start with attachment of ribose to purine bases using phosphoribosylpyrophosphate (PRPP).

The enzyme catalyzing this reaction is known as hypoxanthine/guanine phosphoribosyltransferase (HGPRT - Figure 6.175) and is interesting from an enzymological as well as a medical perspective. First, the enzyme is able to catalyze both of the next two important salvage reactions - converting hypoxanthine to IMP or guanine to GMP.

Hypoxanthine + PRPP

⇅

IMP + PP_i

Guanine + PRPP

⇅

GMP + PP_i

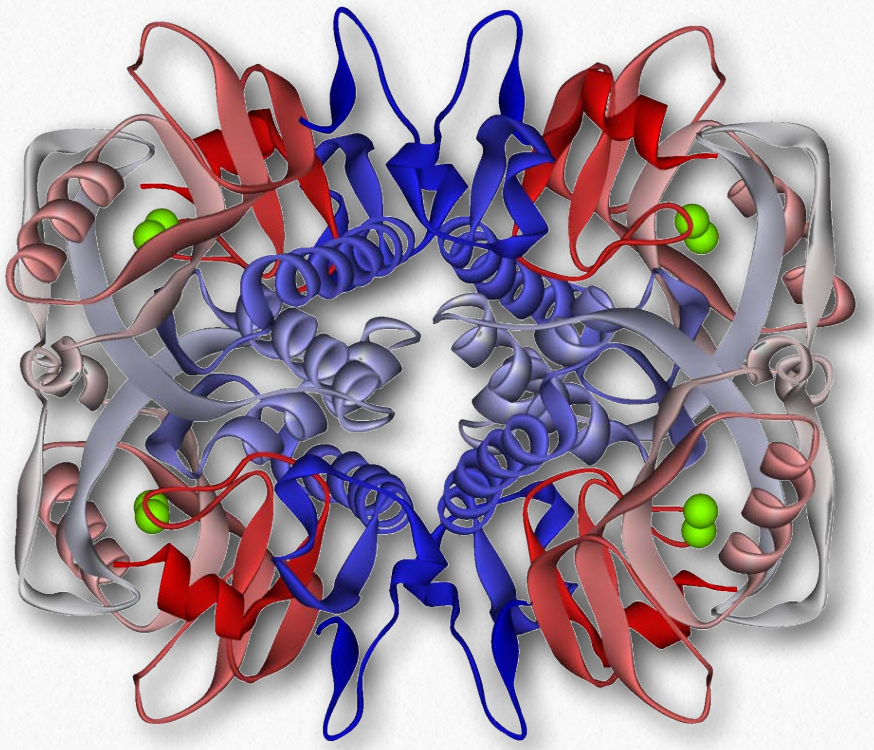


Figure 6.175 - HGPRT

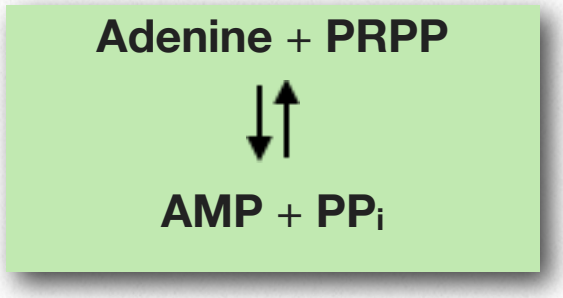
HGPRT is able to bind a variety of substrates at its active site and even appears to bind non-natural substrates, such as acyclovir preferentially over its natural ones.



Medical perspective

From a medical perspective, reduction in levels of HGPRT leads to hyperuricemia, a condition where uric acid concentration increases in the body. Complete lack of HGPRT is linked to Lesch-Nyhan syndrome, a rare, inherited disease in high uric acid concentration throughout the body is associated with severe accompanying neurological disorders.

Reduced production of HGPRT occurs frequently in males and has a smaller consequence (gout) than complete absence. Interestingly, gout has been linked to a decreased likelihood of contracting multiple sclerosis, suggesting uric acid may help prevent or ameliorate the disease.

Expression of HGPRT is stimulated by HIF-1, a transcription factor made in tissues when oxygen is limiting, suggesting a role for HGPRT under these conditions.

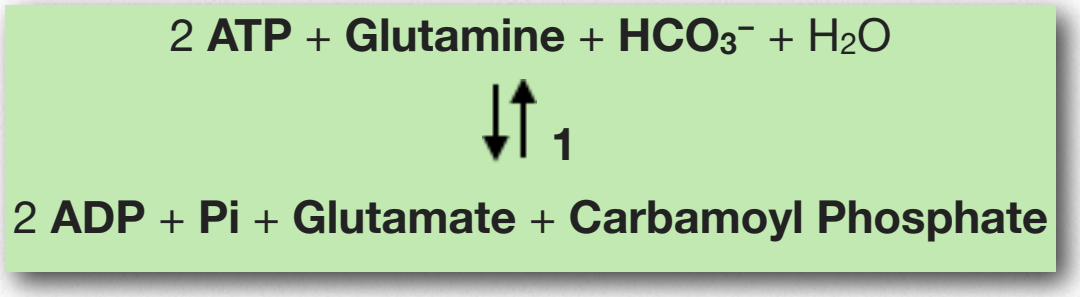
Adenine salvage

The enzyme known as adenine phosphoribosyltransferase (APRT) catalyzes the reaction corresponding to HGPRT for salvaging adenine bases.

Pyrimidine nucleotide metabolism

The *de novo* pathway for synthesizing pyrimidine nucleotides has about the same number of reactions as the purine pathway, but also has a different strategy. Whereas the purines were synthesized attached to the ribose sugar, pyrimidine bases are made apart from the ribose and then attached later.

The first reaction is catalyzed by carbamoyl phosphate synthetase (Figure 6.176).



Two different forms are found in eukaryotic cells. Form I is found in mitochondria and form II is in the cytoplasm.

The reaction catalyzed by carbamoyl phosphate synthetase is the rate limiting step in pyrimidine biosynthesis and corresponds to reaction 1 in Figure 6.178.

Balance

The enzyme is activated by ATP and PRPP and is inhibited by UMP. This helps to balance pyrimidine vs. purine concentrations. High concentrations of a purine (ATP) acti-

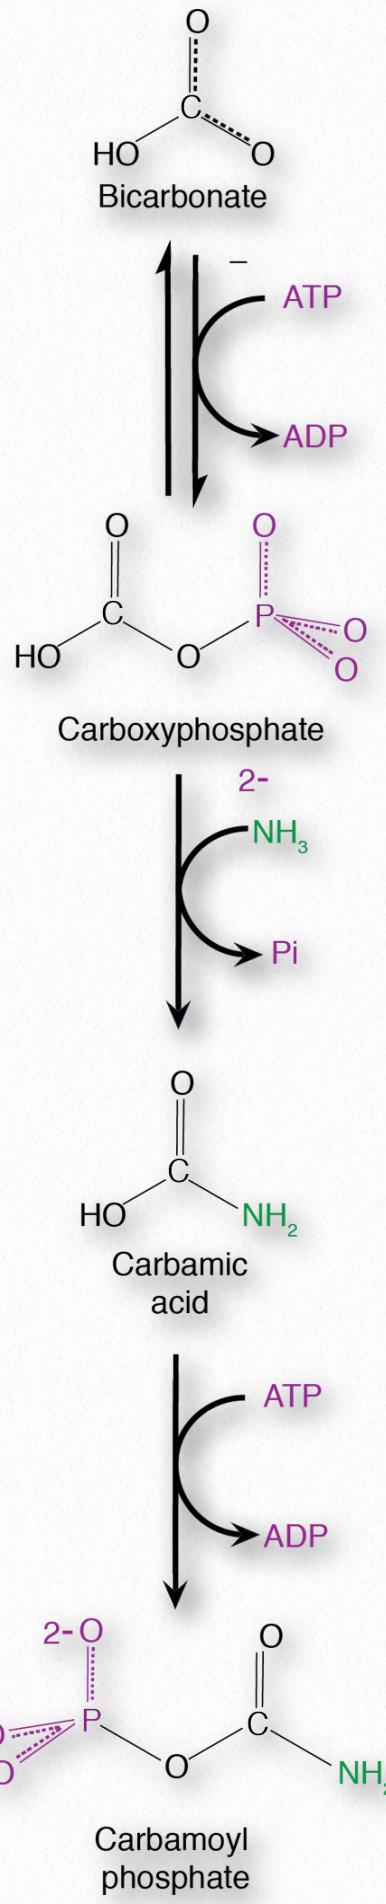


Figure 6.176 - Formation of carbamoyl phosphate in reaction 1

Image by Penelope Irving

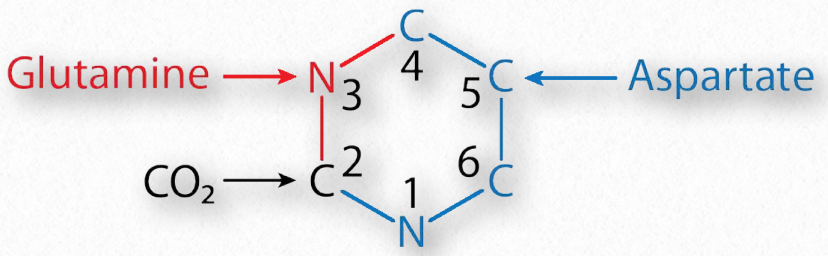

Figure 6.177 - Atom sources in pyrimidines

Image by Pehr Jacobson

vates the synthesis of pyrimidines. PRPP increases in concentration as purine concentration increases, so it too helps to establish that balance. UMP is an end product of pyrimidine metabolism, so the process is self-limiting. The next enzyme in the pathway, aspartate transcarbamoylase (ATCase) also plays a role in the same balance, as we will see. The reaction it catalyzes is shown below and is reaction 2 in Figure 6.178.

Carbamoyl Phosphate + Aspartate ⇅ 2 **Carbamoyl Aspartate + P_i**

ATCase is a classic enzyme exhibiting allosteric regulation and feedback inhibition, having both homotropic and heterotropic effectors (Figure 6.179 and see HERE). With 12 subunits (6 regulatory and 6 catalytic units), the enzyme exists in two states - a low activity T-state and a high activity R-state. Binding of the aspartate substrate to the active site shifts the equilibrium in favor of the R-state.

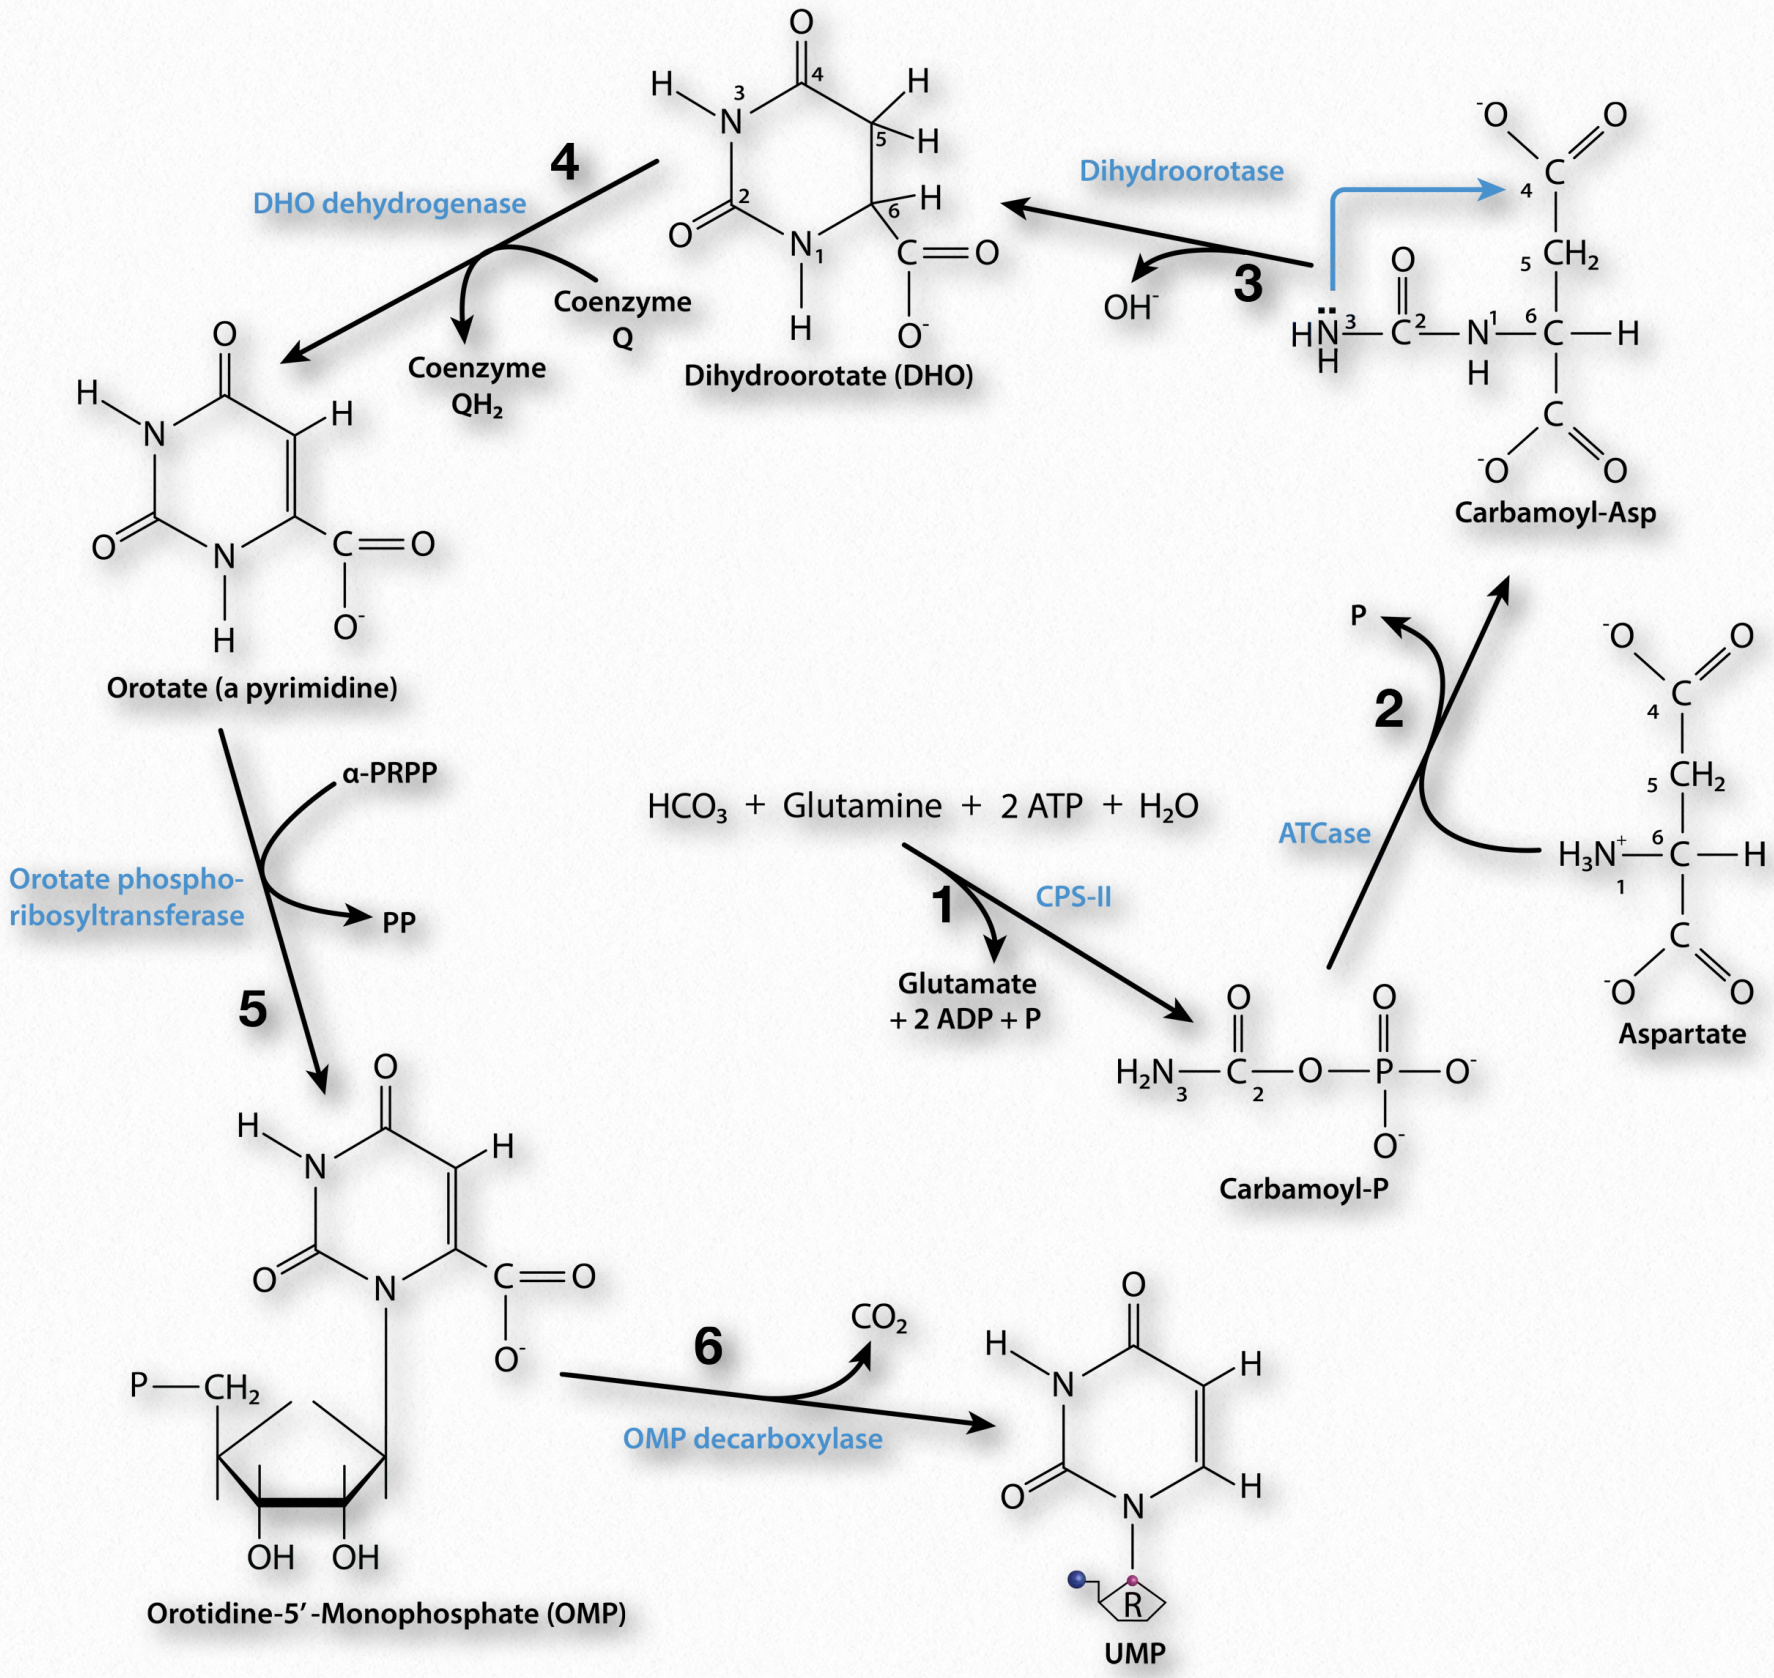

Figure 6.178 - Pyrimidine synthesis by the *de novo* pathway

Image by Pehr Jacobson

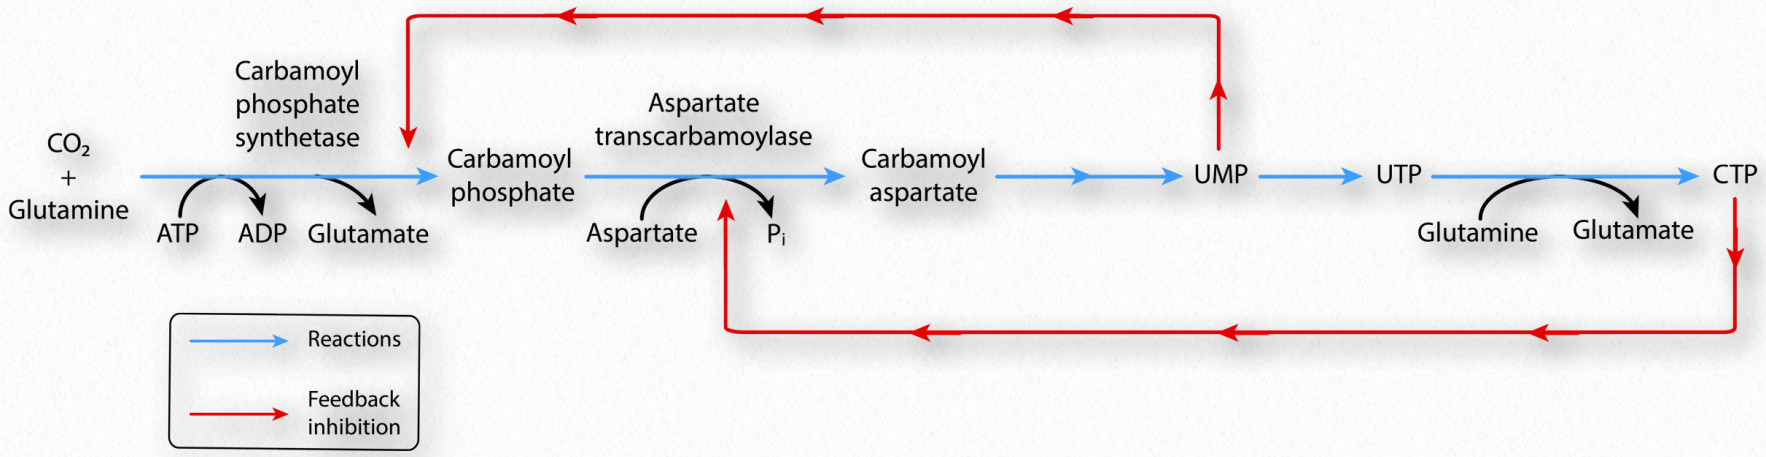

Figure 6.179 - Overview of pyrimidine metabolism feedback regulation

Image by Pehr Jacobson

Aspartate is a homotropic effector of the enzyme, because it acts allosterically on the enzyme and is a substrate for it as well. Similarly, binding of ATP to the regulatory units favors the R-state, whereas binding of CTP to the regulatory units favors the T-state. ATP and CTP are heterotropic effectors of the enzyme because they are not substrates for it, but act allosterically.

YouTube Lectures by Kevin HERE & HERE

Regulation

As was seen with the first enzyme of the pathway, high concentration of purine nucleotides stimulates synthesis of pyrimidines and high concentration of pyrimidines turns off the pathway that synthesizes them.

Dihydroorotase catalyzes reaction 3 and is found in the cytoplasm, as is ATCase.

Carbamoyl Aspartate

⇅ 3

Dihydroorotate + H_2O

Reaction 4 occurs in the mitochondrion, so the product of reaction 3, dihydroorotate, must be transported into the mitochondrion from the cytoplasm. In reaction 4, dihydroorotate is oxidized to orotate. The enzyme catalyzing the reaction is dihydroorotate dehydrogenase.

Dihydroorotate + **NAD^+**

⇅ 4

the reaction of adenylate kinase, the reaction above, when run in the reverse direction, can be a source of ATP when the cell is low on energy.

The next step, catalyzed by NDPK, uses energy of any triphosphate nucleotide (XTP) to produce UTP from UDP.

UDP + XTP

⇅

UTP + XDP

CTP Synthase

UTP is the substrate for synthesis of CTP via catalysis by CTP synthase.

UTP + **Glutamine** + **ATP**

⇅

CTP + **Glutamate** + **ADP** + **P_i**

This enzyme is inhibited by its product, ensuring too much CTP is not made and activated by physiological concentrations of ATP, GTP, and glutamine. One human isozyme, CTPS 1, has been shown to be inactivated by phosphorylation by glycogen synthase kinase 3.

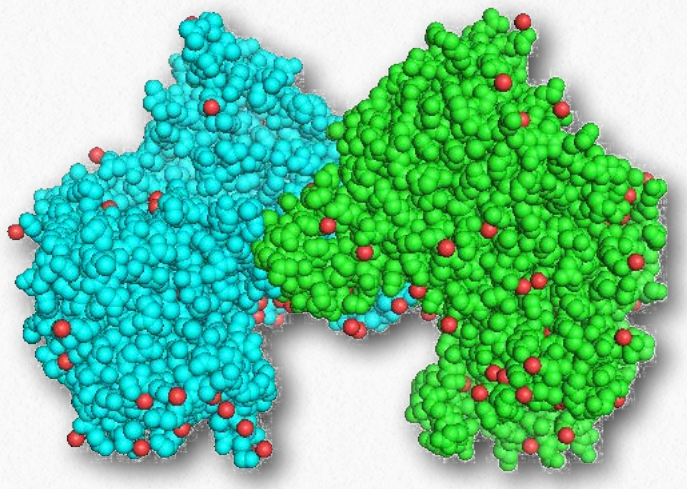

Figure 6.183 - CTP synthase dimer

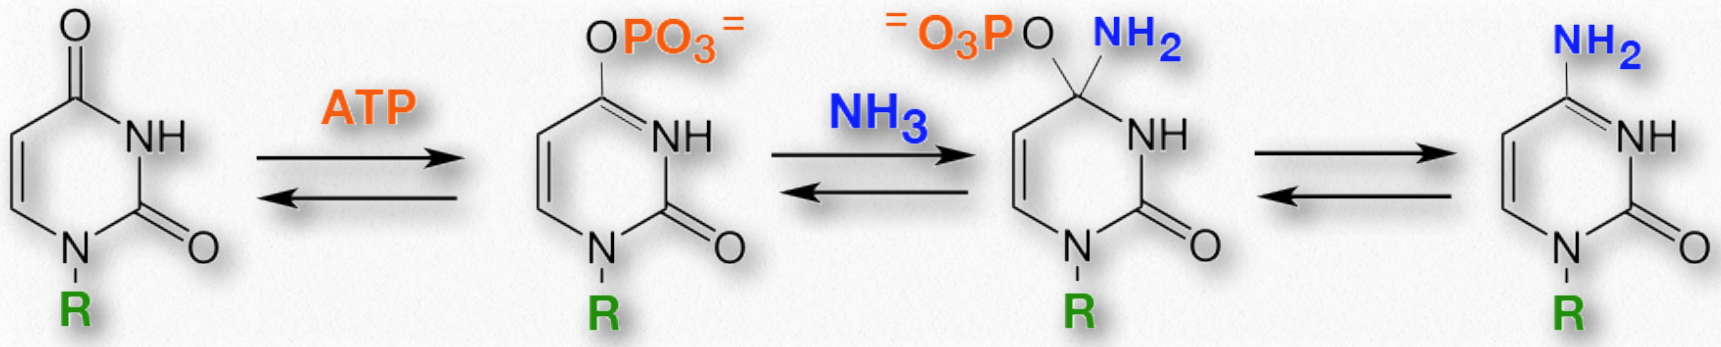

Figure 6.184 - Mechanism of CTP synthase action

CTP synthase has two domains and is a heterodimer (Figure 6.183). It exists as an inactive monomer at low enzyme concentrations or in the absence of UTP and ATP. One domain of the enzyme cleaves the amine group from glutamine and transfers it internally to the UTP. The other domain (synthase domain) binds ATP and initiates the mechanism shown in Figure 6.184 for making CTP.

CTP is the only nucleotide synthesized *de novo* directly as a triphosphate, since it arises directly from UTP. Since deoxyribonucleotides are made from ribonucleoside diphosphates, it means deoxycytidine nucleotides must either be made preferentially from salvage nucleotides or CTP must be dephosphorylated first.

One enzyme that can do this is a membrane-bound enzyme known as apyrase, which sequentially converts CTP to CDP and then CMP.

YouTube Lectures by Kevin HERE & HERE

Pyrimidine salvage reactions

Pyrimidine salvage synthesis allows cells to remake pyrimidine triphosphate nucleotides starting from either the C or U pyrimidine bases, nucleosides, or nucleotides. Figures 1.85 & 6.186 depict salvage pathway reactions. As is apparent in Figure 1.86, there are multiple ways of making the same molecules. For example, uracil can be made into uridine by reaction 11 or by reaction 12.

The figure depicts not only the synthesis of CTP and UTP from basic components, but also shows how these nucleotides can be broken down into smaller pieces.

In many cases, the same enzyme works on cytidine, uridine, and deoxycytidine molecules.

Enzymes of note

There are several enzymes of note in the salvage pathway. Seven enzymes, for example, work on both uracil and cytosine contain-

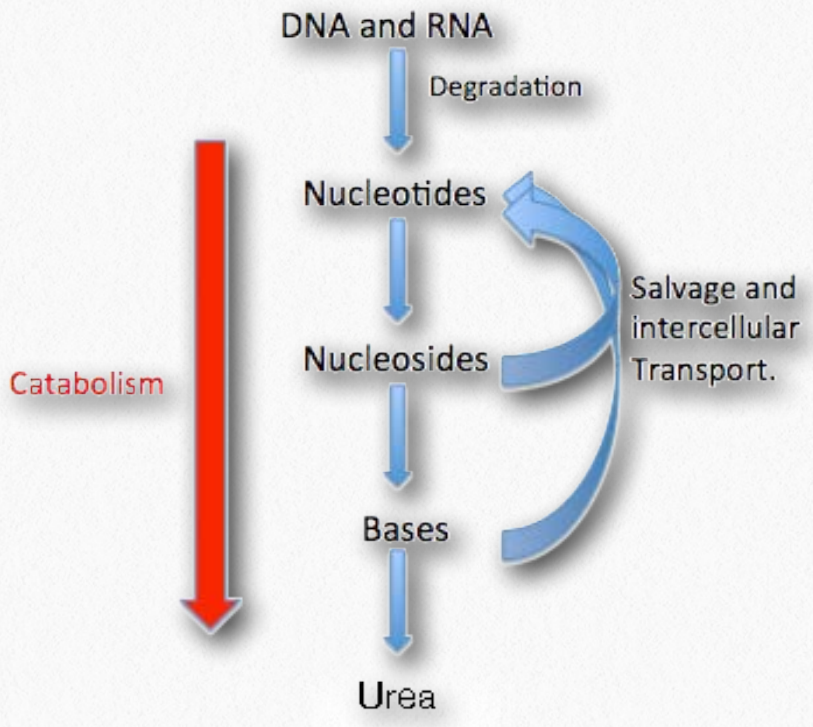

Figure 6.185 - Catabolism and salvage of nucleotides from DNA and RNA

Wikipedia

ing nucleosides/nucleotides. These include NTP phosphatase (reaction 2), NDPK (reaction 3), apyrase (reaction 4), NDP phosphatase (reaction 5), UMP/CMP kinase (reaction 6), pyrimidine-specific 5' nucleotidase (reaction 7), and uridine/ cytidine kinase (reaction 8). The enzymes for reactions 6 and 8 can also use deoxyribonucleosides/ deoxyribonucleotides as substrates.

Cytidine deaminase (reaction #9) converts cytidine to uridine by removing an amine group from the cytosine base and thus is a counter for the UTP to CTP reaction catalyzed by CTP synthetase. Countered reactions allow cells to balance concentrations of nucleosides/nucleotides in either direction if they should get out of balance.

Two other reactions in the figure are worth mentioning. Both UTP and CTP are converted in the breakdown process to UMP and CMP, respectively. Both of these reactions are important for deoxyribonucleotide metabolism. In each case, the monophosphate derivatives are phosphorylated, creating diphosphate derivatives (UDP and CDP) that are substrates for RNR that yield dUDP and dCDP, respectively. dUDP is phosphorylated to dUTP and then pyrophosphate is removed by dUTPase to yield dUMP.

dUMP is a substrate for thymidine synthesis (see HERE). dCDP is converted to dCTP by NDPK

Deoxyribonucleotide metabolism

Deoxyribonucleotides, the building blocks of DNA, are made almost exclusively from ribonucleoside diphosphates. A single enzyme called ribonucleotide reductase (RNR) is responsible for the conversion of each of these to a deoxy form (Figure 6.187). The enzyme's substrates are ribonucleoside diphosphates (ADP, GDP, CDP, or UDP) and the products are deoxyribonucleoside diphosphates (dADP, dGDP, dCDP, or dUDP). Thymidine nucleotides are synthesized from dUDP.

RNR has two pairs of two identical subunits - R1 (large subunit) and R2 (small subunit). R1 has two allosteric binding sites and a catalytic site. R2 forms a tyrosine radical necessary for the reaction mechanism of the enzyme.

There are three classes of RNR enzymes and they differ in the nature or means of generating a radical used in the enzyme's catalytic mechanism. Class I RNRs are found in eukaryotes, eubacteria, bacteriophages, and viruses. They all use a ferrous iron center that loses an electron (converting to ferric iron) to generate a free radical on a tyrosine ring. These enzymes only work in aerobic conditions.

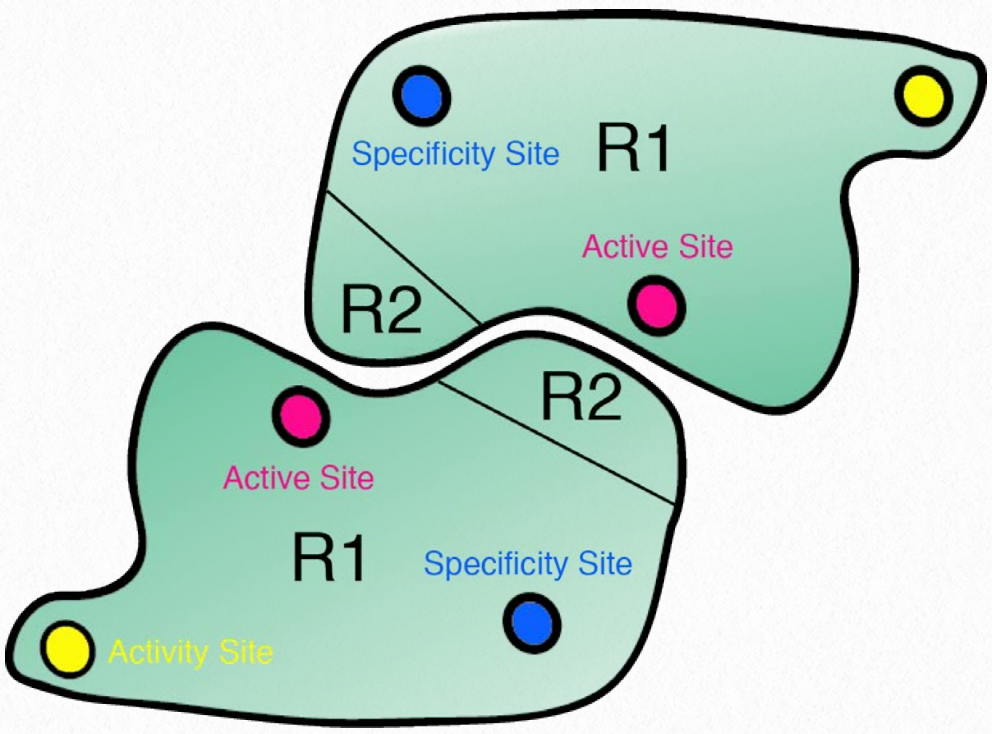

Figure 6.187 Ribonucleotide reductase
Image by Penelope Irving

Class II RNRs use 5'-deoxyadenosyl cobalamin (vitamin B_{12}) to generate a radical and work under aerobic or anaerobic conditions. They are found in eubacteria, archaebacteria, and bacteriophages. Class III RNRs generate a glycine radical using S-adenosyl methionine (SAM) and an iron-sulfur center. They work under anaerobic conditions and are used by archaebacteria, eubacteria, and bacteriophages. Substrates for class I enzymes are ribonucleoside diphosphates. Class II enzymes work on ribonucleoside diphosphates or ribonucleoside triphosphates. Class III enzymes work on ribonucleoside triphosphates.

In class I enzymes, RNR is an iron-dependent dimeric enzyme with each monomeric unit containing a large subunit (known as α or R1) and a small subunit (known as β or R2). The R1 subunit contains regulatory binding sites for allosteric effectors (see below), whereas the R2 subunit houses a tyrosine residue that forms a radical critical to the reaction mechanism of the enzyme. Electrons needed in the reaction are transmitted from NADPH to the enzyme by one of two pathways, reducing a disulfide bond in the enzyme to two sulfhydryls. In the first transfer mechanism, NADPH passes electrons to glutathione, which passes them to glutaredoxin, which then donates them to the RNR enzyme used

in the reaction. In the second mechanism, NADPH passes electrons to FAD, which uses them to reduce thioredoxin, which then passes the electrons to RNR with the same end result as in the first pathway - reduction of a suflhydryl in RNR.

In the reaction mechanism (Figure 6.188), a tyrosine side chain in the R2 unit must be radicalized to start. This electronic change is transmitted through the small R_2 subunit to the active site of the large R1 subunit. Several aromatic amino acid side chains are thought to play a role in that process. Iron atoms in the R2 subunit assist in creation and stabilization of the radical. The tyrosine radical contains an unpaired electron delocalized across its aromatic ring.

Transfer of the electronic instability to the R1 unit results in radicalization of a cysteine (to form a thiyl radical) at the active site. The thiyl radical, thus formed, abstracts a hydrogen atom (proton plus electron) from carbon 3 of ribose on the bound ribonucleoside diphosphate, creating a radical carbon atom. Radicalization of carbon #3 favors release of the hydroxyl group on carbon #2 as water. The extra proton comes from the sulfhydryl of the enzyme's cysteine. In the next step of the process, a proton and two electrons from the same cysteine are transferred to carbon #2 and then carbon #3 takes back the proton originally removed from it to yield a deoxyri-

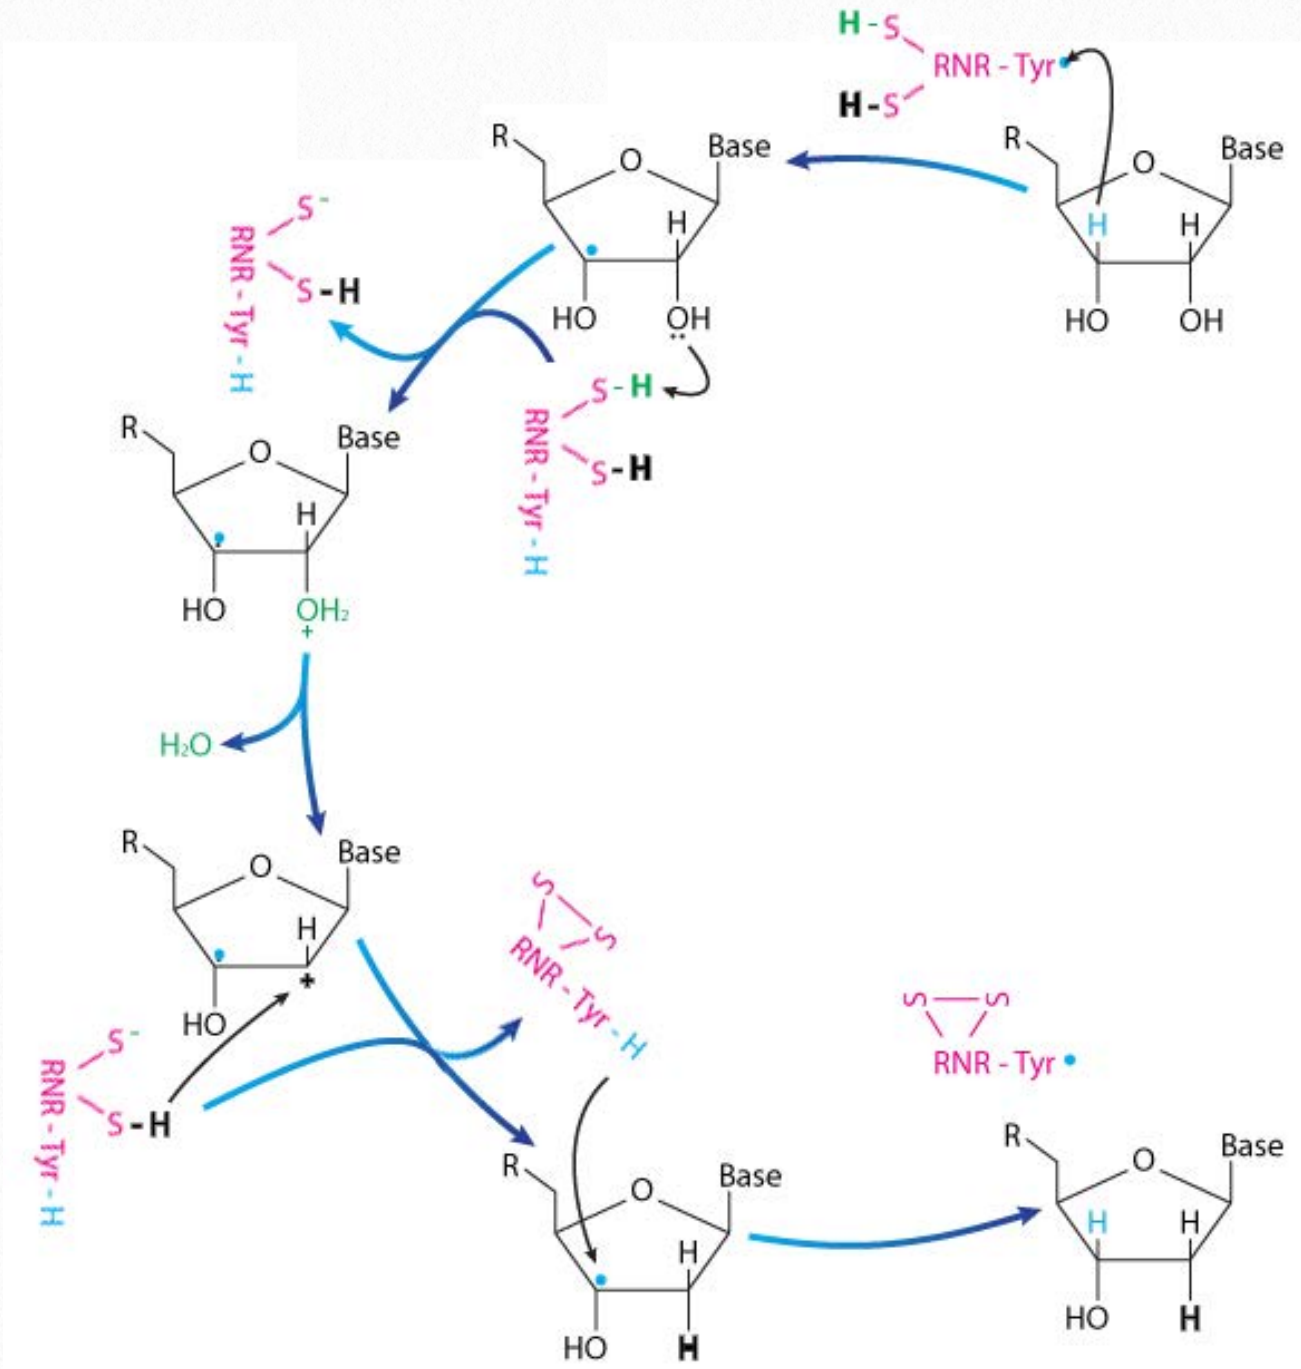

Figure 6.188 Ribonucleotide reductase reaction mechanism
Image by Aleia Kim

bonucleoside diphosphate. The enzyme's thiyl group gains an electron from R2 and the disulfide bond created in the reaction must be reduced by electrons from NADPH again in order to catalyze again.

Regulation

In addition to RNR's unusual reaction mechanism, the enzyme also has a complex system of regulation, with two sets of allosteric binding sites, both found in the R1 subunit. Because a single enzyme, RNR, is responsible for the synthesis of all four deoxyribonucleotides, it is necessary to have mechanisms to ensure that the enzyme produces the correct amount of each dNDP. This is a critical consideration, since imbalances in DNA precursors can lead to mutation.

Consequently, the enzyme must be responsive to the levels of the each deoxyribonucleotide, selectively making more of those that are in short supply, and preventing additional synthesis of those that are abundant. These demands are met by having two separate control mechanisms on the enzyme - one that determines which substrate will be acted on, and another that controls the enzyme's activity.

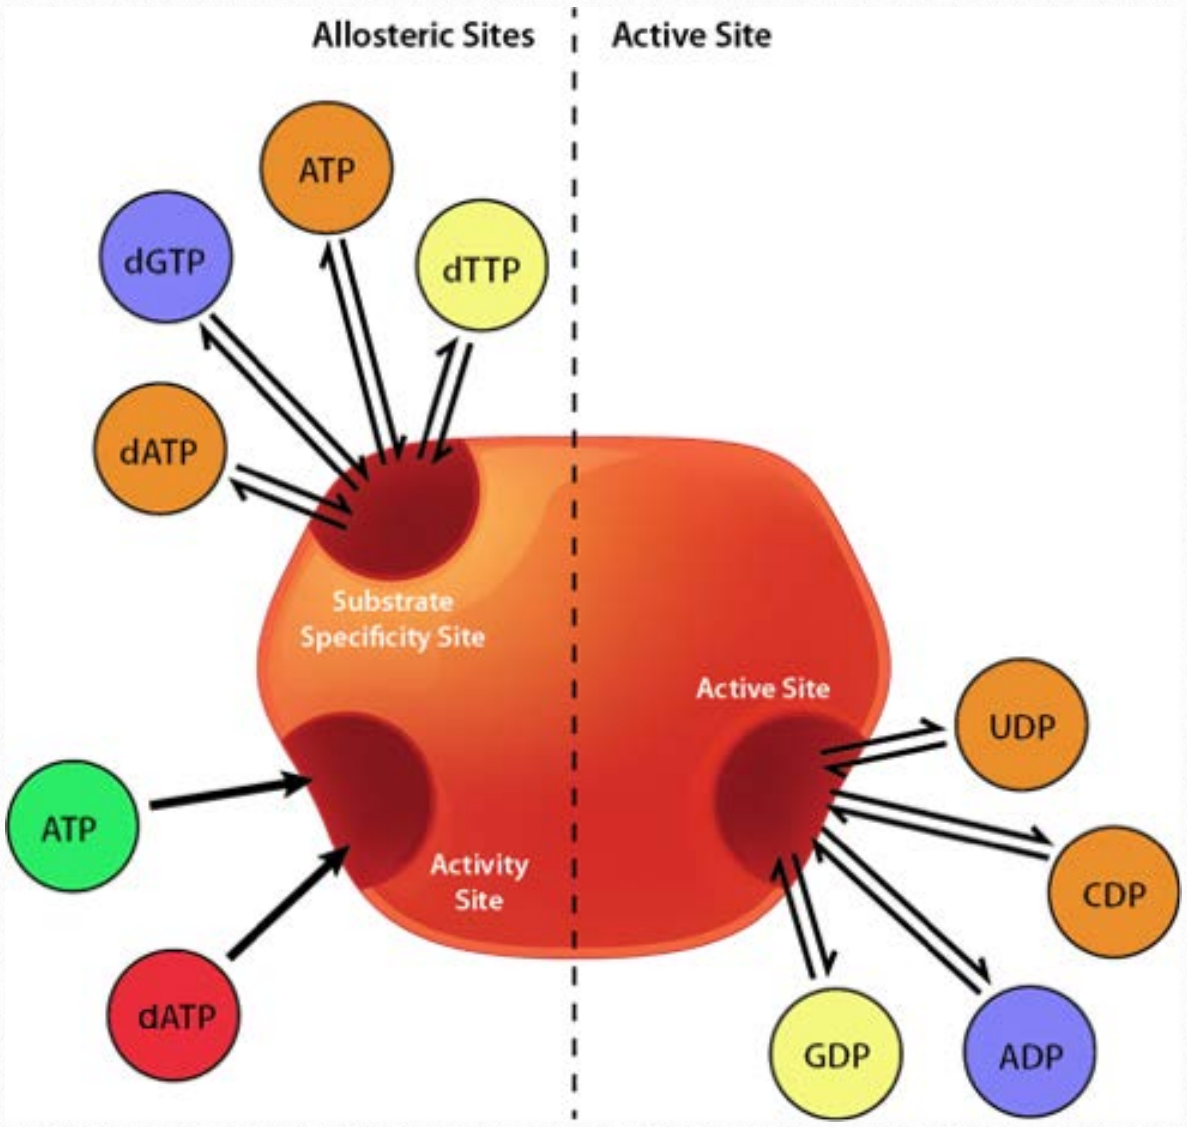

Figure 6.189 Allosteric regulation of RNR activity
Image by Aleia Kim

Two allosteric sites

RNR is allosterically regulated *via* two molecular binding sites - a specificity binding site (binds dNTPs and induces structural changes in the enzyme that determines which substrates preferentially bind at the catalytic site and an activity control site (controls whether or not enzyme is active). The activity control site functions like a simple on/off switch - ATP activates catalysis, dATP inactivates it. (One subset of class I enzymes, however, is not affected by dATP.)

The inactivation of RNR by dATP is an important factor in the disease known as Severe Combined Immunodeficiency Disease (SCID). In SCID, the salvage enzyme adenosine deaminase is deficient, leading to a rise in concentration of dATP in cells of the immune system. dATP shuts down RNR in these cells, thus stopping their proliferation and leaving the affected individual with a very weak or no immune system.

YouTube Lectures by Kevin HERE & HERE

Allosteric effectors

When dTTP is abundant (Figure 6.189), it binds to RNR's specificity site and inhibits binding and reduction of CDP and UDP but stimulates binding and reduction of GDP at the active site of the enzyme. Conversely, binding of ATP or dATP at the specificity site stimulates binding and reduction of CDP and UDP at the active site. Last, binding of dGTP to the specificity site (specificity site B) induces binding and reduction of ADP at the active site.

Students sometimes confuse the active site of RNR with the activity control site (sometimes called the activity site). The active site is where the reaction is catalyzed, and could better be called the catalytic site, whereas the activity site is an allosteric binding site for ATP or dATP that controls whether the enzyme is active. High levels of dATP are an indicator that sufficient dNTPs are available, so the enzyme gets inhibited to stop production of more. Low levels of dATP allow binding of ATP and activation of the enzyme.

In addition to regulation by deoxyribonucleotides and ATP, RNR can be directly inhibited by hydroxyurea.

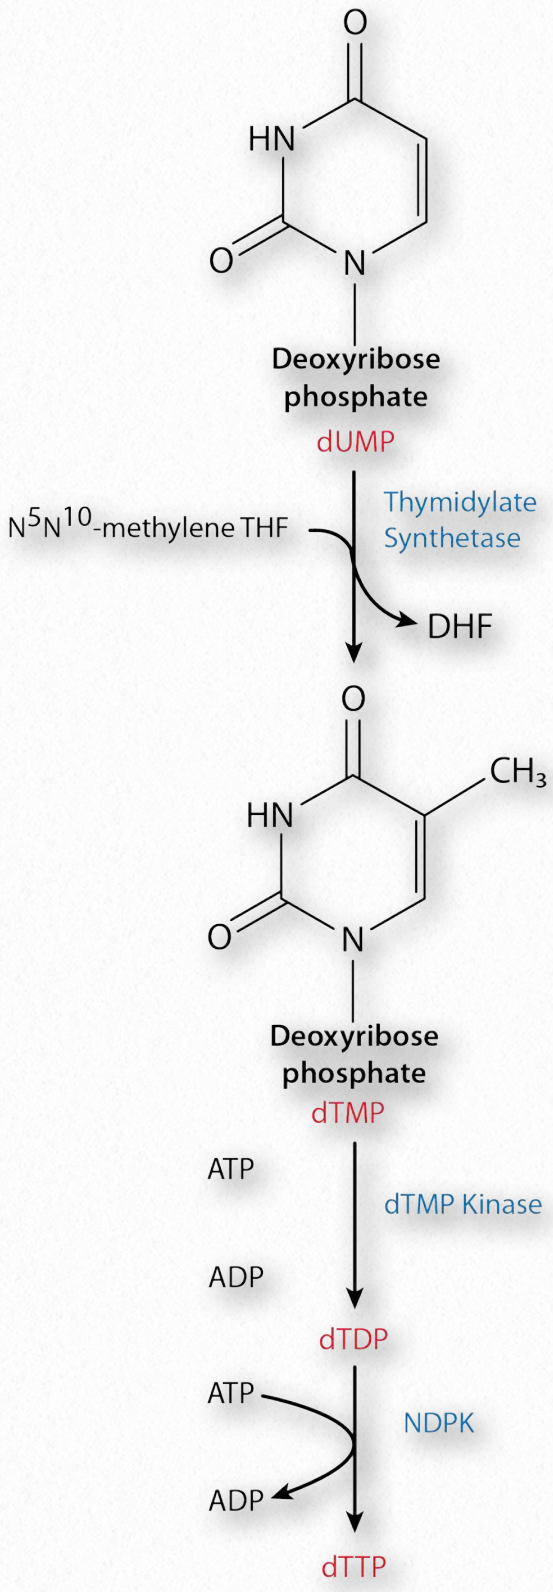

Figure 6.190 - Pathway from dUMP to dTTP

Image by Pehr Jacobson

dTTP synthesis

Synthesis of dTTP by the *de novo* pathway involves a multi-step process from UDP to dTTP. It begins with UDP, which is converted to dUDP by RNR. dUDP is phosphorylated by NDPK to yield dUTP, which is quickly broken down by dUTPase to produce dUMP. The remaining reactions are shown in Figure 6.190.

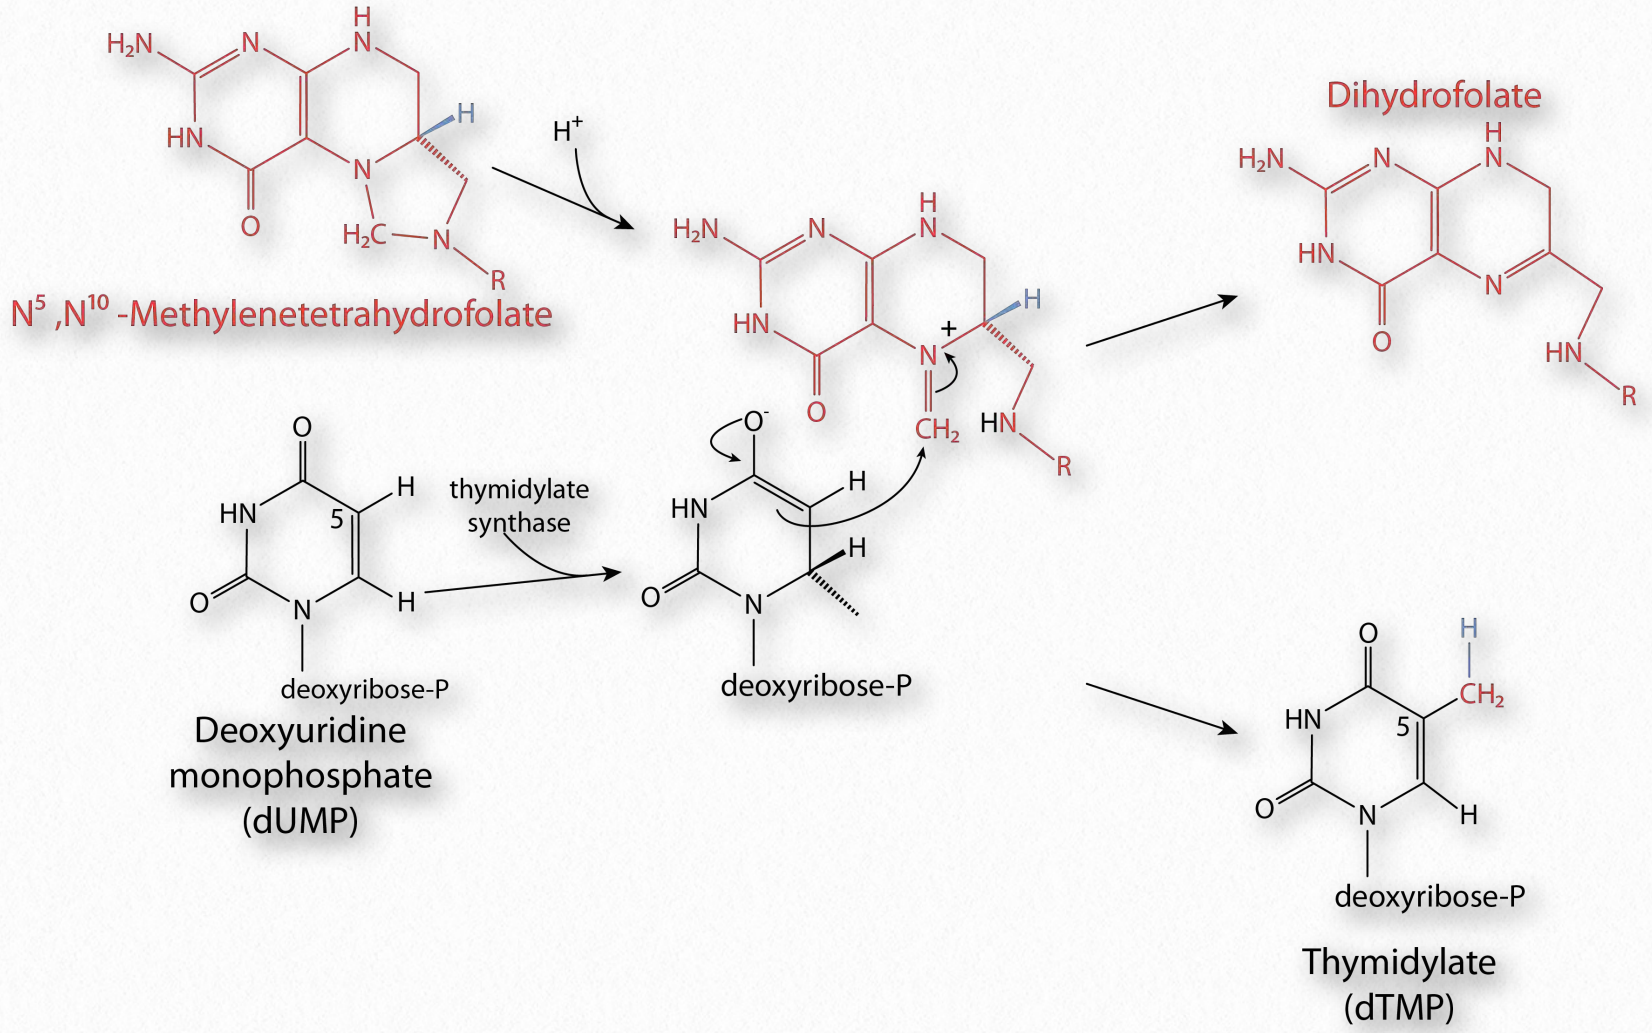

Figure 6.191 - Mechanism of synthesis of dTMP from dUMP

Image by Pehr Jacobson

Important enzymes in the pathway include dUTPase and thymidylate synthetase. dUTPase is important for keeping the concentration of dUTP low so it does not end up in DNA. DNA polymerase can use dUTP just as it does dTTP, and incorporate it into a DNA strand, across from adenine nucleotides.

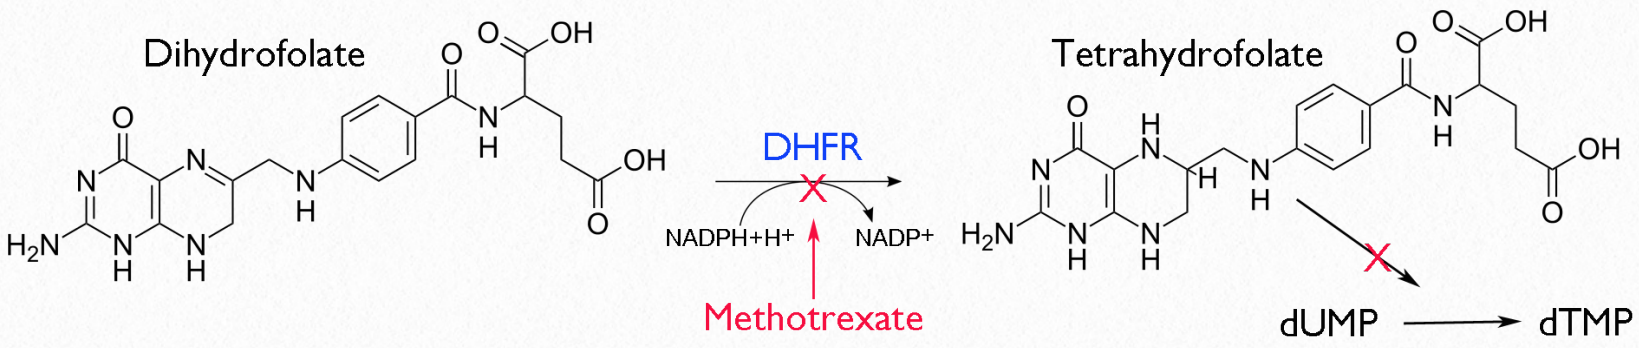

Figure 6.192 Recycling of dihydrofolate to tetrahydrofolate in cells can be inhibited by the drug methotrexate, thus stopping synthesis of thymidine nucleotides

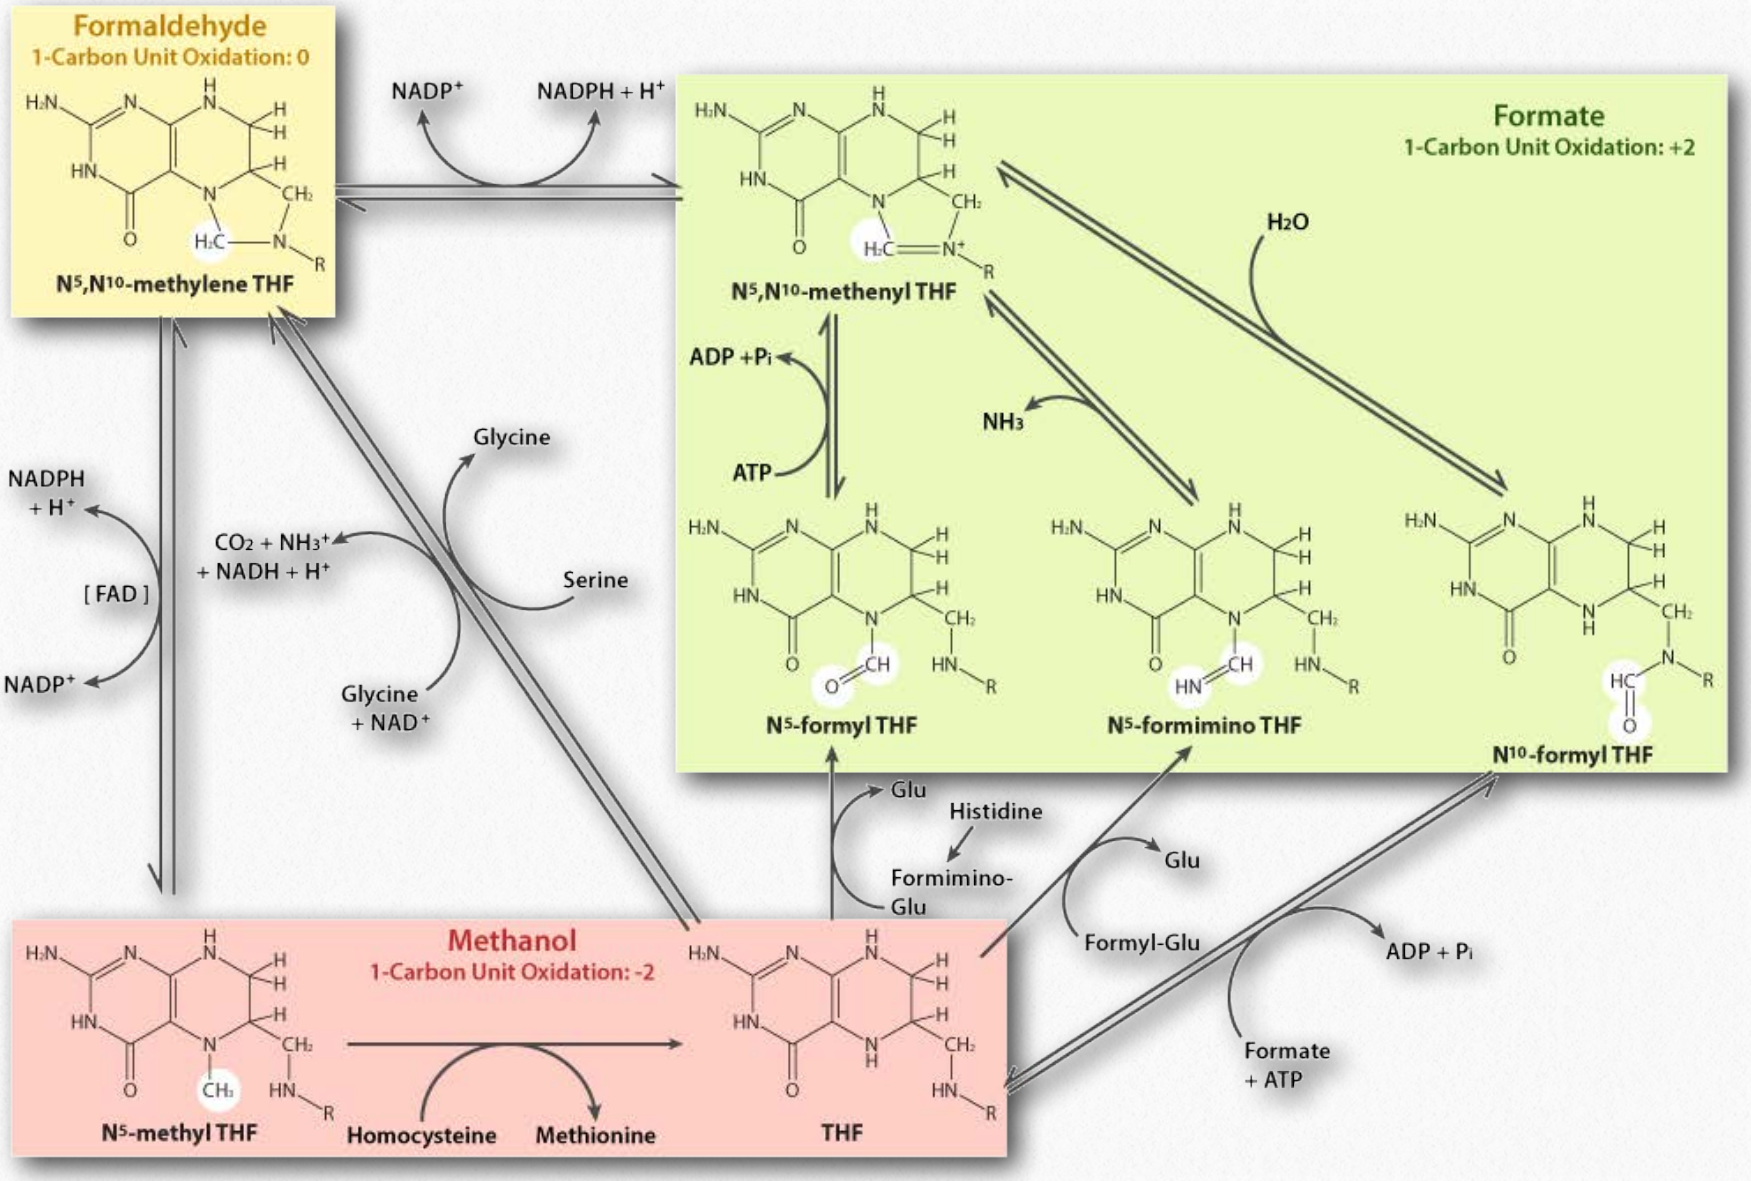

Figure 6.193 - Metabolism of folate molecules

Image by Aleia Kim

Thymidylate synthetase is important because it is a target (directly and indirectly) for anticancer therapies. As shown in Figure 6.191, a methyl group from N^5,N^{10}-methylene-tetrahydrofolate (often called tetrahydrofolate) is donated to dUMP, making dTMP and dihydrofolate (DHF). Folate molecules are in limited quantities in cells and must be recycled, because if they are not, then the reaction to make dTMP cannot occur. Recycling of dihydrofolate to tetrahydrofolate occurs by the reaction shown in Figure 6.192.

The enzyme involved in the conversion of dihydrofolate to tetrahydrofolate, dihydrofolate reductase (DHFR - Figure 6.192), is one target of anticancer drugs because by stopping the regeneration of tetrahydrofolate from dihydrofolate (otherwise a dead end), one can stop production of thymidine nucleotides and, as a result, halt DNA synthesis, thus preventing a cancer cell from dividing. Competitive inhibitors of DHFR include methotrexate (Figure 6.194) or aminopterin. Cells contain numerous folates for performing one carbon metabolism and the path-

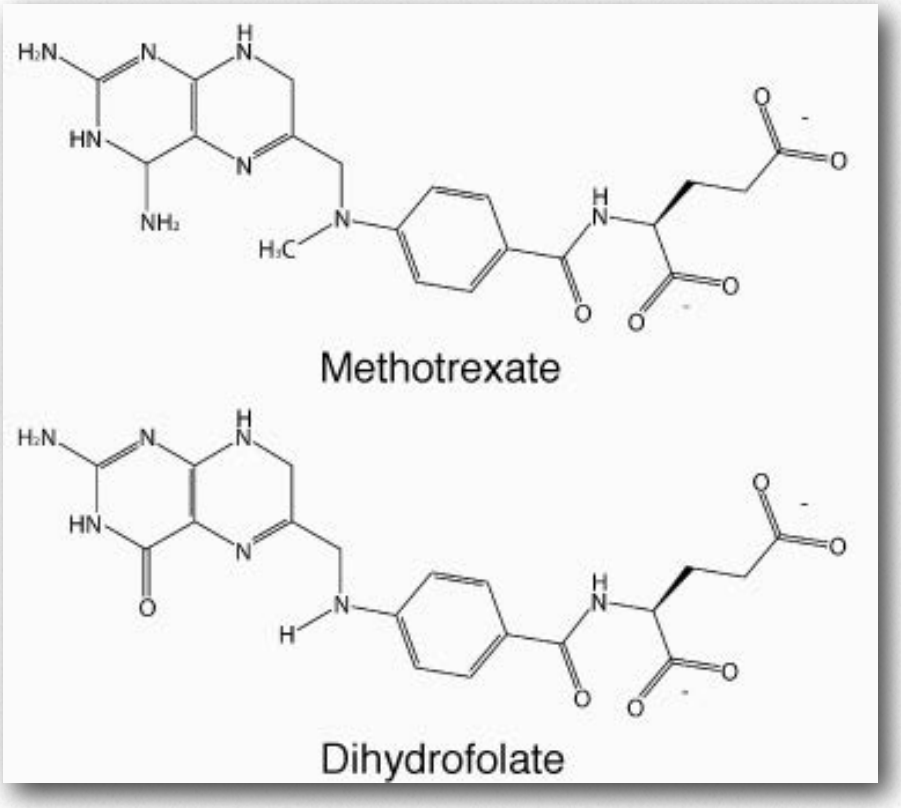

Figure 6.194 Dihydrofolate and competitive inhibitor methotrexate

Image by Ben Carson

ways by which they are all recycled is shown in Figure 6.193.

5-fluorouracil

Yet another important inhibitor of thymidine synthesis is used to treat cancer. This compound, 5-fluorouracil (Figure 6.195 and Movie 6.3) is a suicide inhibitor of thymidylate synthase.

Salvage synthesis

Besides synthesis from simple precursors, nucleotides can also be made from pieces of existing ones. This is particularly relevant, since consumption of food introduces to the

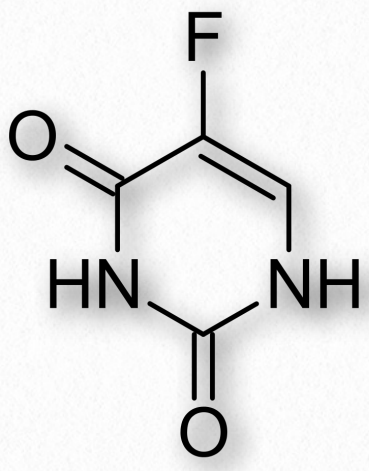

Figure 6.195 - 5-fluorouracil

Wikipedia

body a large collection of proteins, lipids, and nucleic acids that are all more efficiently recycled than degraded. For proteins, the process is simple. Digestion converts them into constituent building blocks (amino acids) and these are re-assembled into proteins of the consuming organism using the genetic code.

Nucleotides

The multi-component structure of nucleotides, though (base, sugar, phosphate) means subsections of them may be re-utilized. Phosphate is recycled simply by entering the phosphate pool of the cell. It is typically built back into triphosphate forms (ultimately) by oxidative phosphorylation and kinase actions. Salvage of bases is different for purines and pyrimidines and is discussed separately HERE and HERE.

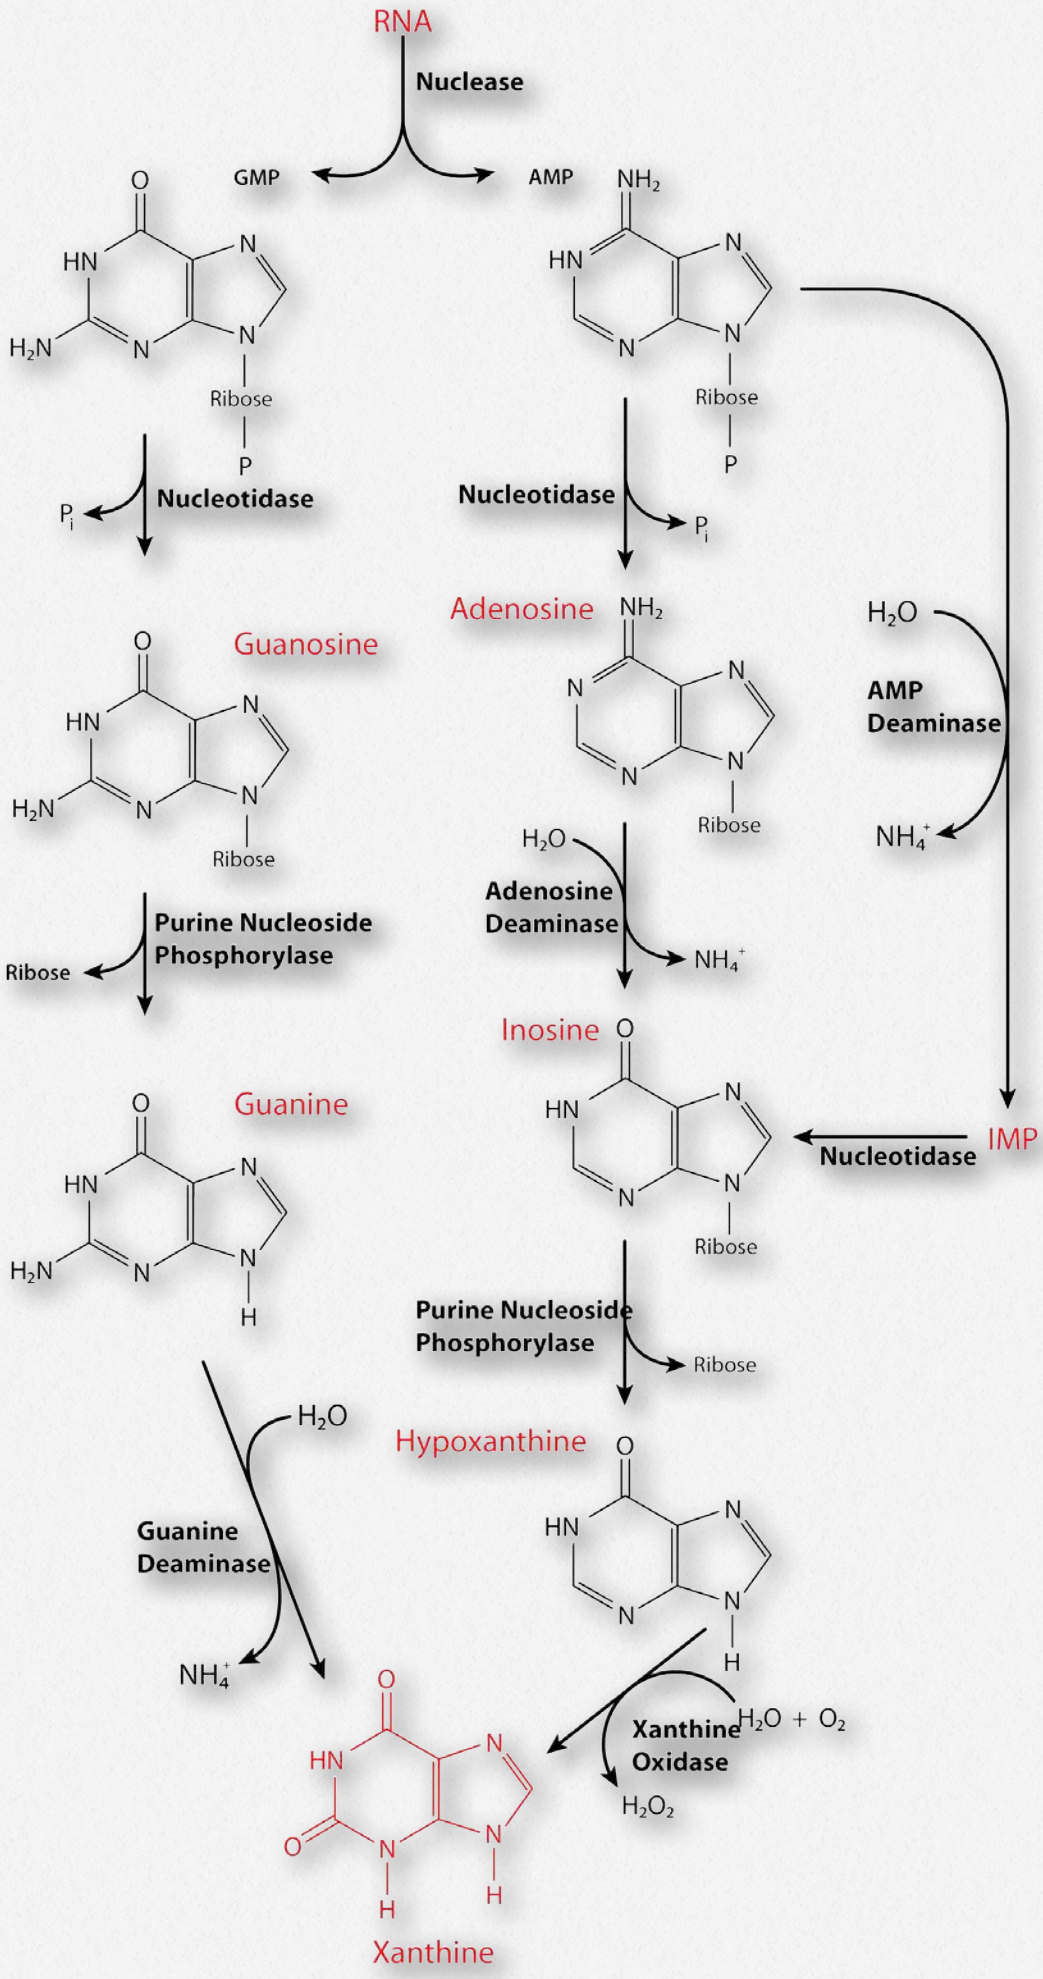

Figure 6.196 - Catabolism of purines - part I

Image by Pehr Jacobson

Nucleotide catabolism

Besides salvage and being built into nucleic acids, nucleotides can also be broken down into simpler component molecules. Some of these molecules, such as uric acid, can have significant impact on organisms (see HERE).

Purine catabolism

Breakdown of purine nucleotides starts with nucleoside monophosphates, which can be produced by breakdown of an RNA, for example, by a nuclease (Figure 6.196).

Metabolism of AMP and GMP converge at xanthine. First, AMP is dephosphorylated by nucleotidase to create adenosine, which is then deaminated by adenosine deaminase to yield inosine. Alternatively, AMP can be deaminated by AMP deaminase to yield IMP.

IMP is also an intermediate in the synthesis pathway for purine anabolism. Dephosphorylation of

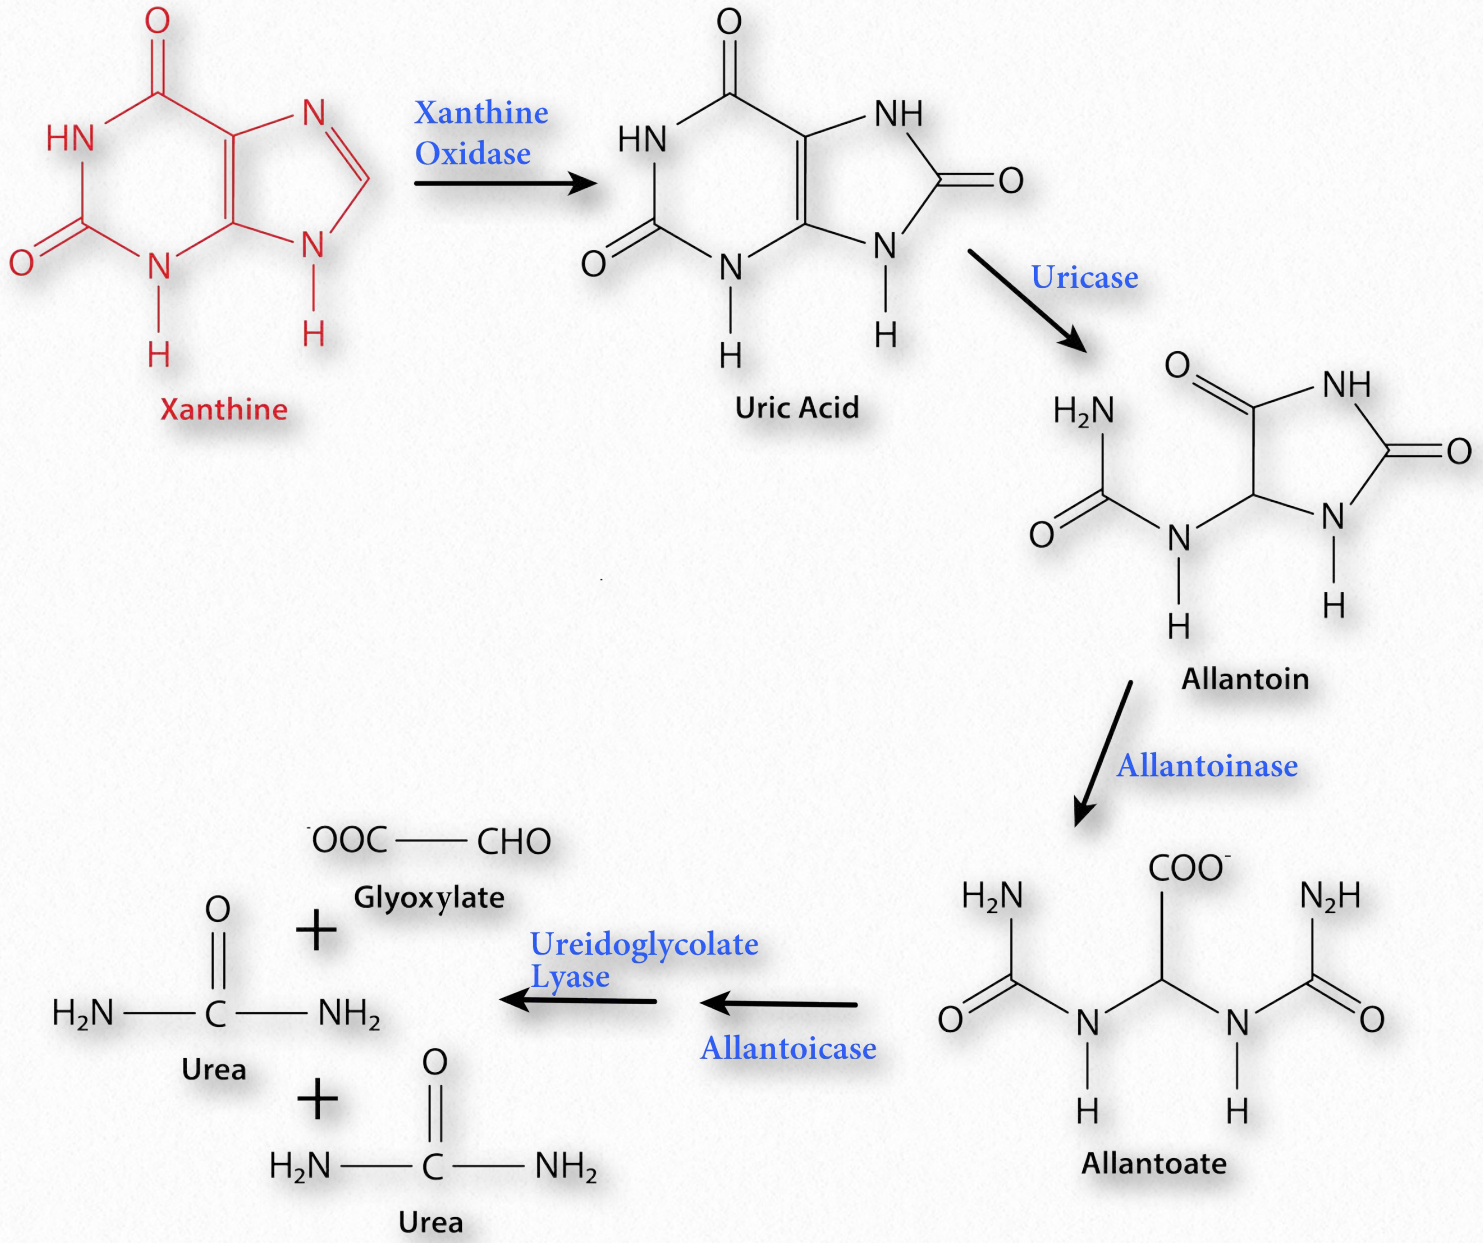

Figure 6.197 - Purine catabolism - part II

Image by Pehr Jacobson

IMP (also by nucleotidase) yields inosine. Inosine has ribose stripped from it by action of purine nucleotide phosphorylase to release hypoxanthine. Hypoxanthine is oxidized to xanthine in a hydrogen peroxide-generating reaction catalyzed by xanthine oxidase.

Hypoxanthine + H_2O + O_2

⇅

Xanthine + **H_2O_2**

Catabolism of GMP proceeds independently, though similarly. First, phosphate is removed by nucleotidase to yield guanosine. Guanosine is stripped of ribose to yield free guanine base, which is deaminated by guanine deaminase (also called guanase) to produce xanthine.

Xanthine oxidase enters the picture a second time in the next reaction catalyzing a second reaction by a similar mechanism to the hypoxanthine oxidation described previously. It is shown on the next page.

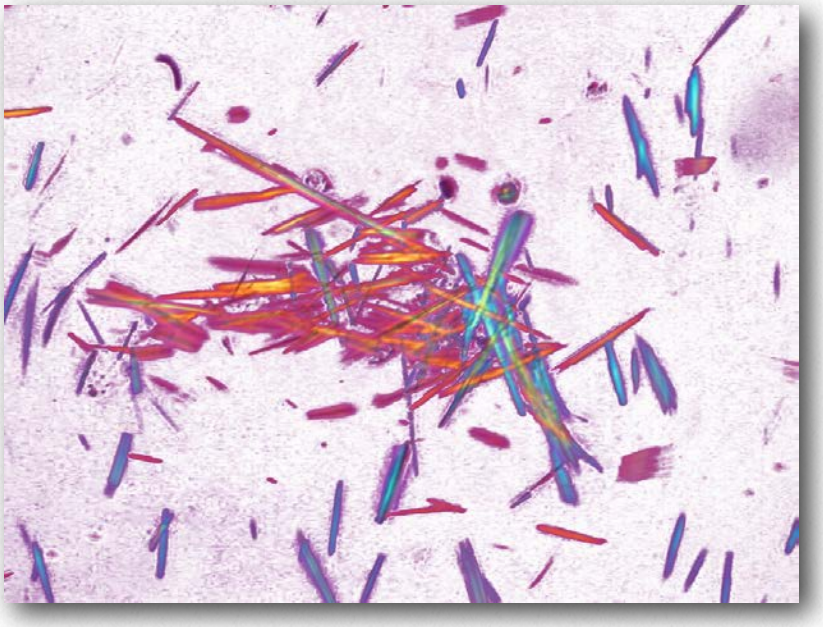

Figure 6.198 - Crystals of uric acid
Wikipedia

Xanthine + H_2O + O_2

⇅

Uric Acid + **H_2O_2**

Uric acid

Uric acid is problematic in some higher organisms (including humans) because it is not very soluble in water. Consequently it precipitates out of solution, forming crystals (Figure 6.198). Those crystals can accumulate in joints and (frequently) in the big toe. Such a condition is known as gout.

Interestingly, there may be a negative correlation between gout and contracting multiple sclerosis. This protective effect may be due to the antioxidant protection afforded by uric acid. Uric acid is the primary excretion form of nitrogen for birds. Dalmation dogs also excrete uric acid instead of urea and may suffer from joint pain as a result of gout-like conditions.

Gout is treated with a hypoxanthine analog known as allopurinol (Figure 6.199). It inhibits action of xanthine oxidase, which favors increase in the concentration of hypoxanthine. The latter is used in salvage synthesis to make additional purines.

Uric acid can be excreted into the urine (in humans) or broken down into allantoin by the uricase enzyme. Since humans lack the enzyme to make allantoin (urea in humans is produced by the urea cycle), its presence in the body means it was produced by non-enzymatic means. This is taken to be an indicator of oxidative stress, since it allantoin is produced non-enzymatically by oxidation of uric acid.

ceeds through uridine by deamination of cytosine. The free bases, thymine and uracil, are released by the enzyme ribosylpyrimidine nucleosidase In the reductive pathway, uracil and thymine reduction by NADPH gives dihydrothymine and dihydrouracil respectively. Addition of water to these creates 3-ureidoisobutyrate and 3-ureidopropionate respectively. Hydrolysis of both these intermediates yields ammonium ion and carbon dioxide (which are made into urea) plus 3-aminoisobutyrate for the thymine pathway and β-alanine for the product of the uracil pathway. 3-aminoisobutyrate is produced during exercise and activates expression of thermogenic genes in white fat cells.

YouTube Lectures by Kevin HERE & HERE

β-alanine is a rate-limiting precursor of carnosine, a dipeptide of histidine and β-alanine (Figure 6.201). Carnosine functions as an antioxidant that scavenges reactive oxygen species. It also acts as an anti-glycating agent to prevent against attachment of sugar molecules to proteins. These are factors in degenerative diseases and may play a role in aging.

Sugars

Last, but not least, the sugars ribose and deoxyribose can be recycled (ribose) or catabolized (ribose and deoxyribose). In the case of ribose, it can be reattached to bases by phos-

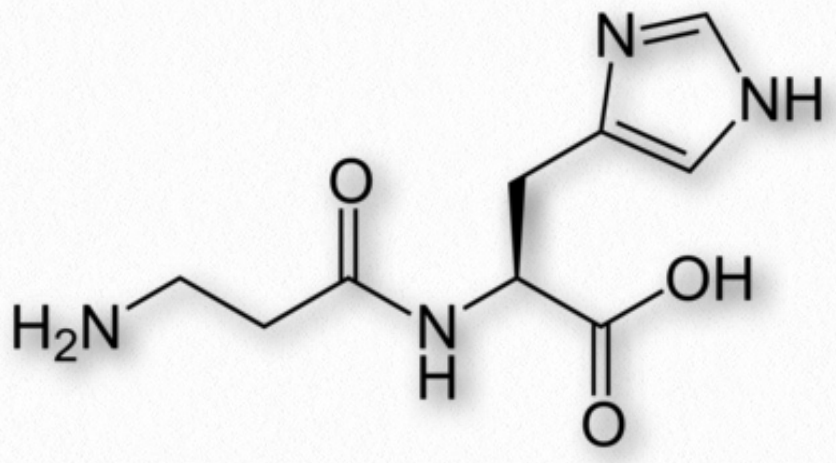

Figure 6.201 - Carnosine

phorylase enzymes, such as uridine phosphorylase, or converted into PRPP for the same purpose, to create nucleosides. Ribose-5-phosphate is an intermediate in the pentose phosphate pathway, allowing it to be converted into other sugars or broken down in glycolysis.

Deoxyribose-5-phosphate can be broken into two pieces by deoxyribose-5-phosphate aldolase. The products of this reaction are glyceraldehyde-3-phosphate and acetaldehyde. The former can be oxidized in glycolysis and the latter can be converted into acetyl-CoA for further metabolism.

Deoxynucleotides

(to the tune of "*Ticket to Ride*")

Metabolic Melodies Website HERE

Tonight I'm feeling quite glad
Because I can say (yeah)
My cells are working like mad
To make DNA

They're making nucleoti-ides
Way down deep and insi-i-ide
Deoxynucleotides
Are on the way

They activate RNR
With an ATP, yeah
Changing a T to an R
Deep inside of me

Deoxynucleoti - ides
That's what the enzyme provi-i-ides
Deoxynucleotides
Are on the way

The enzyme's mechanism's so sly
It is tactical
Using radical
You see
So when it kisses substrate goodbye
It seems magical
In its practical-i-ty

The two prime I will mention
In this exercise, yeah
Its one bit of oxygen
Has got to downsize, yeah

2-prime is de-ox-i-fying
That's what the enzyme is buy-i-ing
2-prime is deoxified
It's gone away

They're gonna go and make DNA
You gotta know that
They're gonna do that in me
They're gonna go and replicate
A polymerase
Is gonna do that for me

Because of structure decrees
In nucleotides, yay
DNA is in b's
But not much in a's

Oh deoxynucleotides
Deoxynucleoti-i-ides
Deoxynucleotides

Information Processing

Man cannot discover new oceans unless he has the courage to lose sight of the shore.

-Andre Gide

"*The blueprints for the construction of one human being requires only a meter of DNA and one tiny cell. ... even Mozart started out this way.*" — L.L. Larison Cudmore

As creatures used to regarding ourselves as exceptional, humans must surely be humbled to realize that the instructions, for making one of our own, reside in a molecule so simple that scientists, for a very long time, did not believe

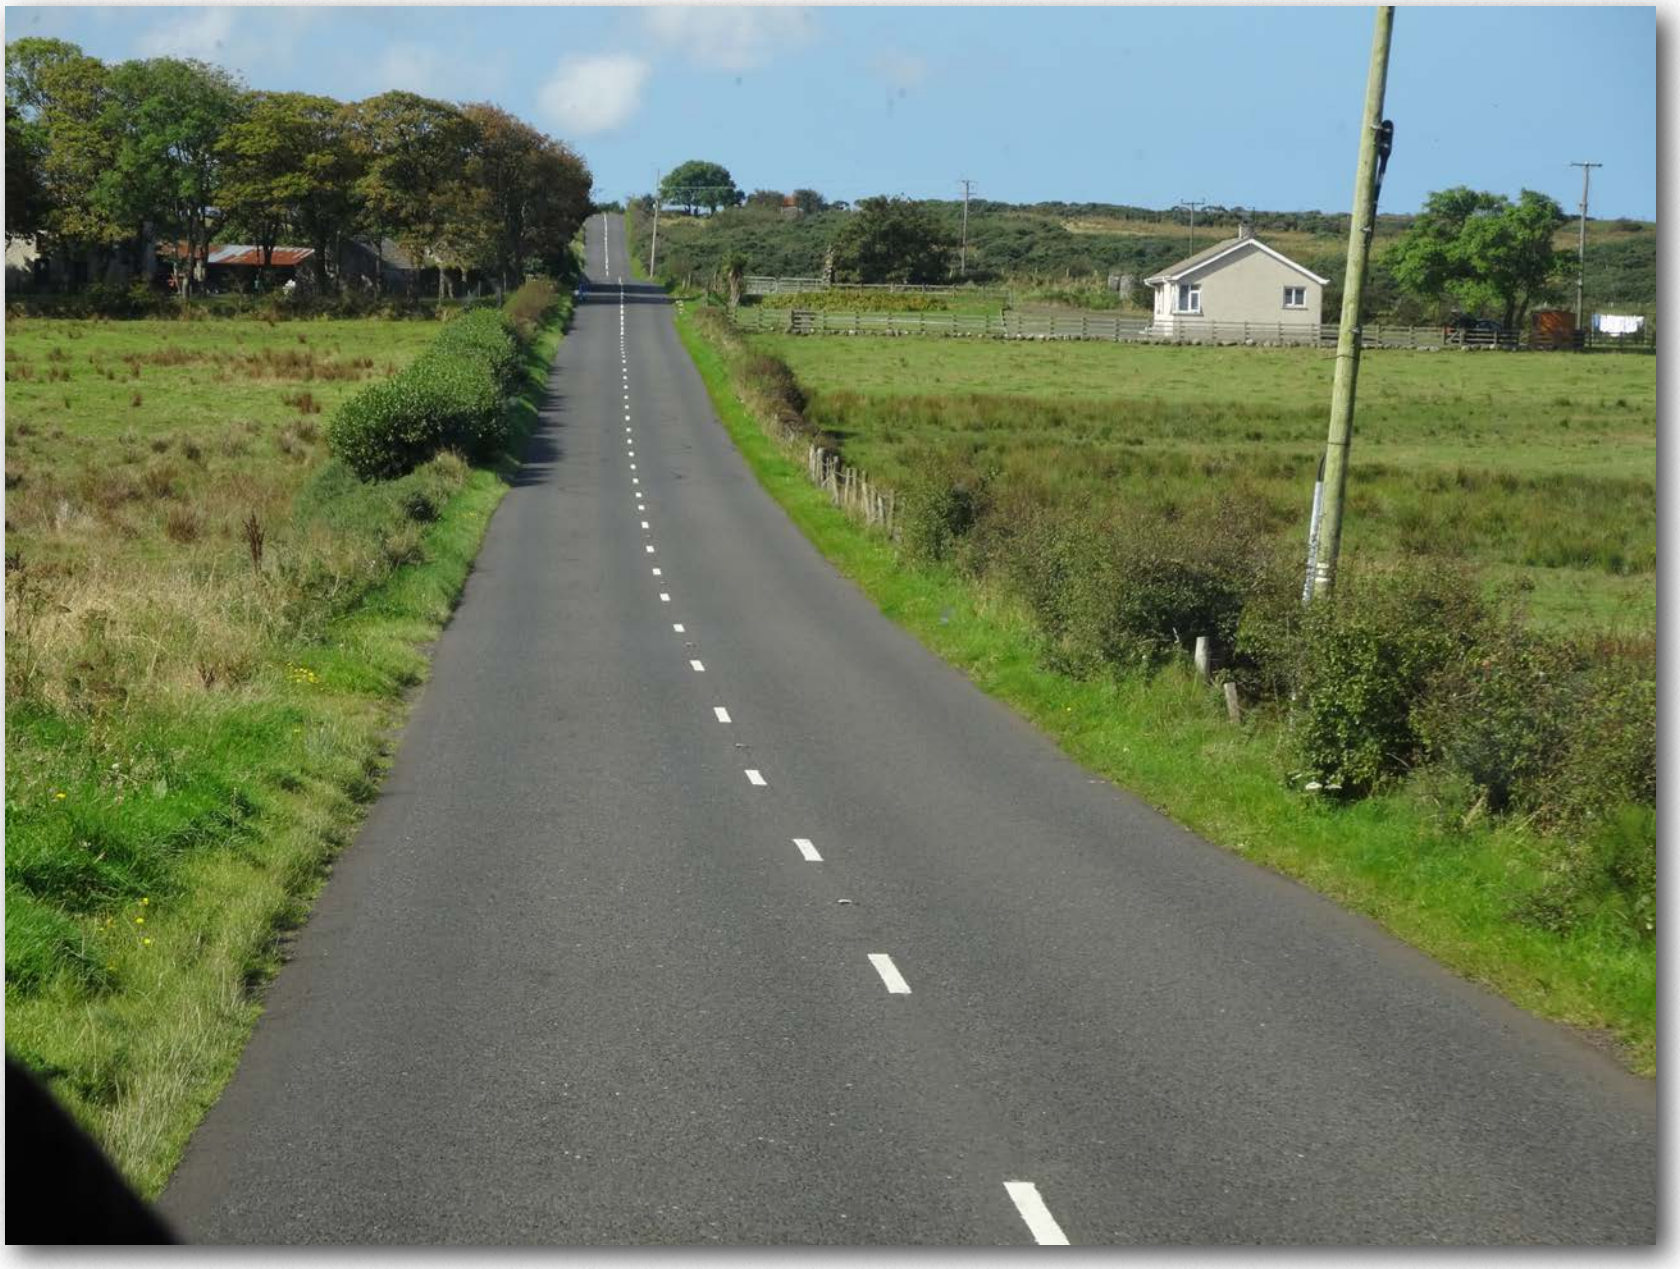
could possibly contain enough information to build even a simple cell. But a large body of evidence, built up over the past century, supports Larison Cudmore's assertion that the information for making you and me (and all the other kinds of living things in the world) is encoded in DNA. Tying in with Mendel's observations about how characteristics are passed on from one generation to the next, the discovery that there was a molecule that carried this information, altered for ever how people thought about heredity.

The elucidation of the structure of DNA provided greater insights into how traits might be encoded in a molecule, and the ways in which the information is used by cells. As we learn more about this topic, scientists have remarked on how the information in our DNA resembles the programs that drive computers. While this analogy is a simplification, there is definitely a sense in which, as Richard Dawkins put it, "the machine code of the genes is uncannily computer-like", with information in our DNA directly determining the properties of the proteins that run our cells. We know, as Ada Yonath described it, that, "DNA is a code of four letters; proteins are made up of amino acids which come in 20 forms. So the ribosome is a very clever machine that reads one language and operates in another. "

If this sounds strange, it is even more intriguing to realize DNA is copied and passed on from cell to cell, from one generation to the next. There is an unbroken line of inheritance from the first cell to every organism alive today. In the words of Lewis Thomas, "All of today's DNA, strung through all the cells of the earth, is simply an extension and elaboration of [the] first molecule."

The nature of this information, how it is copied and passed on, how it is read and interpreted, and how it gives rise to the cellular activities that we can observe, is the subject of this chapter. Another kind of information is also considered, towards the end of the chapter- the molecular information that cells receive from, and send to, each other. Overlaid on the instructions in the genes, this information provides cells with ongoing clues about both their own inner state and the environment around them. The interplay of these two kinds of information is responsible for the form and behavior of all living organisms.

Information Processing: Genes and Genomes



Introduction

For many years, scientists wondered about the nature of the information that directed the activities of cells. What kind of molecules carried the information, and how was the information passed on from one generation to the next? Key experiments, done between the 1920s and the 1950s, established convincingly that this genetic information was carried by DNA. In 1953, with the elucidation of the structure of DNA, it was possible to begin investigating how this information is passed on, and how it is used.

YouTube Lectures by Kevin HERE & HERE

Genomes

We use the word “genome” to describe all of the genetic material of the cell. That is, a genome is the entire sequence of nucleotides in the DNA that is in all of the chromosomes of a cell. When we use the term genome without further qualification, we are generally referring to the chromosomes in the nucleus of a eukaryotic cell. As

you know, eukaryotic cells have organelles like mitochondria and chloroplasts that have their own DNA (Figure 7.1 & 7.2). These are referred to as the mitochondrial or chloroplast genomes to distinguish them from the nuclear genome.

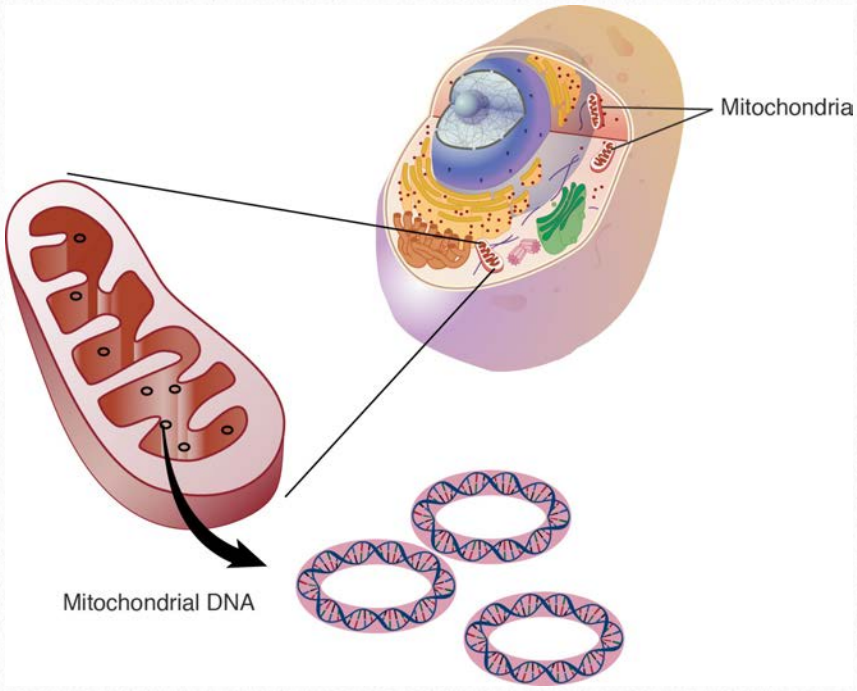


Figure 7.1 - Mitochondria carry their own genome

Starting in the 1980s, scientists began to determine the complete sequence of the genomes of many organisms, in the hope of better understanding how the DNA sequence specifies cellular functions. Today, the complete genome sequences have been determined for thousands of species from all domains of life, and many more are in the process of being worked out by groups of scientists across the world.

Global genome initiative

The Global Genome Initiative, a collaborative effort to sequence at least one species from each of the 9,500 described invertebrate, vertebrate, and plant families is one of many such ventures. The information from these various efforts is collected in enormous online repositories, so that it is freely available to scientists. As the sequence databases compile ever more information, the fields of computational biology and bioinformatics have arisen, to analyze and organize the data in a way that helps biologists understand what the information in DNA means in the cellular context.

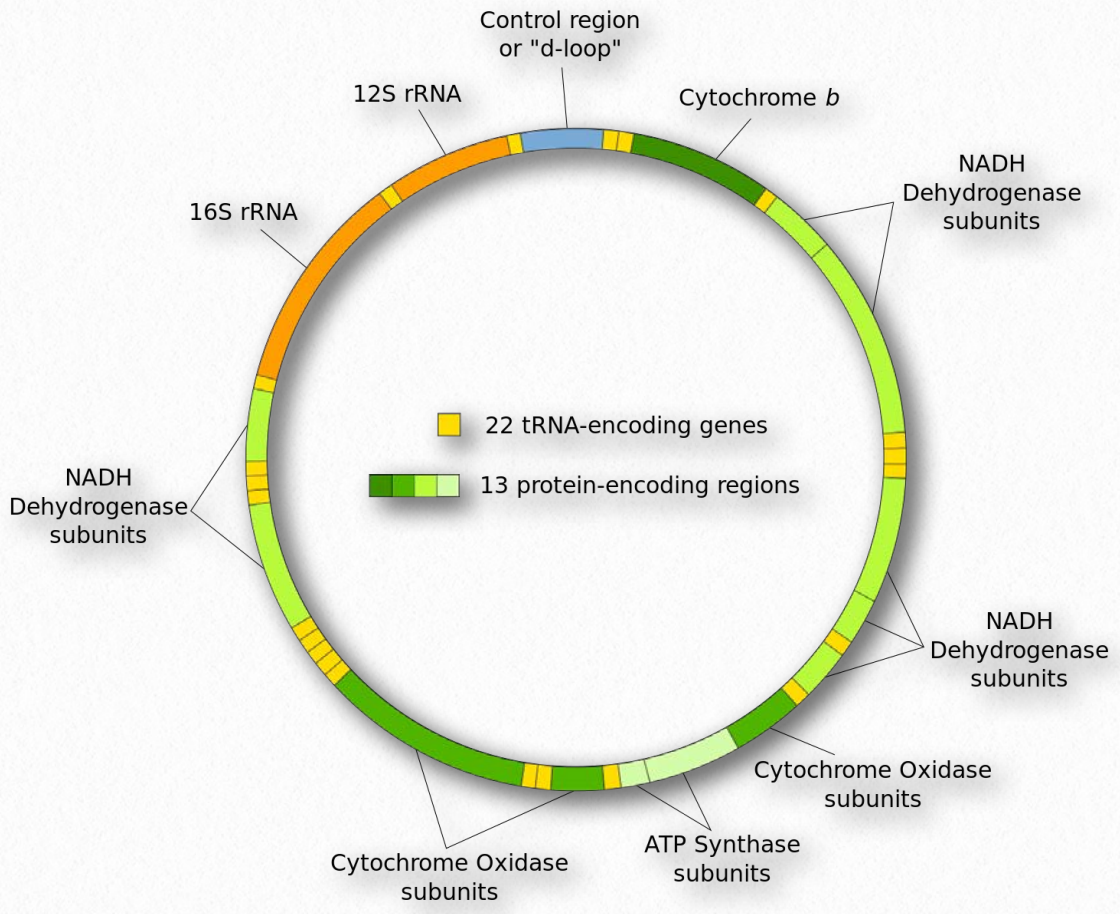

Figure 7.2 - The human mitochondrial genome

Wikipedia

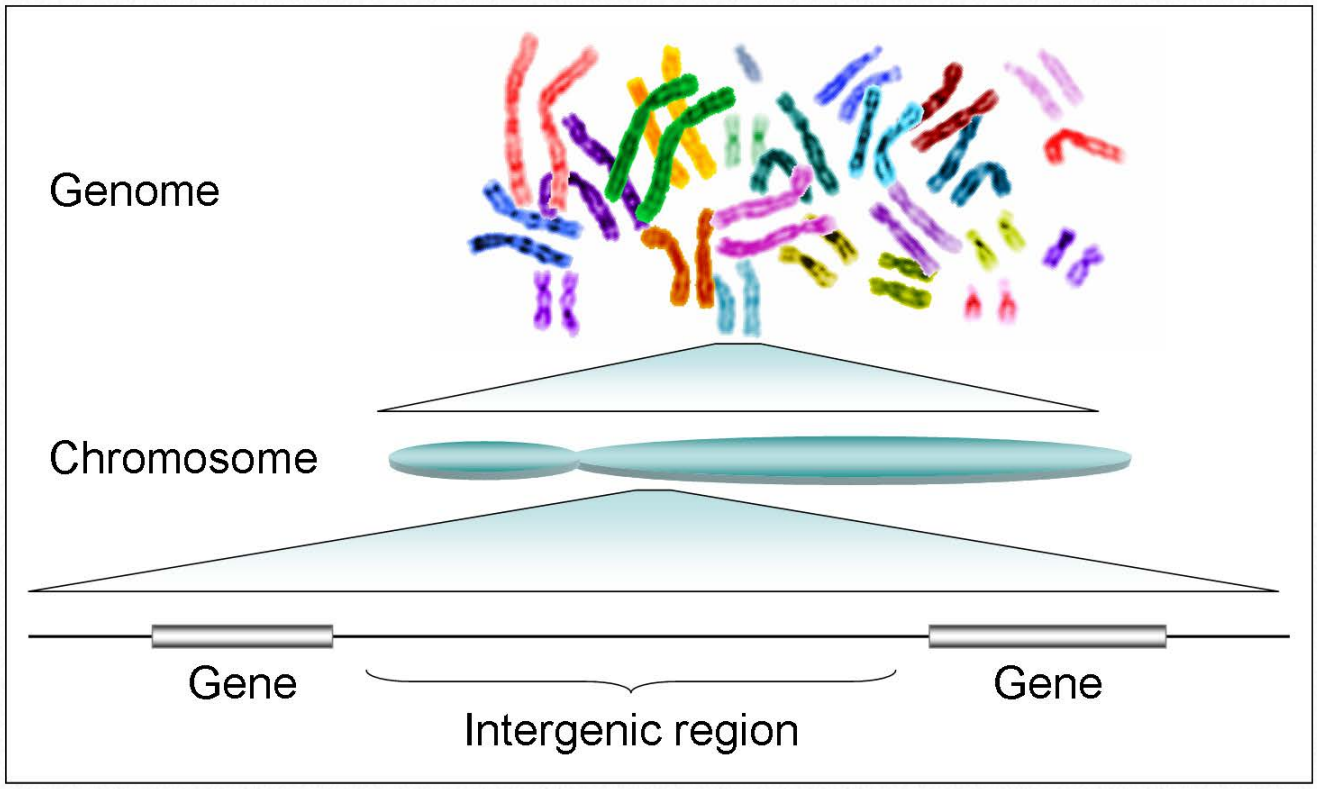

Figure 7.3 - From genomes to genes

Wikipedia

Genes

It has been known for many years that phenotypic traits are controlled by specific regions of the DNA that were termed “genes”. Thus, DNA was envisioned as a long string of nucleotides, in which certain regions, the genes, were separated by non-coding regions that were simply referred to as intergenic sequences (*inter*=between; *genic*=of genes). Early experiments in molecular biology suggested a simple relationship between the DNA sequence of a gene and its product, and led scientists to believe that each gene carried the information for a single protein. Changes, or mutations in the base sequence of a gene would be reflected in

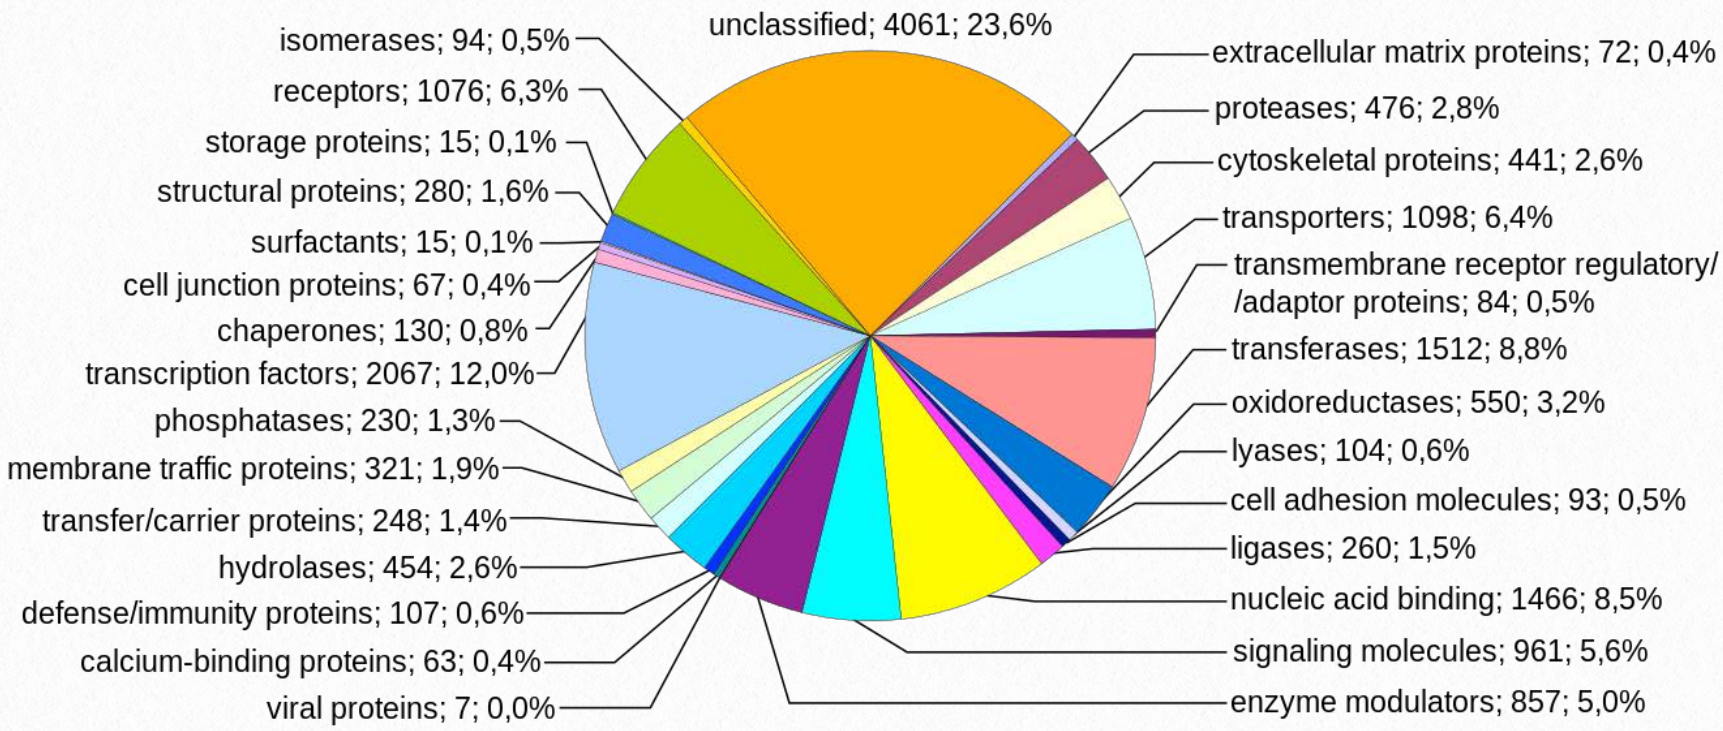

Figure 7.4 - Human genes sorted by class

changes in the gene product, which in turn, would manifest itself in the phenotype or observable trait. This simple picture, while still useful, has been modified by subsequent discoveries that demonstrated that the use of genetic information by cells is somewhat more complicated. Our definition of a gene is also evolving to take new knowledge into consideration.

Matters of size

A common-sense assumption about genomes would be that if genes specify proteins, then the more proteins an organism made, the more genes it would need to have, and thus, the larger its genome would be. Comparison of various genomes shows, surprisingly, that there is not necessarily a direct relationship between the complexity of an organism and the size of its genome (Figure 7.5). To understand how this could be true, it is necessary to recognize that while genes are made up of DNA, all DNA does not consist of genes (for purposes of our discussion, we define a gene as a section of DNA that encodes an RNA or protein product). In the human genome, less than 2% of the total

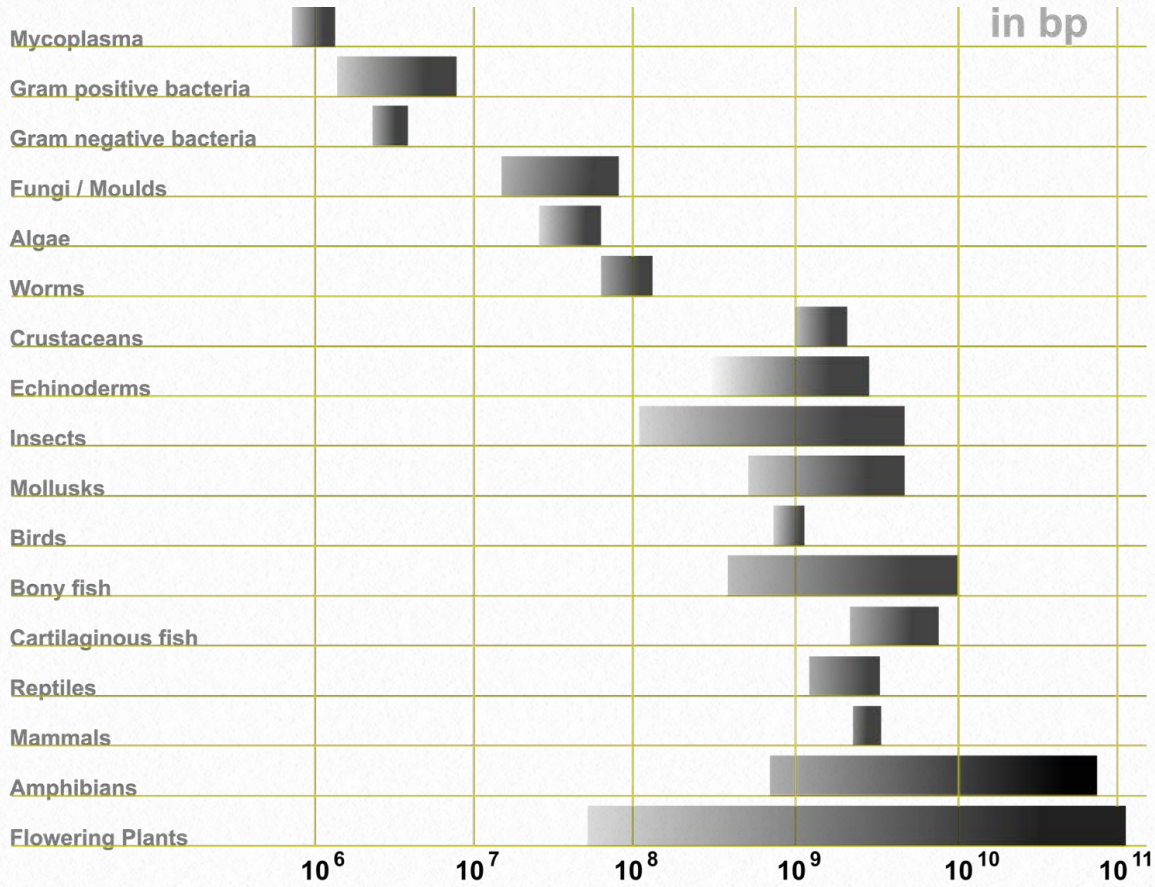

Figure 7.5 - Sizes of various genomes

Wikipedia

DNA seems to be the sort of coding sequence that directs the synthesis of proteins. For many years, non-coding DNA in genomes was believed to be useless, and was described as "junk DNA" although it was perplexing that there seemed to be so much "useless" sequence. Recent discoveries have, however, demonstrated that much of this so-called junk DNA may play important roles in evolution, as well as in regulation of gene expression.

Introns

So, what is all the non-coding DNA doing there? We know that even coding regions in our DNA are interrupted by non-coding sequences called introns. This is true of most eukaryotic genomes. An examination of

genes in eukaryotes shows that non-coding intron sequences can be much longer than the coding sections of the gene, or exons. Most exons are relatively small, and code for fewer than a hundred amino acids, while introns can vary in size from several hundred base-pairs to many kilobase-pairs (thousands of base-pairs) in length. For many genes in humans, there is much more of intron sequence than coding (a.k.a. exon) sequence. Intron sequences account for roughly a quarter of the genome in humans.

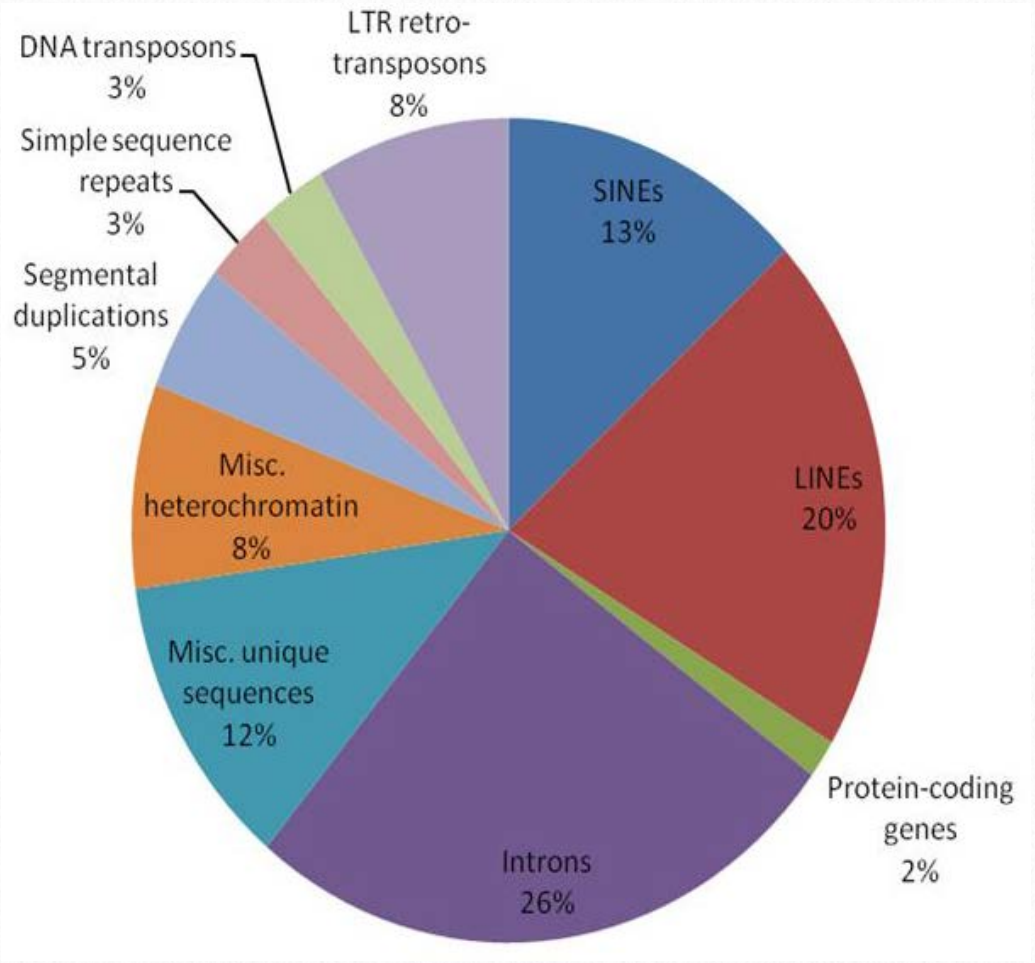

Figure 7.6 - Components of the human genome
Wikipedia

Other non-coding sequences

What other kinds of non-coding sequences are there? One function for some DNA sequences that do not encode RNA or proteins is in specifying when and to what extent a gene is used, or expressed. Such regions of DNA are called regulatory regions and each gene has one or more regulatory sequences that control its expression. However, regulatory sequences do not account for all the rest of the DNA in our genomes, either.

YouTube Lectures by Kevin HERE & HERE

Transposable sequences

Surprisingly, almost half of the human genome appears to consist of several kinds of repetitive sequences. Many of the repetitive sequences are known to be transposable elements (transposons), sections of DNA that can move around within the genome. Sometimes referred to as "jumping genes" these transposable elements can move from one chromosomal location to another, either through a simple "cut and paste" mechanism that cuts the sequence out of one region of the DNA and inserts it into another location, or through a process called retrotransposition involving an RNA intermediate.

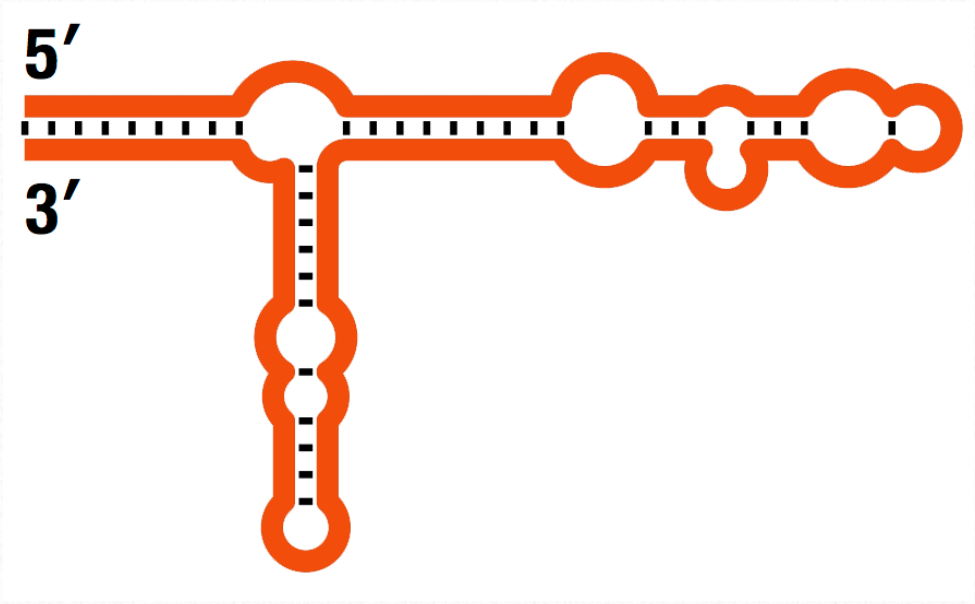

Figure 7.7 - 5S rRNA structure

Wikipedia

LINES & SINES

There are millions of copies of each of two major classes of such transposable elements, the LINEs (Long Interspersed Elements) and SINEs (Short Interspersed Elements) in our genomes.

LINEs and SINEs are both a kind of transposable element called retrotransposons, sequences that are copied into RNA, then reverse transcribed back into DNA before being inserted into new locations. This movement is typically not sequence specific, meaning that the transposons can be inserted randomly in the genome, in many cases within coding regions. As might be expected, this can disrupt the function of the gene. Transposons may also insert within regulatory regions, and change the expression of the genes they control. As a major cause of mutation in genomes, transposons play an important role in evolution.

Finally, recent findings have shown that much of the genome is transcribed into RNAs, even though only about 2% encodes proteins. What are the RNAs that do not encode proteins? Ribosomal RNAs (Figure 7.7) and transfer RNAs, together with the small nuclear RNAs that function in splicing, account for some of these non-translated transcripts, but not all. The remaining RNAs are regulatory RNAs, small molecules that play an important role in regulating gene expression. As we understand more about genomes, it is becoming evident that the so-called “junk” DNA is anything but.

Information Processing: DNA Replication

Copying instructions

The only way to make new cells is by the division of pre-existing cells. Single-celled organisms undergo division to produce more cells like themselves, while multicellular organisms arise through division of a single cell, generally the fertilized egg. Each time a cell divides, all of its DNA must be copied faithfully so that a copy of this information can be passed on to the daughter cell. This process is called DNA replication. It is the means by which genetic information can be transmitted down generations of cells, and it ensures that every new cell has a complete copy of the genome. In the next section, we will examine the process by which the DNA of a cell is completely and accurately copied.

YouTube Lectures by Kevin
HERE & HERE

The structure of DNA elucidated by Watson and Crick in 1953 immediately suggested a mechanism by which double-stranded DNA could be copied to give two identical copies of the DNA. They proposed that the two strands of the DNA molecule,

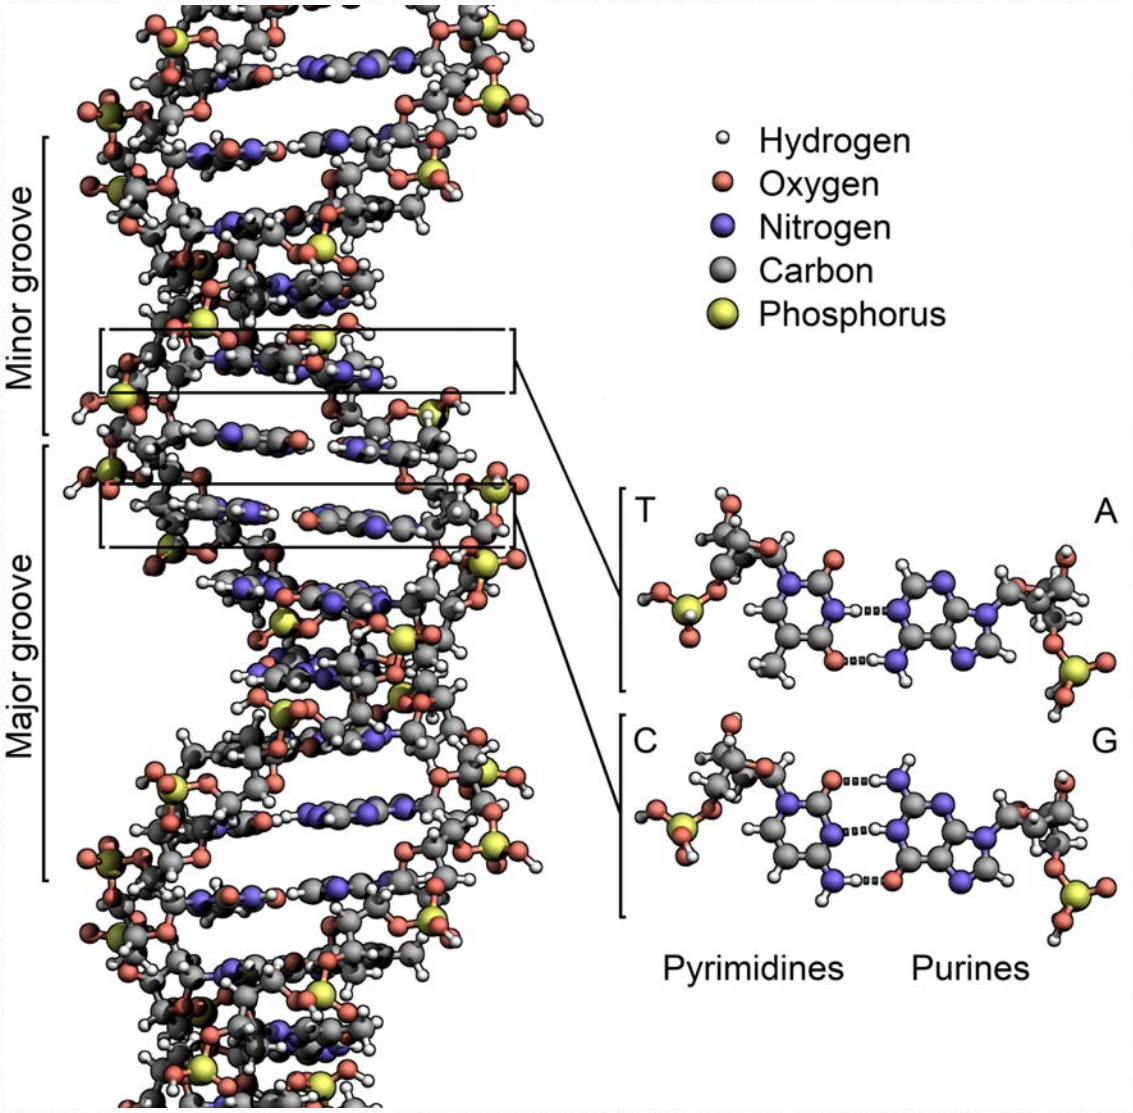

Figure 7.8 - Watson & Crick's DNA structure

Wikipedia

which are held together by hydrogen bonds between the base-paired nucleotides, would separate and each serve as a template on which a complementary strand could be assembled (Figure 7.8). The base-pairing rules would ensure that this process would result in the production of two identical DNA molecules. The beautiful simplicity of this scheme was shown to be correct in subsequent experiments by Meselson and Stahl, that demonstrated that DNA replication was semi-conservative, i.e., that after replication, each of the two resulting DNA molecules was made up of one old strand and one new strand that had been assembled across from it (Figure 7.9).

Building materials

What are the ingredients necessary for building a new DNA molecule? As noted above, the original, or parental DNA molecule serves as the template. New DNA molecules are assembled across from each template by joining together free DNA nucleotides as directed by the base pairing rules, with As across from Ts and Gs across from Cs.

The nucleotides used in DNA synthesis are deoxyribonu-

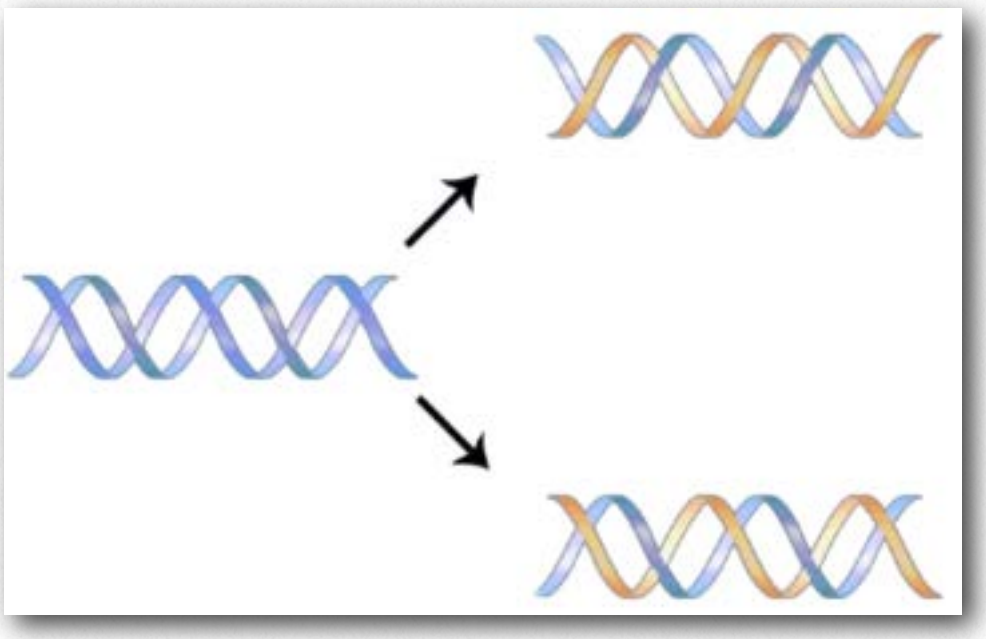

Figure 7.9 - Semi-conservative replication

Image by Martha Baker

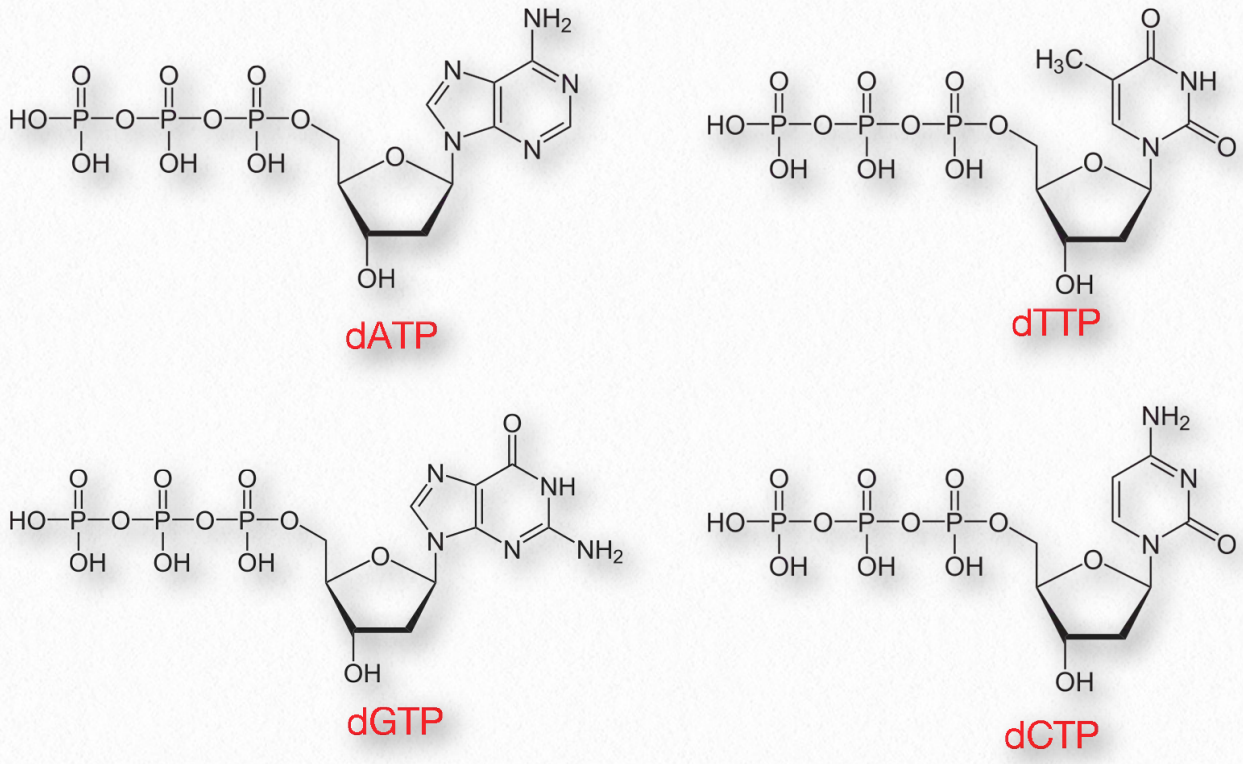

Figure 7.10 - The building blocks of DNA

cleoside triphosphates or dNTPs. As can be inferred from their name, such nucleotides have a deoxyribose sugar and three phosphates, in addition to one of the four DNA bases, A, T, C or G (Figure 7.10).

When dNTPs are added into a growing DNA strand, two of those phosphates will be cleaved off, as described later, leaving the nucleotides in a DNA molecule with only one phosphate per nucleotide. This reaction is catalyzed by enzymes known as DNA polymerases, which create phosphodiester linkages between one nucleotide and the next.

Challenges

Before examining the actual process of DNA replication, it is useful to think about what it takes to accomplish this task successfully. Consider the challenges facing a cell in this process:

- The sheer number of nucleotides to be copied is enormous: e.g., in human cells, on the order of several billions.
- A double-helical parental DNA molecule must be unwound to expose single strands of DNA that can serve as templates for the synthesis of new DNA strands.
- Unwinding must be accomplished without introducing topological distortion into the molecule.
- The unwound single strands of DNA must be kept from coming back together long enough for the new strands to be synthesized.
- DNA polymerases cannot begin synthesis of a new DNA strand *de novo* and require a free 3' OH to which they can add deoxynucleotides.
- DNA polymerases can only extend a strand in the 5' to 3' direction. The 5' to 3' growth of both new strands means that one of the strands is made in pieces.
- The use of RNA primers requires that the RNA nucleotides must be removed and re-

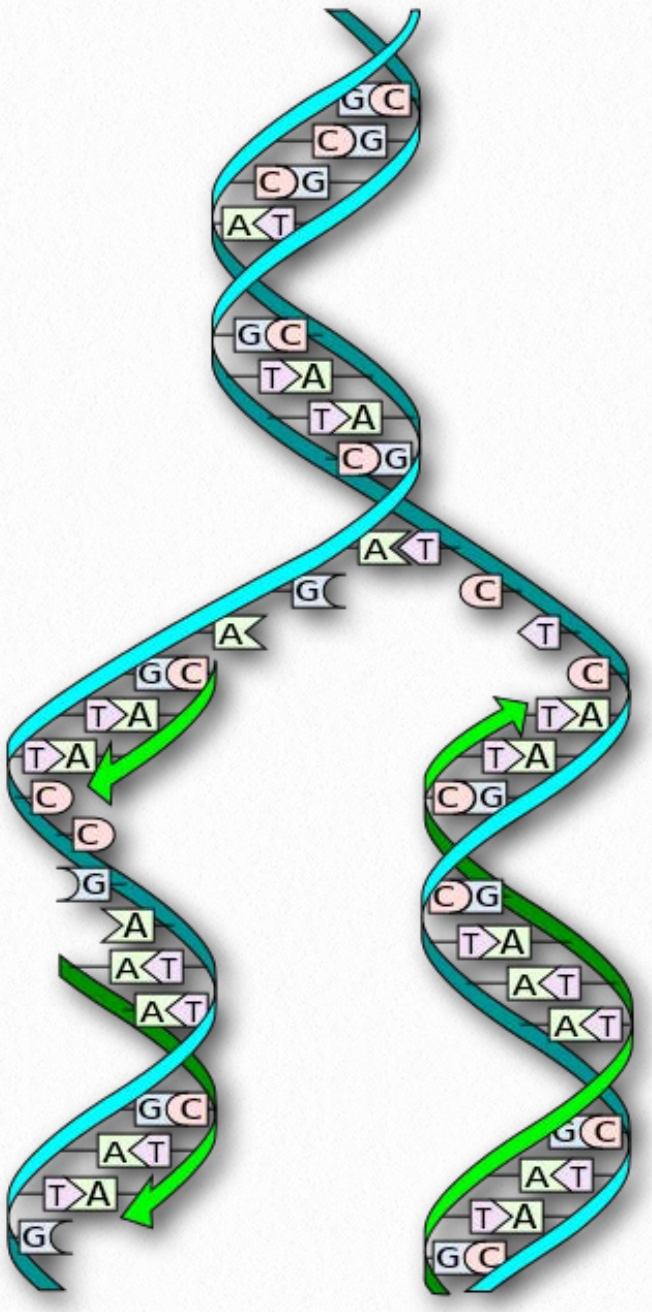

Figure 7.11 - Replication of DNA

Wikipedia

placed with DNA nucleotides and the resulting DNA fragments must be joined.

• The copying of all the parental DNA must be accurate, so that mutations are not introduced into the newly made DNA..

Addressing challenges

With this in mind, we can begin to examine how cells deal with each of these challenges. Our understanding of the process of DNA replication is derived from studies using bacteria, yeast, and other systems. These investigations have revealed that DNA replication is carried out by the action of a large number of proteins that act together as a complex protein machine. Numerous proteins involved in replication have been identified and characterized, including multiple different DNA polymerases in both prokaryotes and eukaryotes. Although the specific proteins involved are different in bacteria and eukaryotes, it is useful to understand the basic considerations that are relevant in all cells. A generalized account of the steps in DNA replication is presented below, focused on the challenges mentioned above.

• The sheer number of nucleotides to be copied is enormous: e.g., in human cells, on the order of several billions.

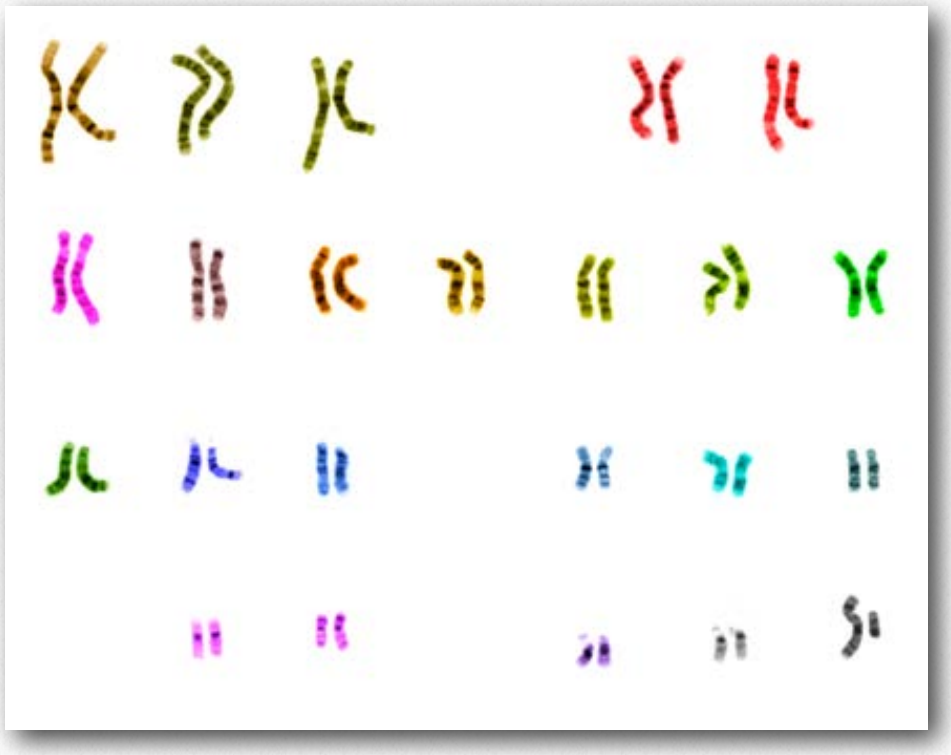

Figure 7.12 - Human chromosomes

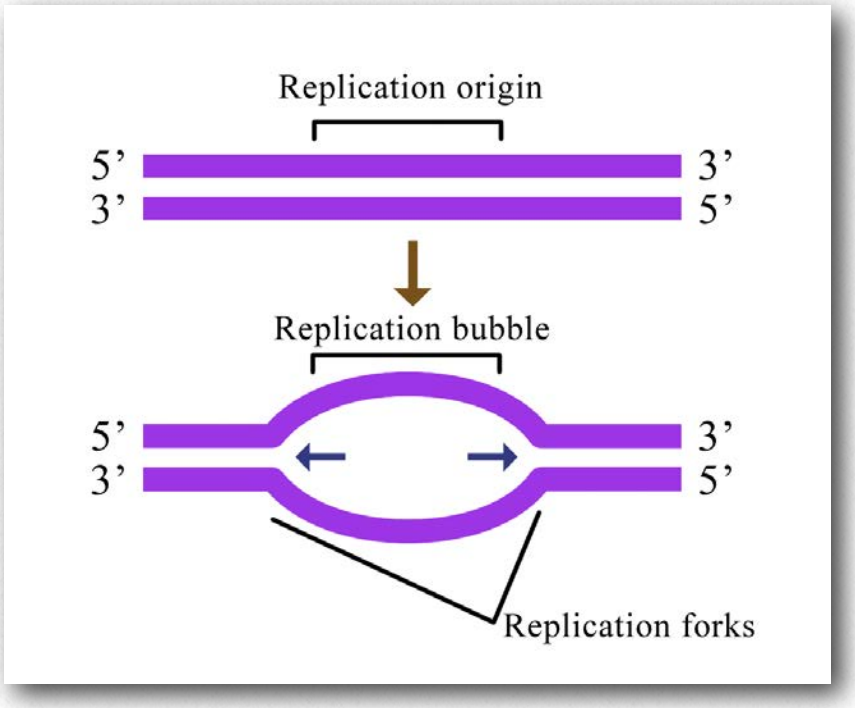

Figure 7.13 - Bidirectional replication from an origin

Martha Baker

Cells, whether bacterial or eukaryotic, have to replicate all of their DNA before they can divide. In cells like our own, the vast amount of DNA is broken up into many chromosomes, each of which is composed of a linear strand of DNA (Figure 7.12). In cells like those of *E. coli*, there is a single circular chromosome.

In either situation, DNA replication is initiated at sites called origins of replication.

These are regions of the DNA molecule that are recognized by special proteins called initiator proteins that bind the DNA. In *E.coli*, origins have small regions of A-T-rich sequences that are "melted" to separate the strands,

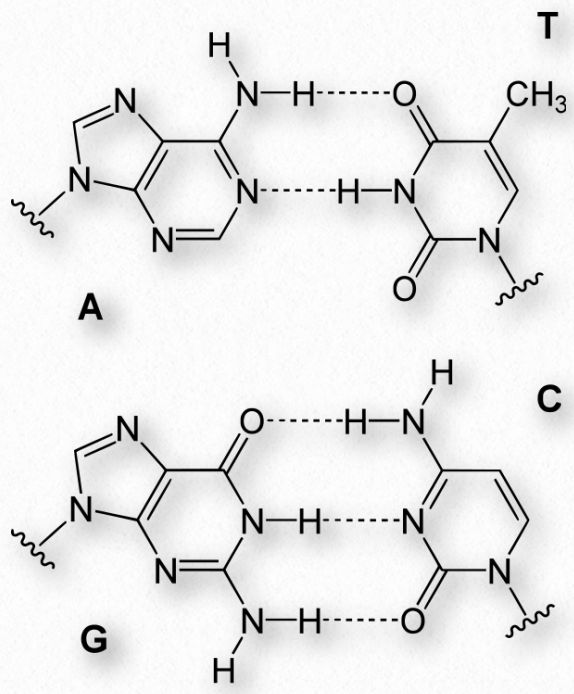

Figure 7.15 - A-T and G-C base pairs

when the initiator proteins bind to the origin or replication. As you may remember, A-T base-pairs, which have two hydrogen bonds between them are more readily disrupted

Prokaryotic DNA Replication	Eukaryotic DNA replication
Occurs inside the cytoplasm	Occurs inside the nucleus
Only one origin of replication per molecule of DNA	Have many origins of replication in each chromosome
Origin of replication is about 100-200 or more nucleotides in length	Each origin of replication is formed of about 150 nucleotides
Replication occurs at one point in each chromosome	Replication occurs at several points simultaneously in each chromosome
Only have one origin of replication	Has multiple origins of replication
Initiation is carried out by protein DnaA and DnaB	Initiation is carried out by the Origin Recognition Complex
Topoisomerase is needed	Topoisomerase is needed
Replication is very rapid	Replication is slow

Figure 7.14 - Prokaryotic vs. eukaryotic DNA replication

Wikipedia

than G-C base-pairs which have three apiece (Figure 7.15).

How many origins of replication are there on a chromosome? In the case of *E. coli*, there is a single origin of replication on its circular chromosome. In eukaryotic cells there may be many thousands of origins of replication, with each chromosome having hundreds (Figure 7.16). DNA replication is, thus, initiated at multiple points along each chromosome in eukaryotes. Electron micrographs of replicating DNA from eukaryotic cells show many replication bubbles on a single chromosome. This makes sense in light of the large amount of DNA that there is to be copied in cells like our own, where beginning at one end of each chromosome and replicating all the way through to the other end from a single origin would simply take too long. This is despite the fact that the DNA polymerases in human cells are capable of building new DNA strands at the very respectable rate of about 50 nucleotides per second!

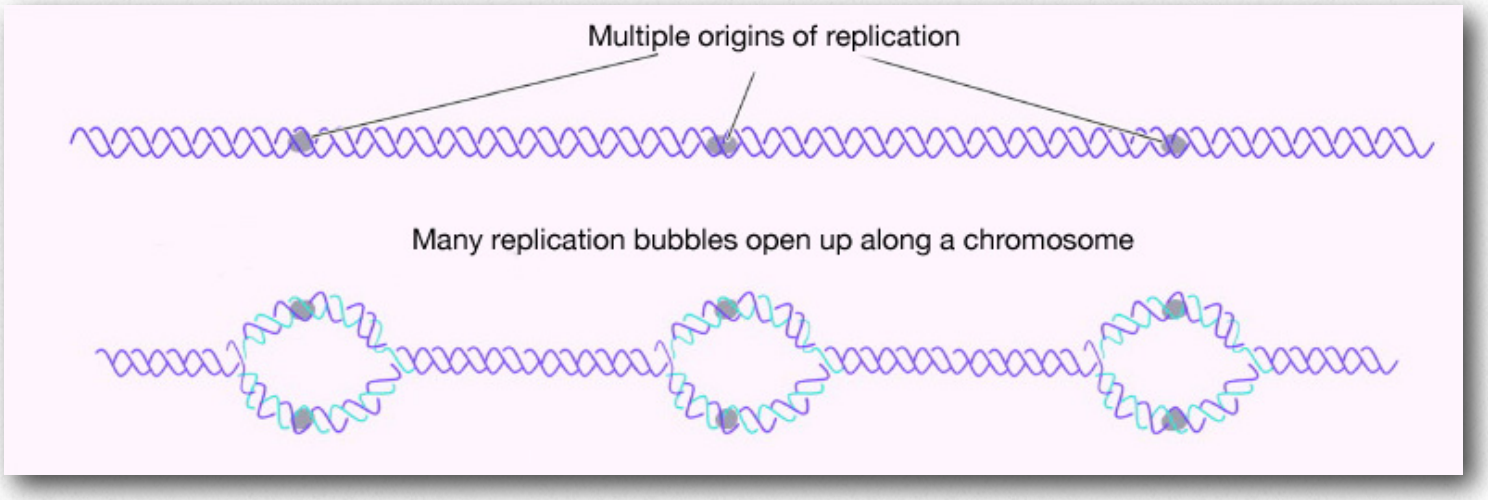

Figure 7.16 - Multiple replication bubble on a eukaryotic chromosome
Image by Martha Baker

YouTube Lectures by Kevin HERE & HERE

- A double-helical parental molecule must be unwound to expose single strands of DNA that can serve as templates for the synthesis of new DNA strands.

Unwinding

Once a small region of the DNA is opened up at each origin of replication, the DNA helix must be unwound to allow replication to proceed. The unwinding of the DNA helix requires the action of an enzyme called helicase.

Helicase uses the energy released when ATP is hydrolyzed, to break the hydrogen bonds between the bases in DNA and separate the two strands (Figure 7.17). Note that a replication bubble is made up of two replication forks that "move" or open up, in opposite directions. At each replication fork, the parental DNA strands must be un-

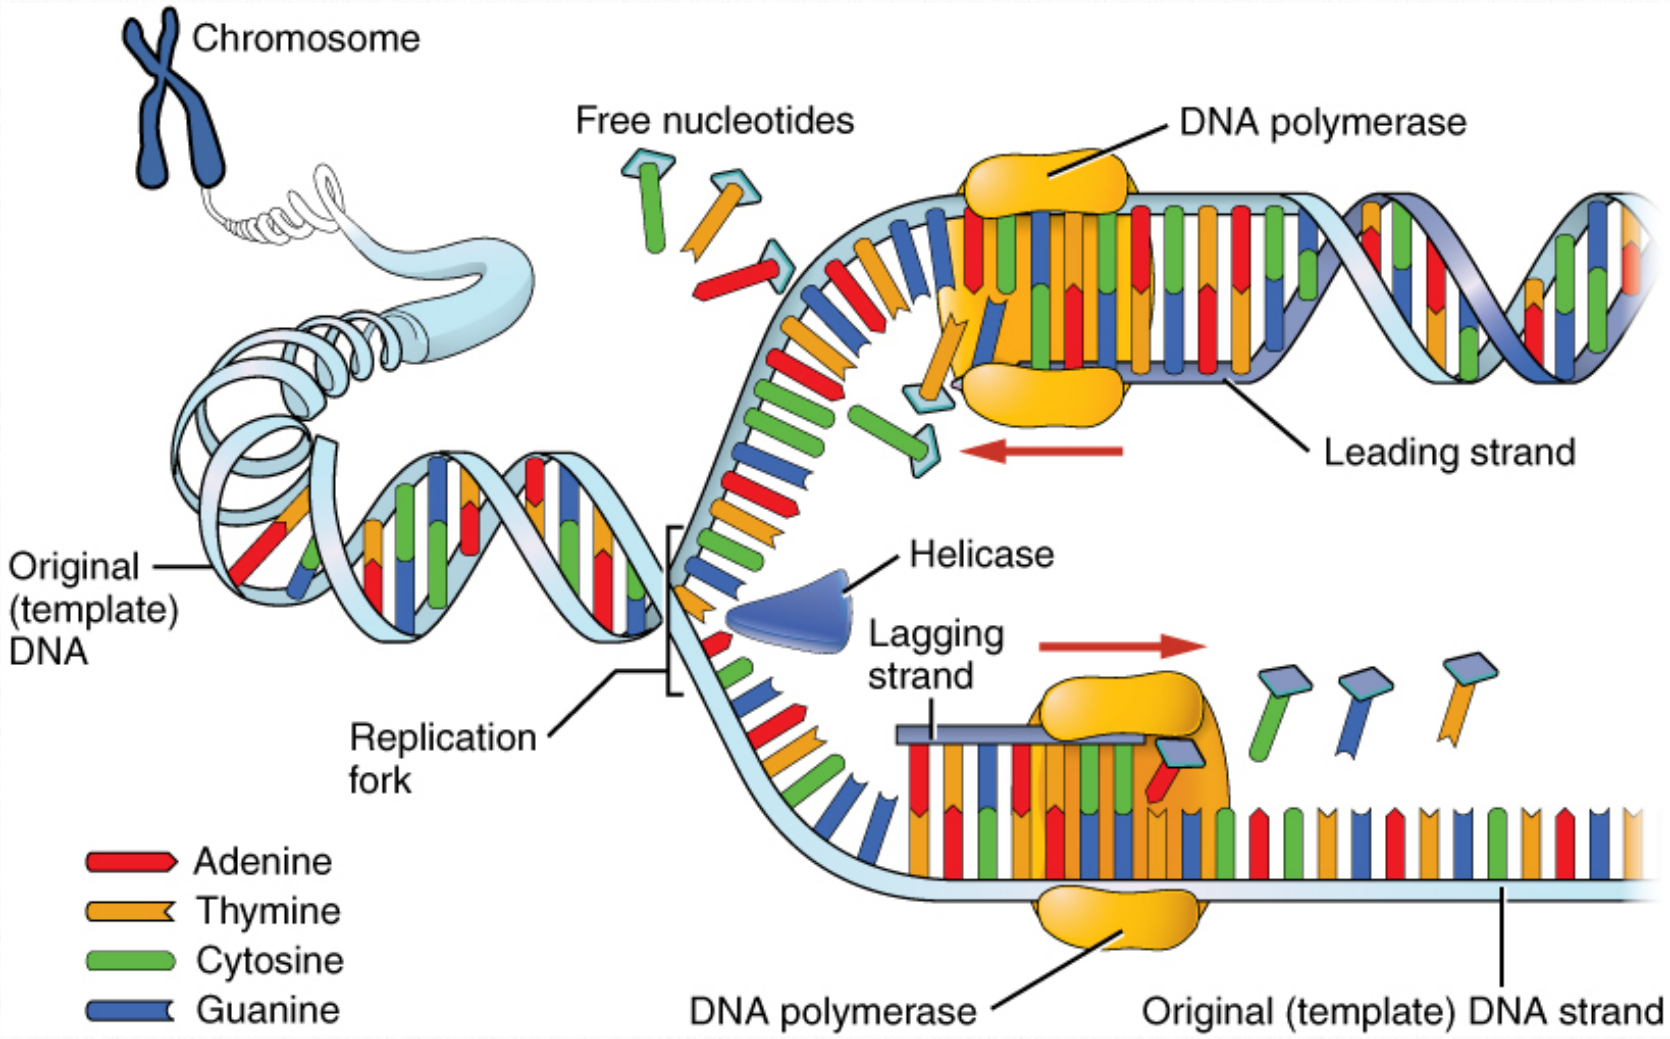

Figure 7.17 - View of a eukaryotic DNA replication fork with helicase shown in blue

Wikipedia

wound to expose new sections of single-stranded template.

- This unwinding must be accomplished without introducing topological distortion into the molecule.

What is the effect of unwinding one region of the double helix? Local unwinding of the double helix causes over-winding (increased positive supercoiling) ahead of the unwound region.

The DNA ahead of the replication fork has to rotate, or it will get twisted on itself and halt replication. This is a major problem, not only for circular bacterial chromosomes, but also for linear eukaryotic chromosomes, which, in principle, could rotate to relieve the stress caused by the increased supercoiling.

Topoisomerases

The reason this is problematic is that it is not possible to rotate the entire length of a chromosome, with its millions of base-pairs, as the DNA at the replication fork is unwound. How, then, is this problem solved? Enzymes called topoisomerases can relieve the topological stress caused by local “unwinding” of

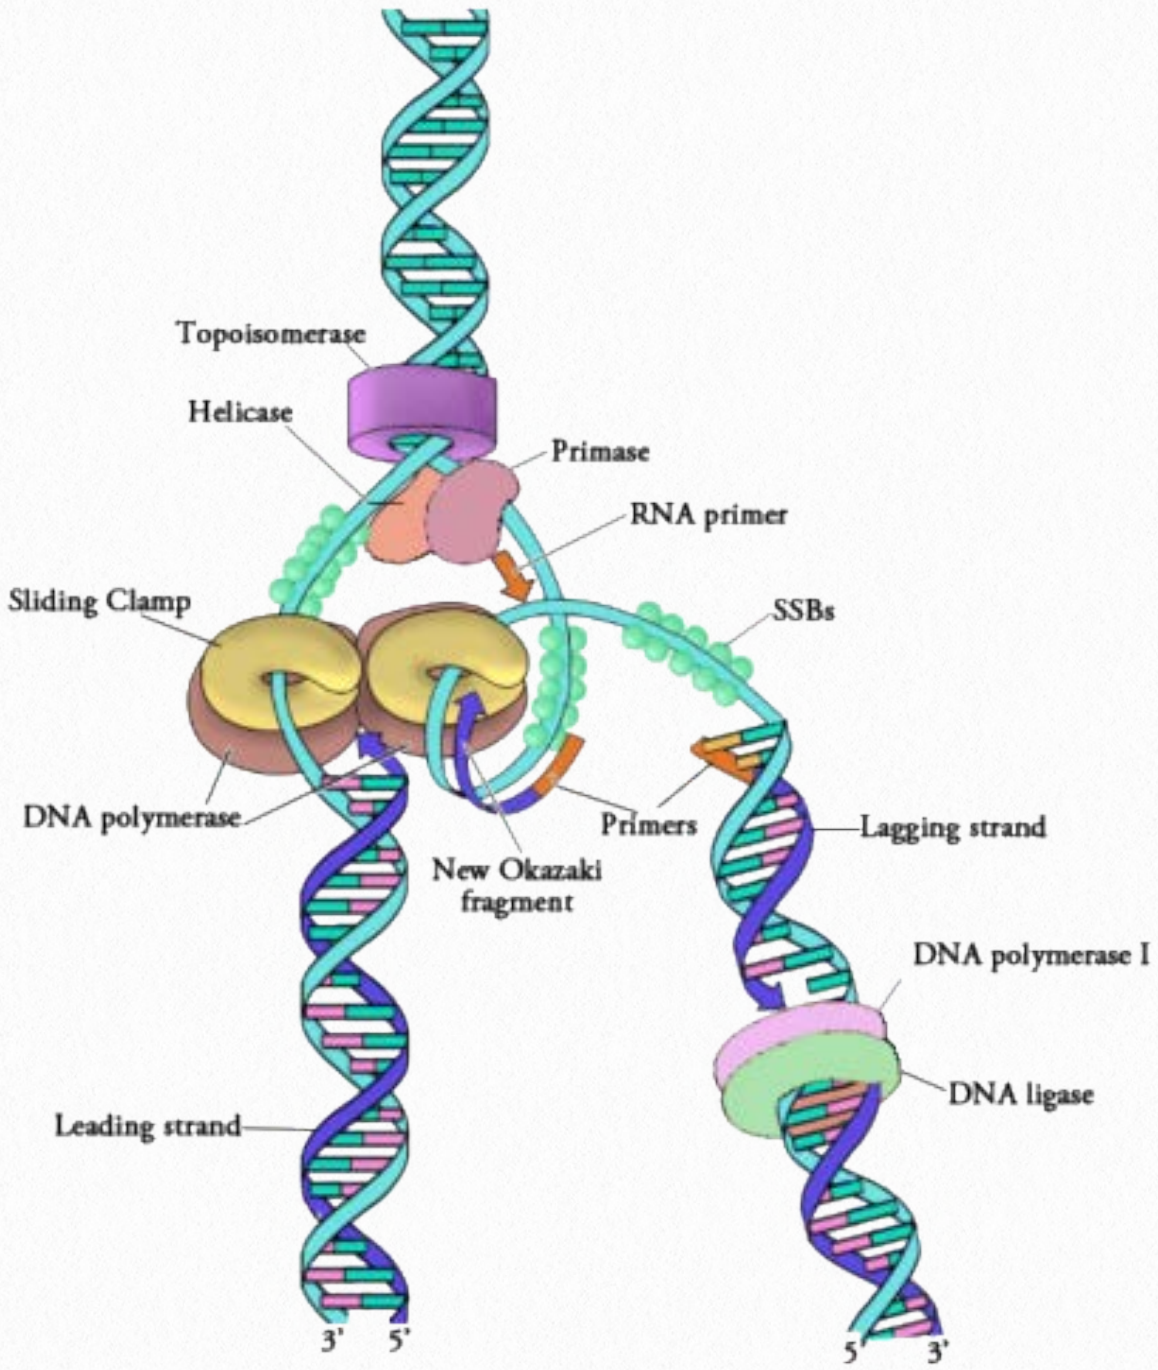

Figure 7.18 - Proteins at a prokaryotic DNA replication fork
Image by Martha Baker

the extra winds of the double helix. They do this by cutting one or both strands of the DNA and allowing the strands to swivel around each other to release the tension before rejoining the ends. In *E. coli*, the topoisomerase that performs this function is called gyrase.

•The separated single strands of DNA must be kept from coming back together so the new strands to be synthesized.

Single-strand DNA binding protein

Once the two strands of the parental DNA molecule are separated, they must be prevented from going back together to form double-stranded DNA. To ensure that unwound regions of the parental DNA remain single-stranded and available for copying, the separated strands of the parental DNA are bound by many molecules of a protein called single-strand DNA binding protein (SSB - Figure 7.18).

•DNA polymerases cannot begin synthesis of a new DNA strand *de novo* and require a free 3' OH to which they can add DNA nucleotides.

Although single-stranded parental DNA is now available for copying, DNA polymerases cannot begin synthesis of a complementary strand *de novo*. This simply means that DNA

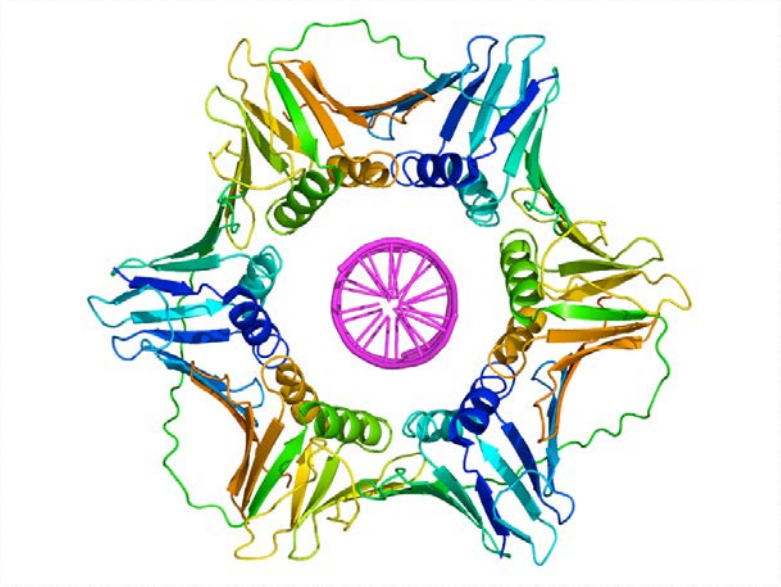

Figure 7.19 - Top view of the sliding clamp (outside) surrounding DNA strand (inside)

polymerases can only add new nucleotides on to the 3' end of a pre-existing chain, and cannot start a chain of nucleotides on their own. Because of this limitation, some enzyme other than a DNA polymerase must first make a small region of nucleic acid, complementary to the parental strand, that can provide a free 3' OH to which DNA polymerase can add a deoxyribonucleotide. This task is accomplished by an enzyme called a primase, which assembles a short stretch of RNA base-paired to the parental DNA template. This provides a short base-paired region, called the RNA primer, with a free 3'OH group to which DNA polymerase can add the first new DNA nucleotide (Figure 7.12).

Sliding clamp

Once a primer provides a free 3'OH for extension, other proteins get into the act. These proteins are involved in loading the DNA polymerase onto the primed template and keeping it associated with the DNA. The first of these is the clamp loader. As its name suggests, the clamp loader helps to load a protein complex called the sliding clamp onto the DNA at the replication fork (Figure 7.19 and 7.20). The sliding clamp, a multi-subunit ring-shaped protein, is then joined by the DNA Polymerase. The function of the sliding clamp is to keep the polymerase associated

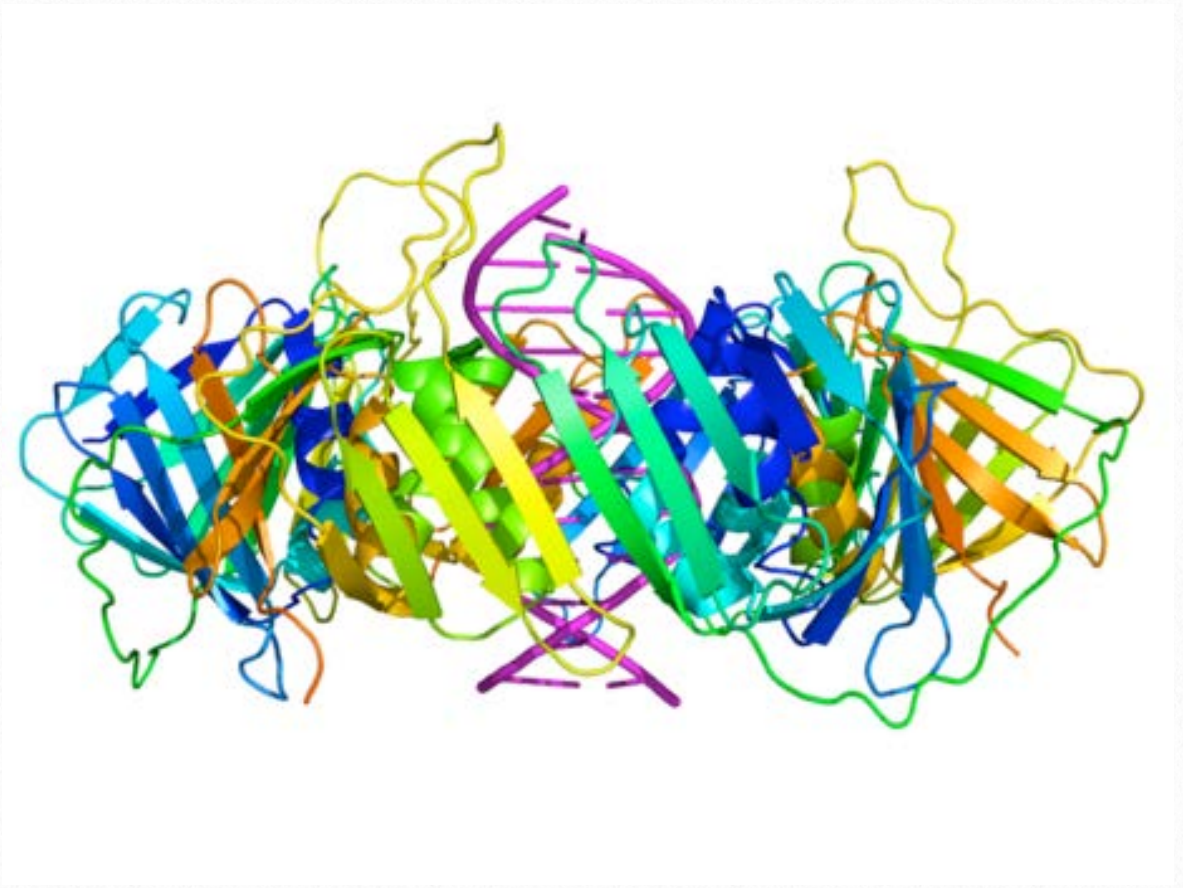

Figure 7.20 - Side view of the sliding clamp surrounding a DNA strand (in purple)

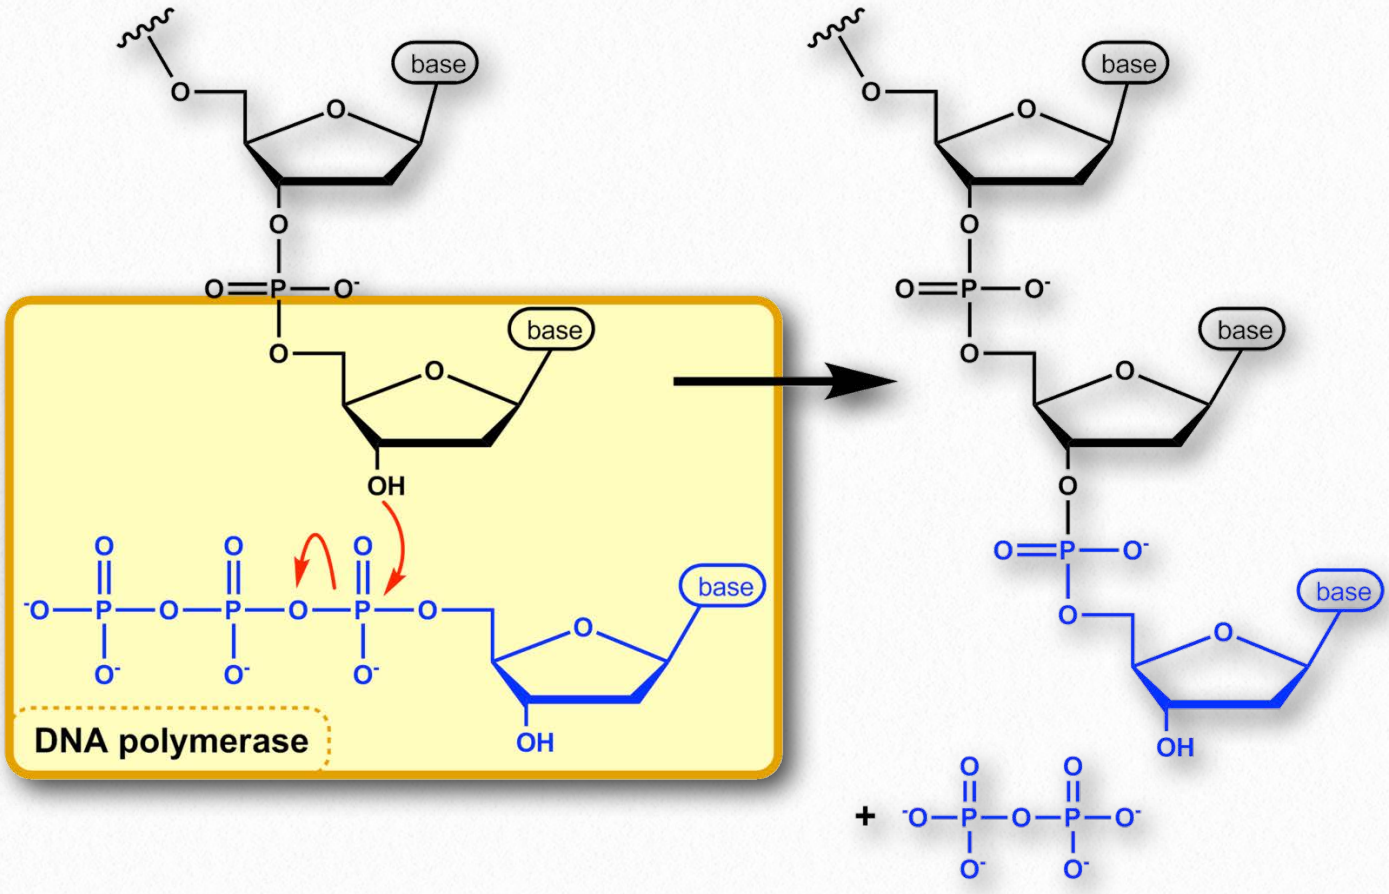

Figure 7.21 - Mechanism of DNA chain growth

Wikipedia

with the replication fork - in fact, it has been described as a seat-belt for the DNA polymerase. The sliding clamp ensures that the DNA polymerase is able to synthesize long stretches of new DNA before it dissociates from the template. The property of staying associated with the template for a long time before dissociating is known as the processivity of the enzyme. In the presence of the sliding clamp, DNA polymerases are much more processive, making replication faster and more efficient.

YouTube Lectures by Kevin HERE & HERE

Extending the primer

The DNA polymerase is now poised to start synthesis of the new DNA strand (in *E. coli*, the primary replicative polymerase is called DNA polymerase III). As you already know, the synthesis of new DNA is accomplished by the addition of new nucleotides complementary to those on the parental strand. DNA polymerase catalyzes the reaction by which an incoming deoxyribonucleotide, complementary to the template, is added onto the 3' end of the previous nucleotide, starting with the 3'OH on the end of the RNA primer. The importance of the 3'OH group lies in the nature of the reaction that builds a chain of nucleotides.

The reaction catalyzed by the DNA polymerase occurs through the nucleophilic attack by the 3'OH group at the end of a nucleic acid strand on the α phosphate of the incoming dNTP (Figure 7.21). The immediate hydrolysis of the pyrophosphate that is cleaved off the incoming dNTP drives the reaction forward. The sequential addition of new

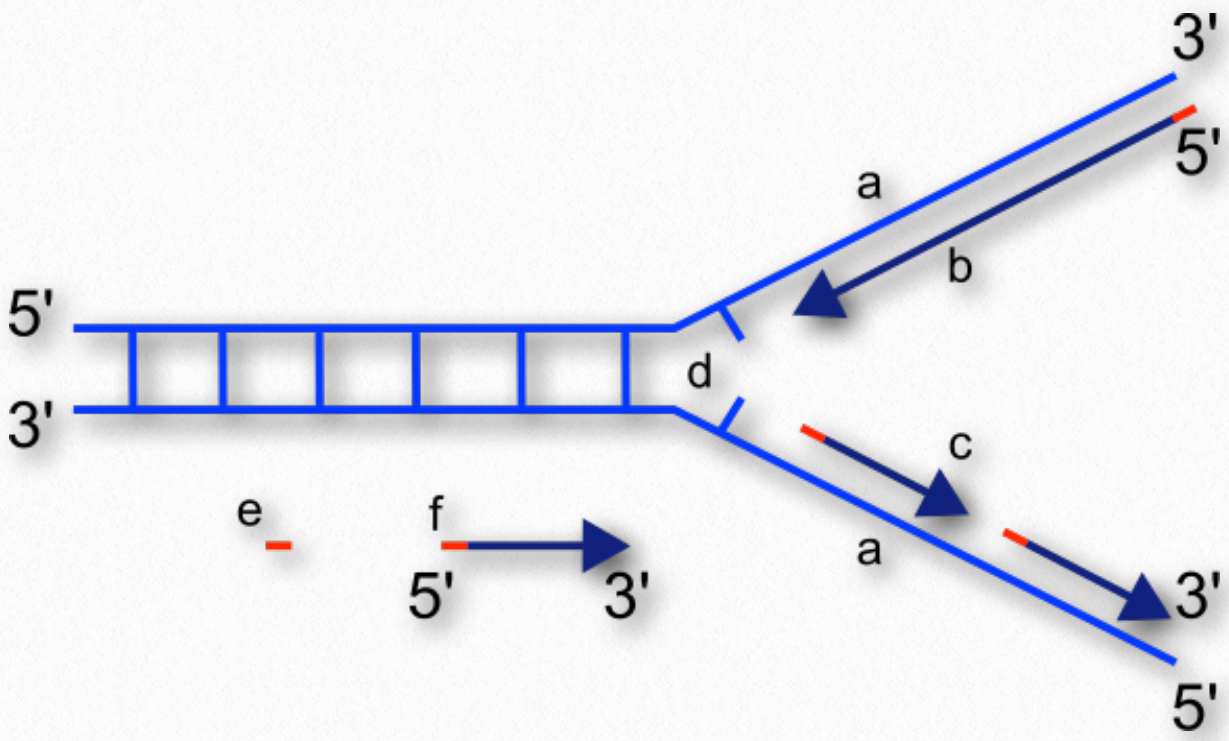

Figure 7.22 - Bidirectional DNA replication with template strand (a), leading strand (b), Okazaki fragments (c), replication fork (d), RNA primer (e), and DNA extended RNA primers (f)

Wikipedia

nucleotides at the 3' end of the growing chain of DNA accounts for the fact that the strand grows in a 5'to 3' direction.

The 5' phosphate on each incoming nucleotide is joined by the DNA polymerase to the 3' OH on the end of the growing nucleic acid chain, to make a phosphodiester bond. Each added nucleotide provides a new 3'OH, allowing the chain to be extended for as long as the DNA polymerase continues to synthesize the new strand. As we already noted, the new DNA strands are synthesized by the addition of DNA nucleotides to the end of an RNA primer. The new DNA molecule thus has a short piece of RNA at the beginning.

•DNA polymerases can only extend a strand in the 5' to 3' direction. The 5' to 3' growth of both new strands means that one of the strands is made in pieces.

Leading strand

We know that DNA polymerases can only build a new DNA strand in the 5' to 3' direction. We also know that the two parental strands of DNA are anti-parallel. This means that at each replication fork, one new strand, called the leading strand can be synthesized continuously in the 5' to 3' direction because it is being made in the same direction that the replication fork is opening up.

Lagging strand

The synthesis of the other new strand, called the lagging strand, also proceeds in the 5' to 3' direction. But because the template strands are running in opposite directions, the lagging strand is being extended in the direction opposite to the opening of the replication fork (Figure 7.22). As the replication fork opens up, the region behind the original start point for the lagging strand will need to be copied. This means another RNA primer must be laid down and extended. This process repeats

itself as the replication fork opens up, with multiple RNA primers laid down and extended, producing many short pieces that are later joined. These short nucleic acid pieces, each composed of a small stretch of RNA primer and about 1000-2000 DNA nucleotides, are called Okazaki fragments, for Reiji Okazaki, the scientist who first demonstrated their existence.

• The use of RNA primers requires that the RNA nucleotides must be removed and replaced with DNA nucleotides.

Primer removal

We have seen that each newly synthesized piece of DNA starts out with an RNA primer, effectively making a new nucleic acid strand that is part RNA and part DNA. The newly made DNA strand cannot be allowed to have pieces of RNA attached. So, the RNA nucleotides must be removed and the gaps filled in with DNA nucleotides (Figure 7.23). This is done by DNA polymerase I in *E. coli*. This enzyme begins adding DNA nucleotides at the end of each Okazaki fragment. However, the end of one Okazaki fragment is adjacent to the RNA primer at the beginning of the next Okazaki fragment. DNA polymerase I has an exonuclease activity acting in the 5' to 3' direction that removes the RNA nucleotides ahead of it, while the polymerase activity replaces the RNA nucleotides with dNTPs. Once all the RNA nucleotides have been re-

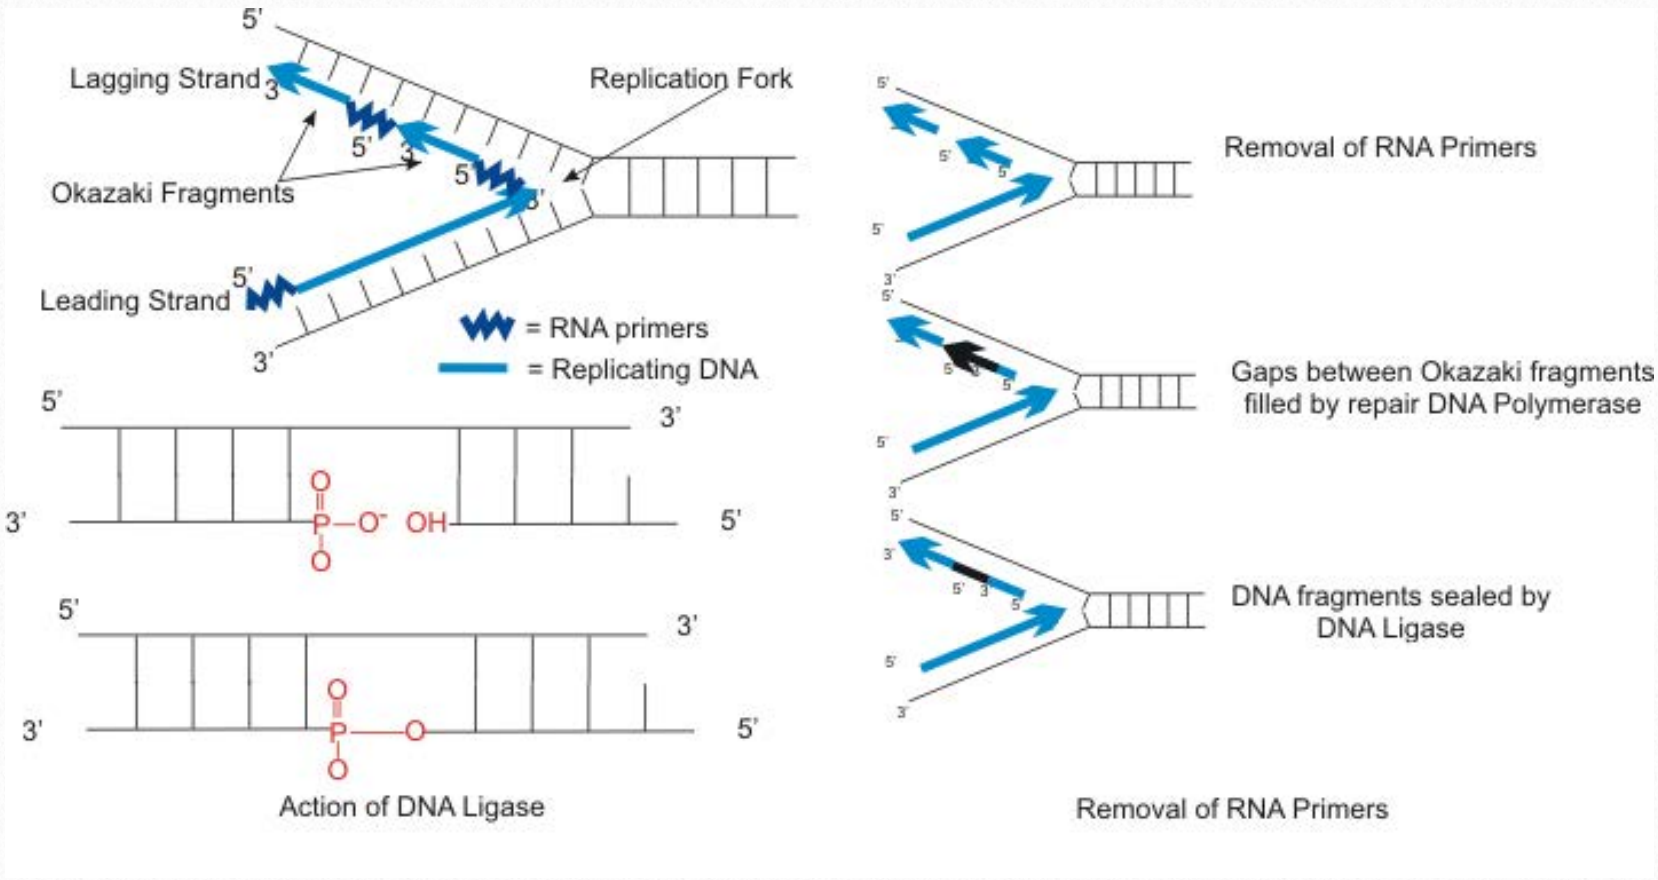

Figure 7.23 - Removal of RNA primers and joining of Okazaki fragments

Wikipedia

moved, the lagging strand is made up of stretches of DNA. The DNA pieces are then joined together by the enzyme DNA ligase.

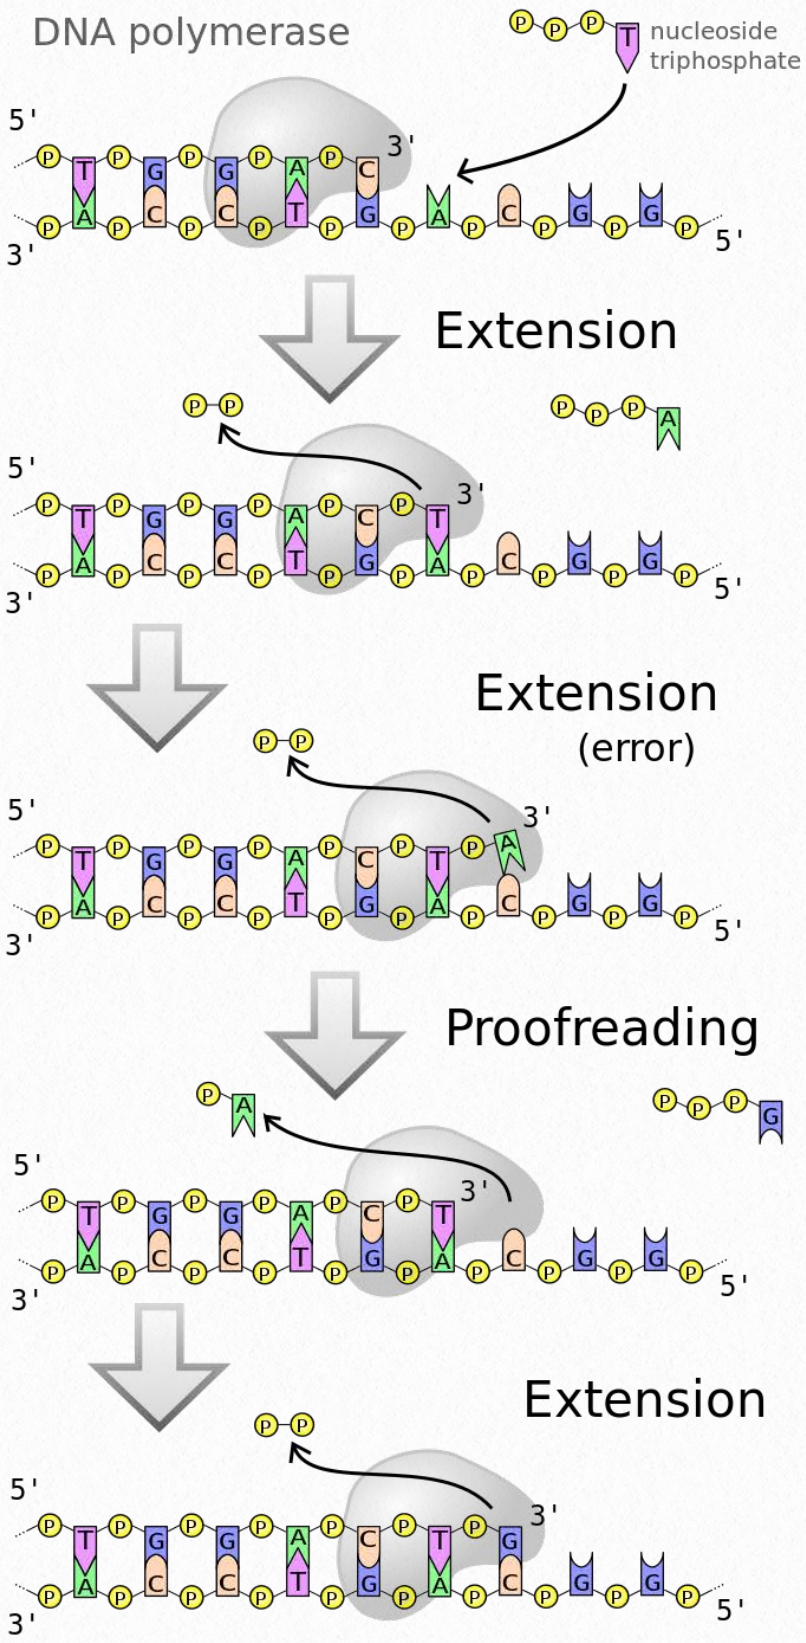

Figure 7.24 - Error corrected by DNA polymerases

The steps outlined above essentially complete the process of DNA replication. But one issue still remains.

- Ensuring accuracy in the copying of so much information

Accuracy

How accurate is the copying of information by DNA polymerase? As you are aware, changes in DNA sequence (mutations) can change the amino acid sequence of the encoded proteins and that this is often, though not always, deleterious to the functioning of the organism. When billions of bases in DNA are copied during replication, how do cells ensure that the newly synthesized DNA is a faithful copy of the original information?

DNA polymerases, as we have noted earlier work fast (averaging 50 bases a second in human cells and up to 200 times faster in *E. coli*). Yet, both human and bacterial cells seem to replicate their DNA quite accurately. This is because replicative DNA polymerases have a proofreading function that enables the polymerase to detect when the wrong base has been inserted across from a template strand, back up and remove the mistakenly inserted base, before continuing with synthesis (Figure 7.24).

Multiple activities

This is possible because most DNA po-

lymerases are dual-function enzymes. They can extend a DNA chain by virtue of their 5' to 3' polymerase activity. Some polymerases like DNA polymerase I can also remove RNA primers in the 5’ to 3’ direction, though that is not a common activity of polymerases. Many polymerases, however have an ability to backtrack and remove the last inserted base because they possess a 3' to 5' exonuclease activity.

The exonuclease activity of a DNA polymerase allows it to excise a wrongly inserted base, after which the polymerase activity inserts the correct base and proceeds with extending the strand.

In other words, the DNA polymerase is monitoring its own accuracy (also termed its *fidelity*) as it makes new DNA, correcting mistakes immediately before moving on to add the next base. This mechanism, which operates during DNA replication, corrects many errors as they occur, reducing by about a 100-fold the mistakes made when DNA is copied.

DNA polymerases

As noted earlier, both prokaryotic and eukaryotic cells have multiple DNA polymerases. In *E.coli*, for example, DNA polymerase III is the major replicative polymerase (a.k.a. replicase) while DNA polymerase I is responsible for DNA repair as well as removal of RNA primers and their replacement with DNA nucleotides during replication. DNA polymerase II plays a role in restarting replication after DNA damage stalls replication, while DNA polymerases IV and V are both required in trans-lesion, or bypass, synthesis, which allows replication past sites of DNA damage.

YouTube Lectures by Kevin HERE & HERE

Eukaryotic polymerases

In eukaryotes, there are over fifteen different DNA polymerases. The primary replicative polymerases in the nucleus are ∂ and ε. DNA polymerase α is also important for replication because it has primase and repair activities. Replication is initiated in eukaryotic cells by DNA polymerase α, which binds to the initiation complex at the origin

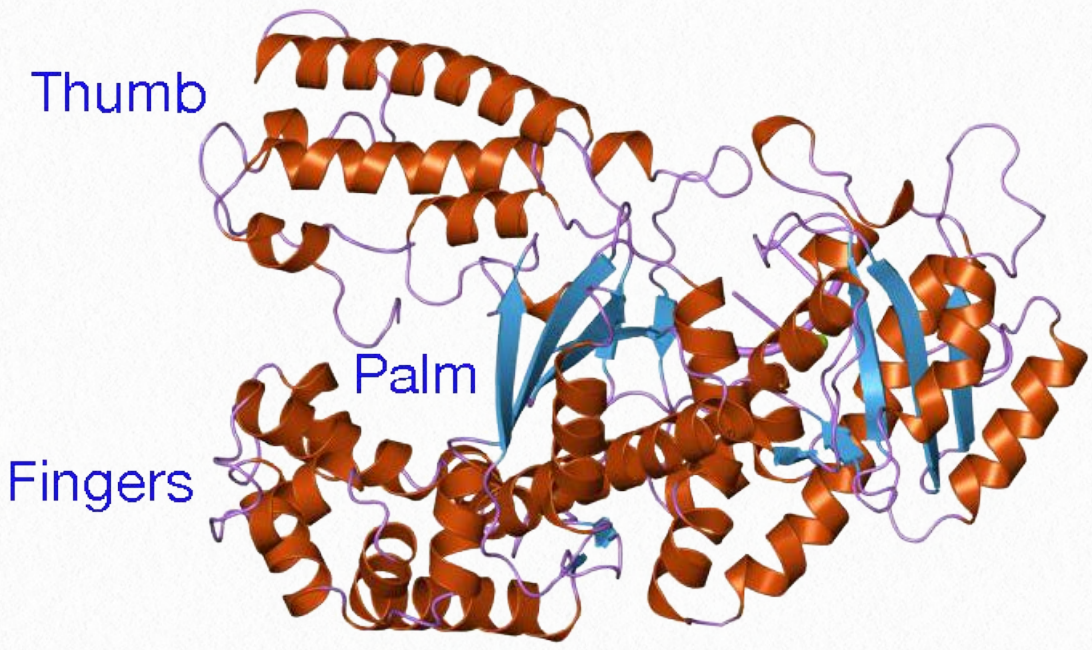

Figure 7.25 DNA polymerase I with hand structure

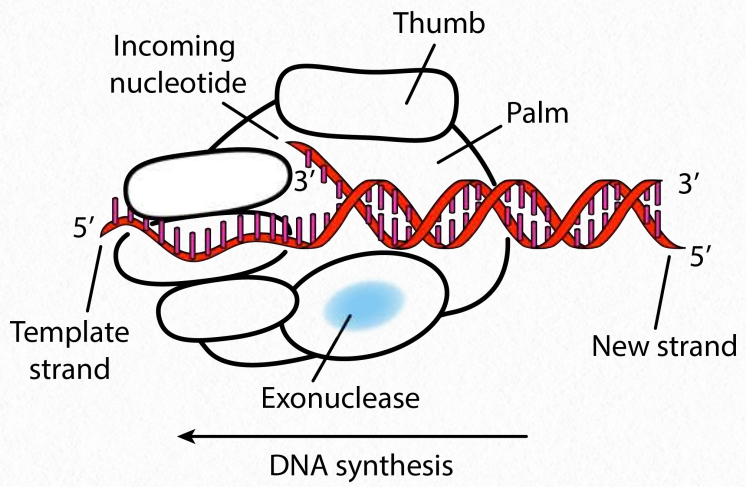
and lays down an RNA primer, followed by about 25 nucleotides of DNA. It is then replaced by another polymerase, in a step called the pol switch. DNA polymerase ∂ or ε then continues synthesizing DNA, depending on the strand. The role of polymerase ε appears to be synthesis of the leading strand due to its high processivity and accuracy, whereas polymerase ∂ extends Okazaki fragments on the lagging strands. Proteins analogous to the clamp loader and sliding clamp are also present. The protein RFC plays the role of clamp loader, while another protein, PCNA acts like the sliding clamp. Several other DNA polymerases like β, γ and μ function in repairing gaps. Yet others are involved in trans-lesion synthesis following DNA damage and are associated with hypermutation.

Despite their diversity, DNA polymerases share some common structural features. X-ray crystallographic studies have shown that these enzymes have a structure that has been compared to a human right hand (Figures 7.25 & 7.26). The «palm» of the hand forms a cleft in which the DNA lies. The cleft is also the where the polymerase catalytic activity resides. This is where the incoming nucleotide is added on to the growing chain. «The fingers» position the DNA in the active site, while the «thumb» holds the DNA as it exits the polymerase. A separate domain contains the exonuclease (proofreading) activity of the enzyme.



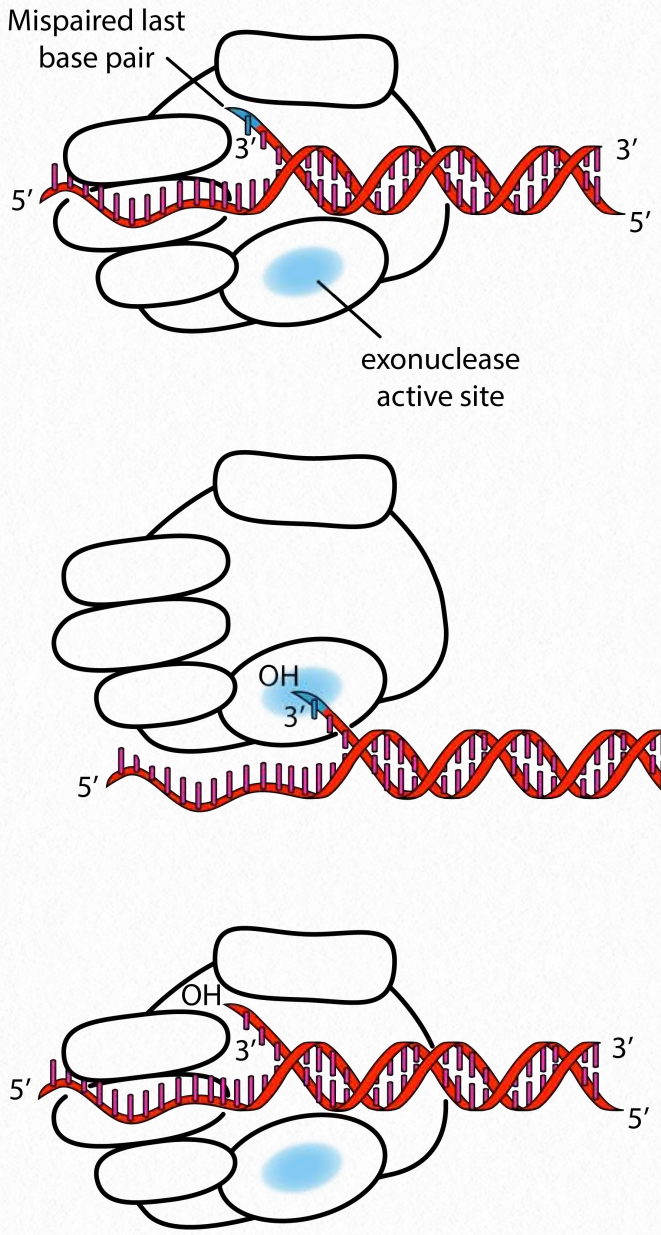


Figure 7.26 - Proofreading by DNA polymerase

Image by Pehr Jacobson

The enzyme alternates between its polymerizing activity and its proofreading activity.

Figure 7.27 - **Mammalian DNA polymerases**

When a mismatched base pair is in the polymerase catalytic site, the 3'end of the growing strand is moved from the polymerase site to the exonuclease active site (Figure 7.26). The mispair at the end is removed by the exonuclease, followed by repositioning of the 3' end in the polymerase active site to continue synthesis.

Termination of replication

In circular bacterial chromosomes, there are specific sequences known as terminator or Ter sites. These are multiple short sequences that serve as termination sites, allowing the replication forks traveling clockwise and anticlockwise across the circular chromosome to meet at one of the sites.

The binding of a protein, Tus, at a Ter site prevents further movement of the replication fork and ends replication. The parental and newly made circular DNA are, at this point topologically interlinked and must be separated with the help of topoisomerase.

The end-replication problem

There is no fixed site for termination in linear eukaryotic chromosomes. As the replication forks reach the ends of the chromosome, the leading strand can be synthesized all the way to the end of the template strand. On the lagging strand, the need for an RNA primer to start synthesis creates a challenge. When the RNA primer at the extreme end of the lagging strand is removed, there is a small stretch of the template strand

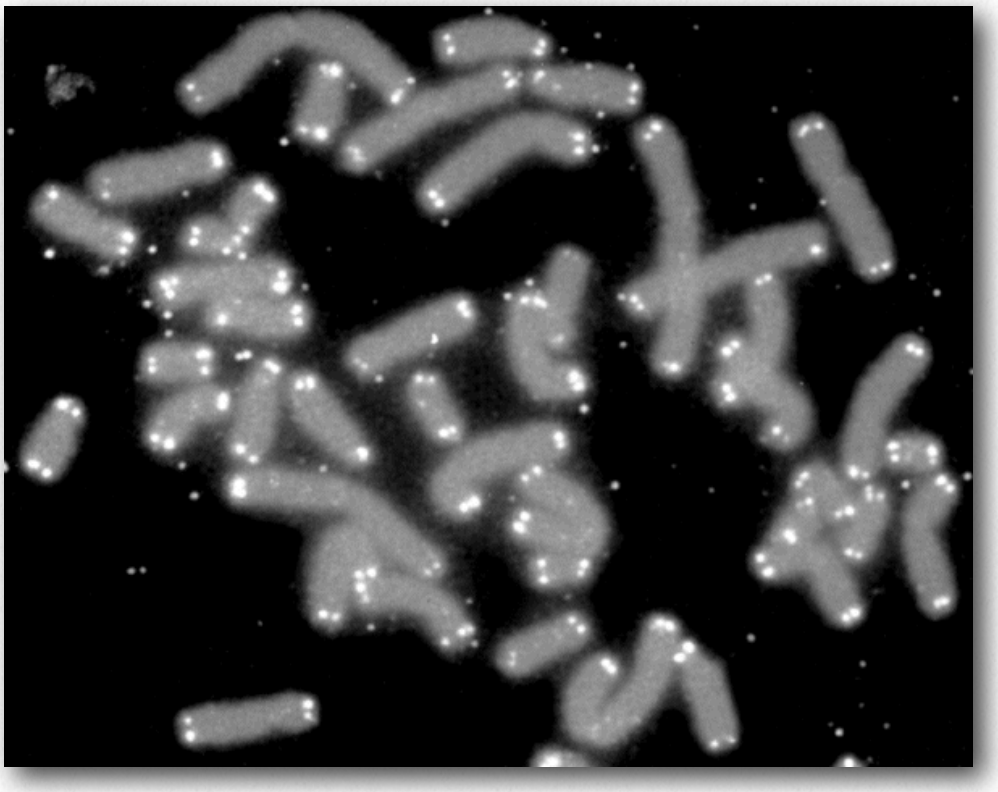

Figure 7.28 - Chromosomes with telomeres marked in white

that cannot be copied. As a result, in each round of replication a short sequence at the ends of the chromosome will be lost. Over time, with many cycles of replication, chromosomes would become noticeably shorter. This shortening of chromosomes has been observed *in vitro*, in cultured mammalian somatic cells. It is also seen in intact organisms, with increasing age.

Telomeres

What effect does the loss of sequence from the ends of the chromosomes have on cells? We know that the ends of chromosomes are characterized by structures called telomeres (Figure 7.28). Telomeres are made up of many copies of short repeated sequences (in humans, the repeat is TTAGGG) and special proteins that specifically bind to these sequences. This structure of telomeres is useful in distinguishing the ends of chromosomes from double-strand breaks in DNA, thus preventing the DNA repair mechanisms in cells from joining chromosomes end to end.

The other advantage of the repeated sequences, which do not encode proteins, is that losing some of the repeats does not lead to loss of important coding information. Thus, the repeats act as a sort of buffer zone, where the loss of sequence does not doom the cell. However, the shortening of chromosomes cannot continue indefinitely. After a certain number of replication cycles, cells are known to stop dividing and enter a state known as replicative senescence. This suggests that the shortening of the telomeres serves as a sort of clock, with the extent of shrinkage of the chromosomes serving as a measure of aging. Eventually cells that enter senescence will die.

Problems with sequence loss

Even if our cells are able to function with shorter chromosomes during our lifetimes, this leaves us with another problem. If our chromosomes grow shorter with age, then presumably our children, who inherit our chromosomes will be born with shorter chromosomes than we started with. They, in turn, would have their chromosomes shrink as they

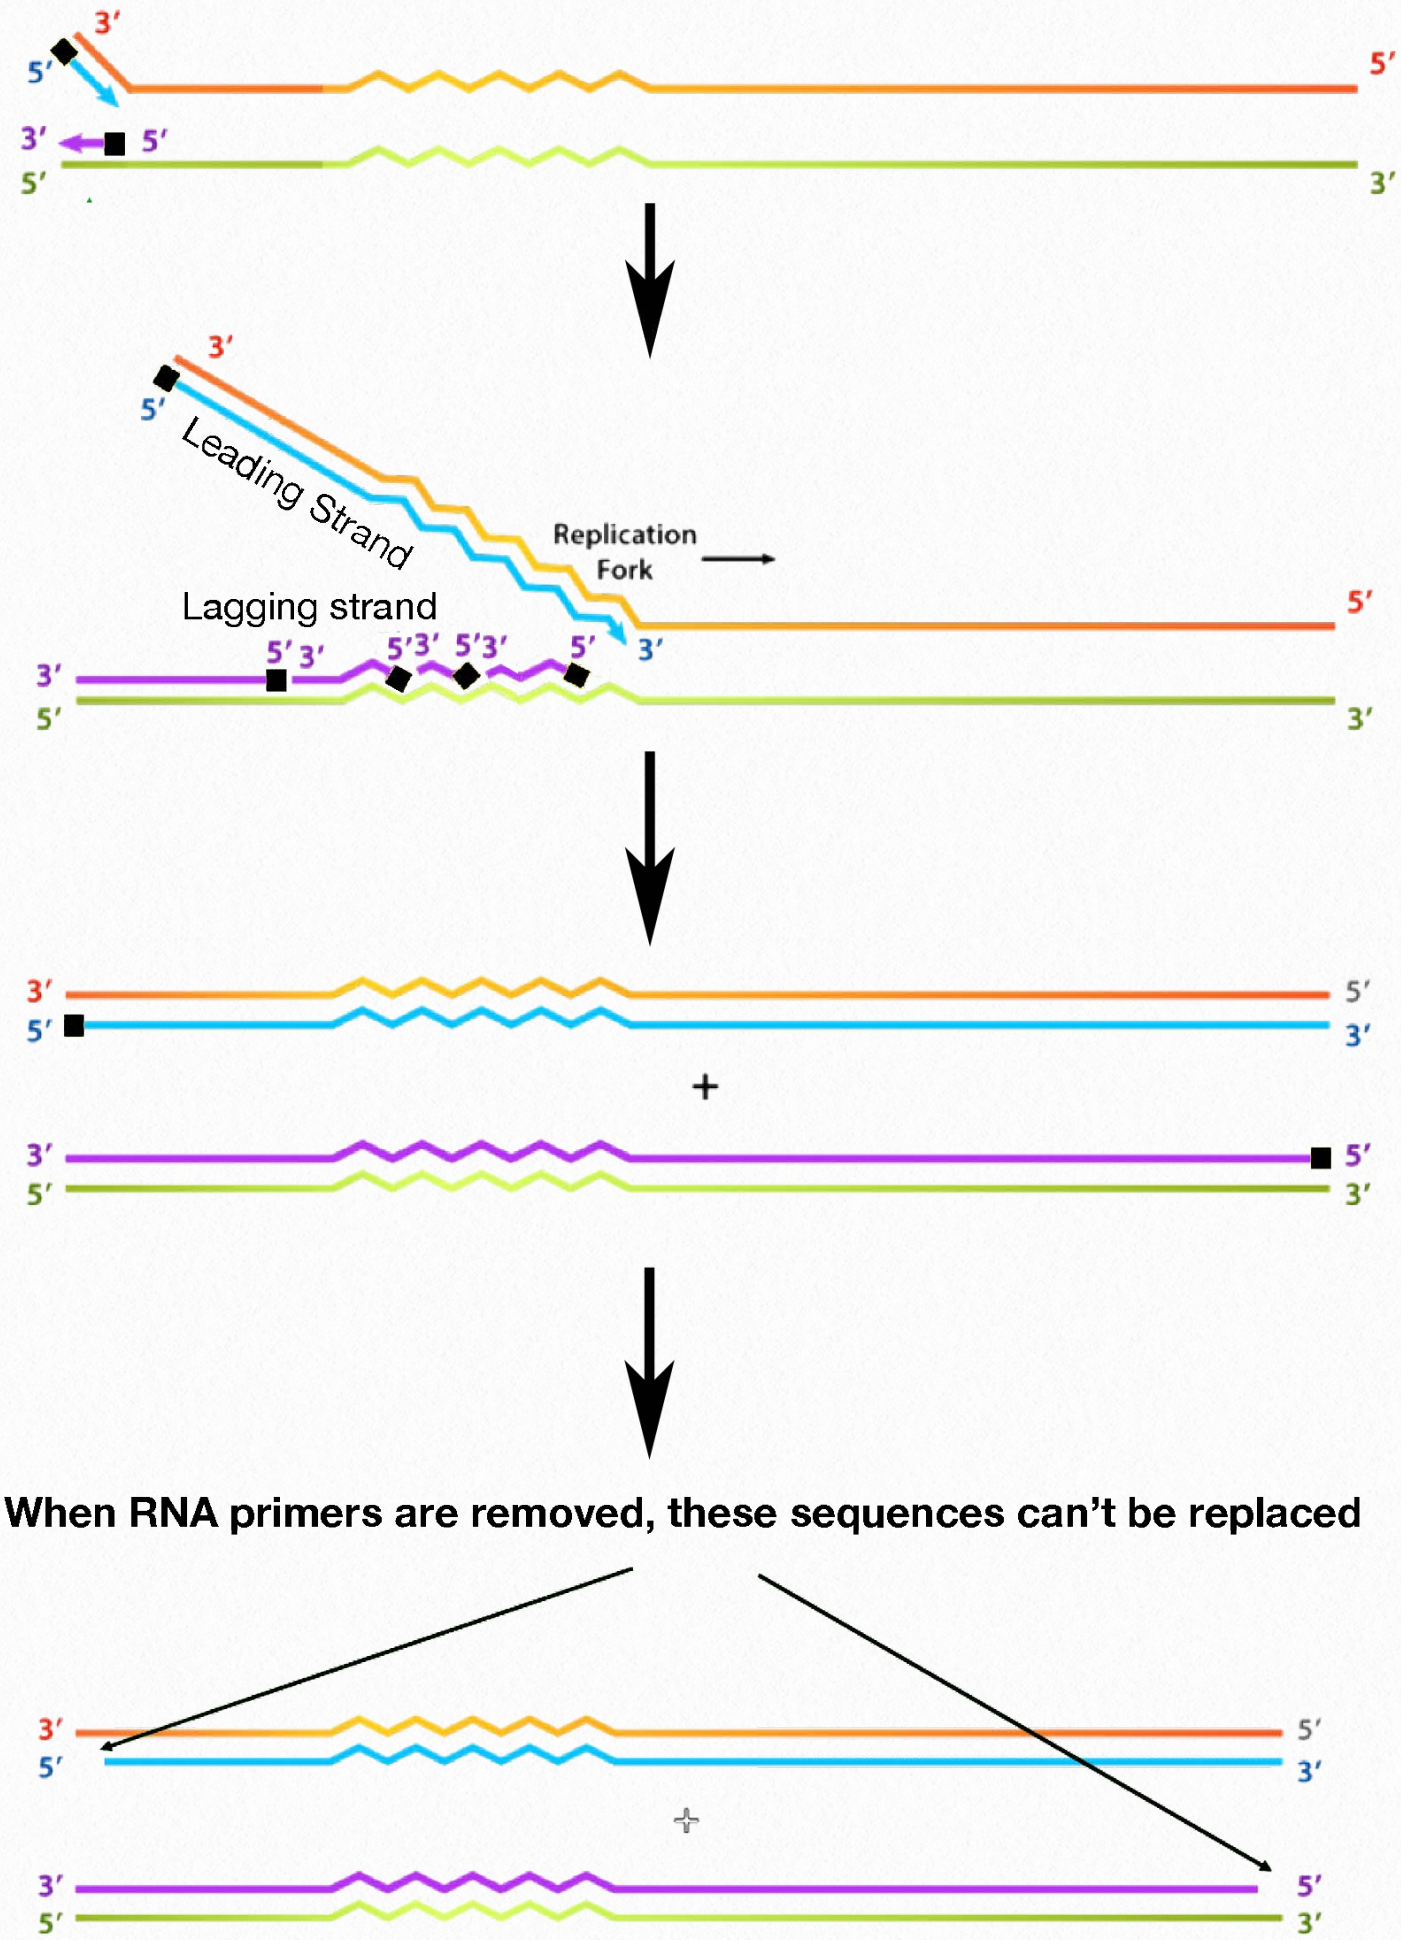

Figure 7.29 - Replication of a linear chromosome results in loss of sequences at the very ends with each round of replication

grew older, and their children would have even shorter chromosomes. Over the course of multiple generations, this would lead to the point where further chromosome shrinkage would result in cells that would enter senescence very early in life and die soon after. This obviously does not happen. Generation after generation of children are born with full-length chromosomes, so there is a mechanism that must ensure that at least in the reproductive cells, chromosomes do not get shorter.

To understand this mechanism, it is necessary to first examine the end of a newly made DNA molecule (Figure 7.29). While the leading strand, which grows in the same direction as the movement of the replication fork, can copy its template all the way to the end, the lagging strand encounters a problem. RNA primers are, as we noted, needed to start each of the Okazaki fragments of the lagging strand. The primers must be removed later, and the RNA nucleotides replaced with DNA nucleotides. When the RNA primer across from the end of the parental strand is removed, the RNA nucleotides cannot be replaced by DNA nucleotides because the DNA polymerase has no primer to start from. A short region of the template cannot, therefore be copied.

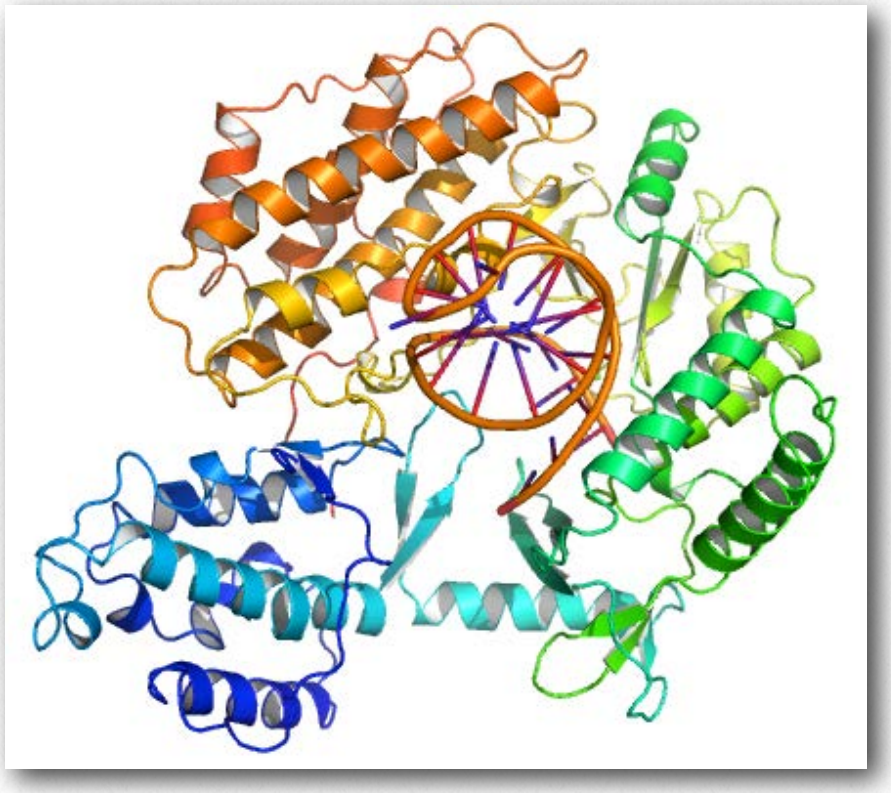

Figure 7.30 - Telomerase holding its RNA template (in center)

Wikipedia

YouTube Lectures by Kevin HERE & HERE

Telomerase

How can this problem be solved? It can be seen from Figure 7.29 that the end of the original template strand has a short 3' overhang resulting from the removal of the RNA primer across from it. In order to fill in this region, another primer would be needed, situated past the end of the template strand. But in order to build such a primer, it would be necessary for the template overhang to be longer. If it were possible to make the template strand longer, then another primer could be placed across from its end and the end of the strand could be copied. Such an extension of the template strand is exactly what happens in our reproductive cells. The parental template strand is extended by the enzyme telomerase, which adds telomere repeats and lengthens the template. We will see shortly how it accomplishes that feat.

RNA template

Telomerase is an unusual enzyme, in that it is made up of two components, an RNA and a reverse transcriptase. A reverse transcriptase is an RNA-dependent DNA polymerase, an enzyme that copies an RNA template to make DNA. The RNA component of the human telomerase, called hTERC, has a sequence that is complementary to the telomere repeat, TAGGG. As seen in Figure 7.31, this RNA can base-pair with the last telomere repeat on the parental DNA strand, while a portion of the RNA remains unpaired.

Template for extension

The function of the unpaired region of the RNA is to serve as a template that can be used to extend the overhanging 3' end of the original DNA molecule. The protein component of telomerase has reverse transcriptase activity and can copy the RNA sequence into DNA. In human telomerase, the protein component is known as hTERT (telomerase reverse transcriptase). As seen in Figure 7.31 and 7.32, the reverse transcriptase extends the original 3' overhang using the RNA component as its template. The telomerase can then dissociate, and repeat the process multiple times to add many repeats of the telomere sequence.

Once the overhang has been extended by the addition of at least several telomere repeats, there is now room for the synthesis of an RNA primer complementary to the newly extended overhang (pointing back towards the rest of the chromosome). This primer can then be extended to complete synthesis of the lagging strand all the way to the end of the original parental DNA strand. Thus, the addition of telomere repeats on the parental DNA strands keeps the newly made DNA strands from becoming shorter with each cycle of replication. The fact that this happens in germ cells (reproductive cells) explains why each generation does not have shorter chro-

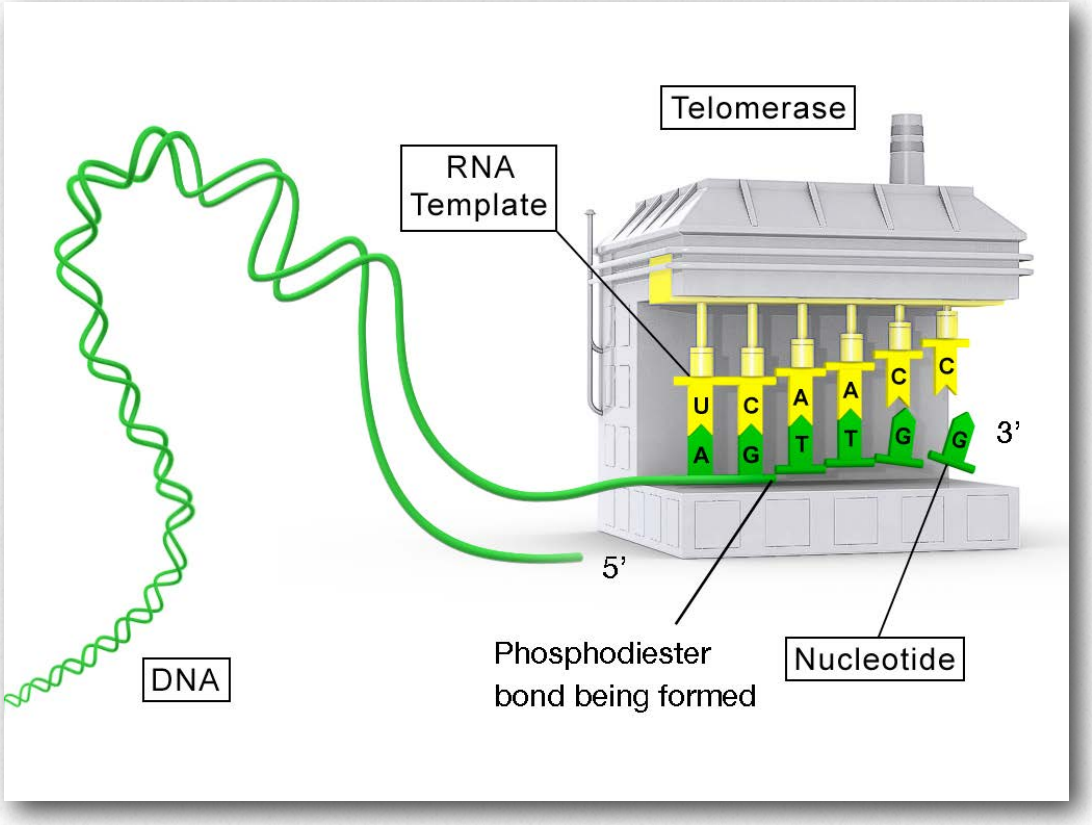

Figure 7.31 - Telomerase extends the template strand using its own RNA as template

Wikipedia

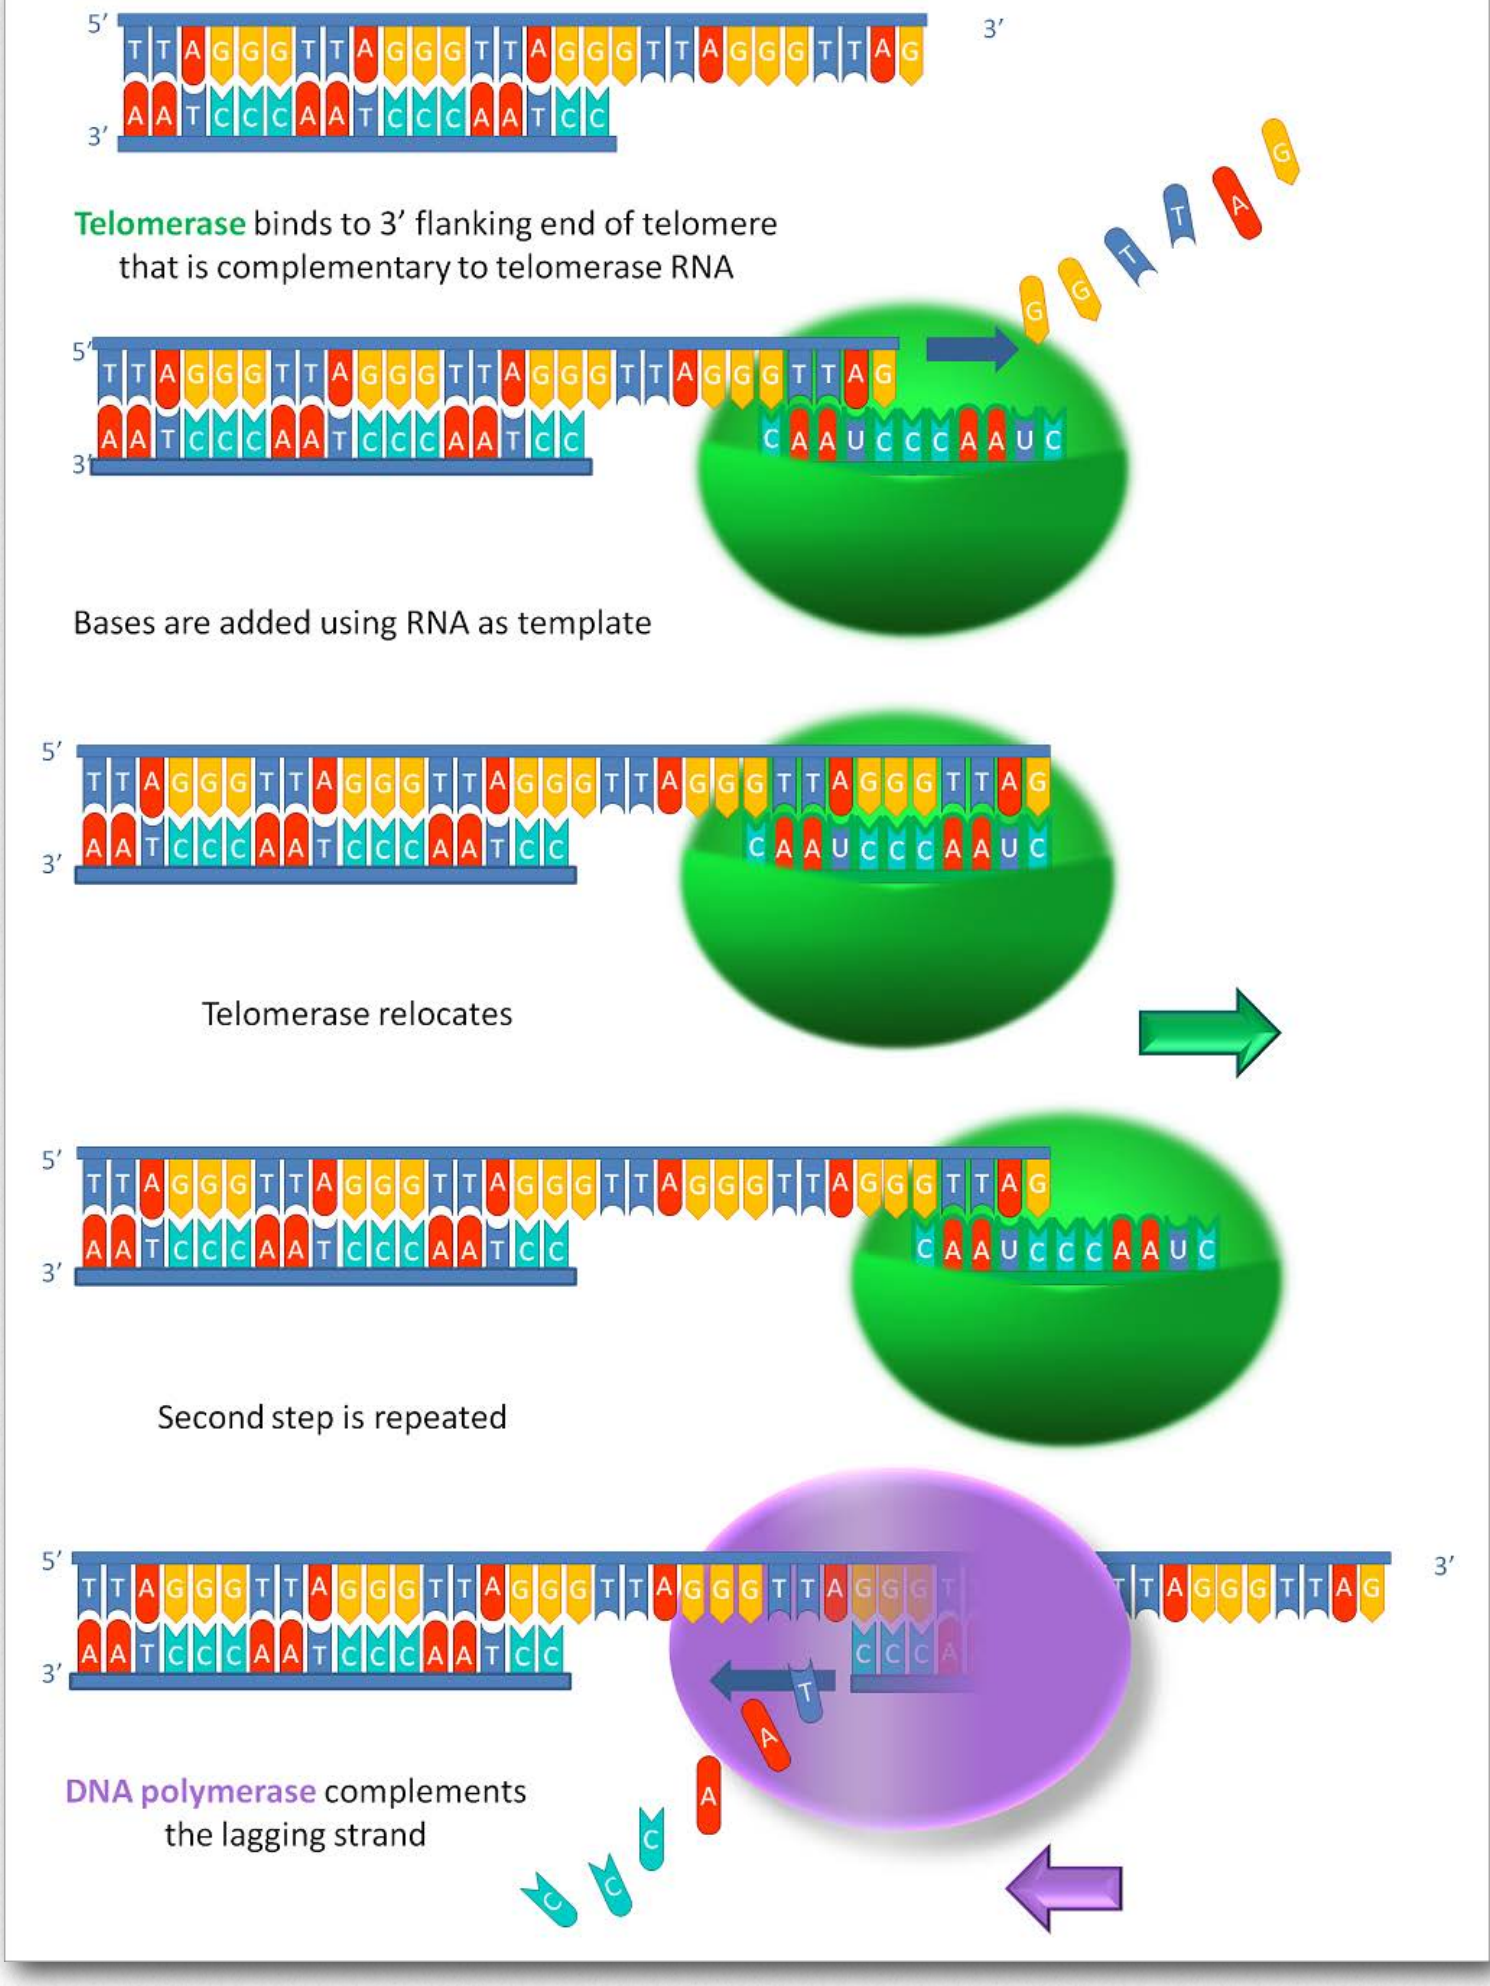

Figure 7.32 - Growing telomeres with telomerase and DNA polymerase. First, the 3' end of the template is extended by telomerase, then DNA polymerase completes synthesis of the lagging strand

Wikipedia

mosomes than the parental generation.

The proofreading function of DNA polymerases monitors the accuracy of DNA replication while the enzyme telomerase keeps chromosomes that will be passed on to offspring from shortening. Between them, these two activities ensure that the genetic information is copied accurately, and that succeeding generations receive a full complement of the genetic information

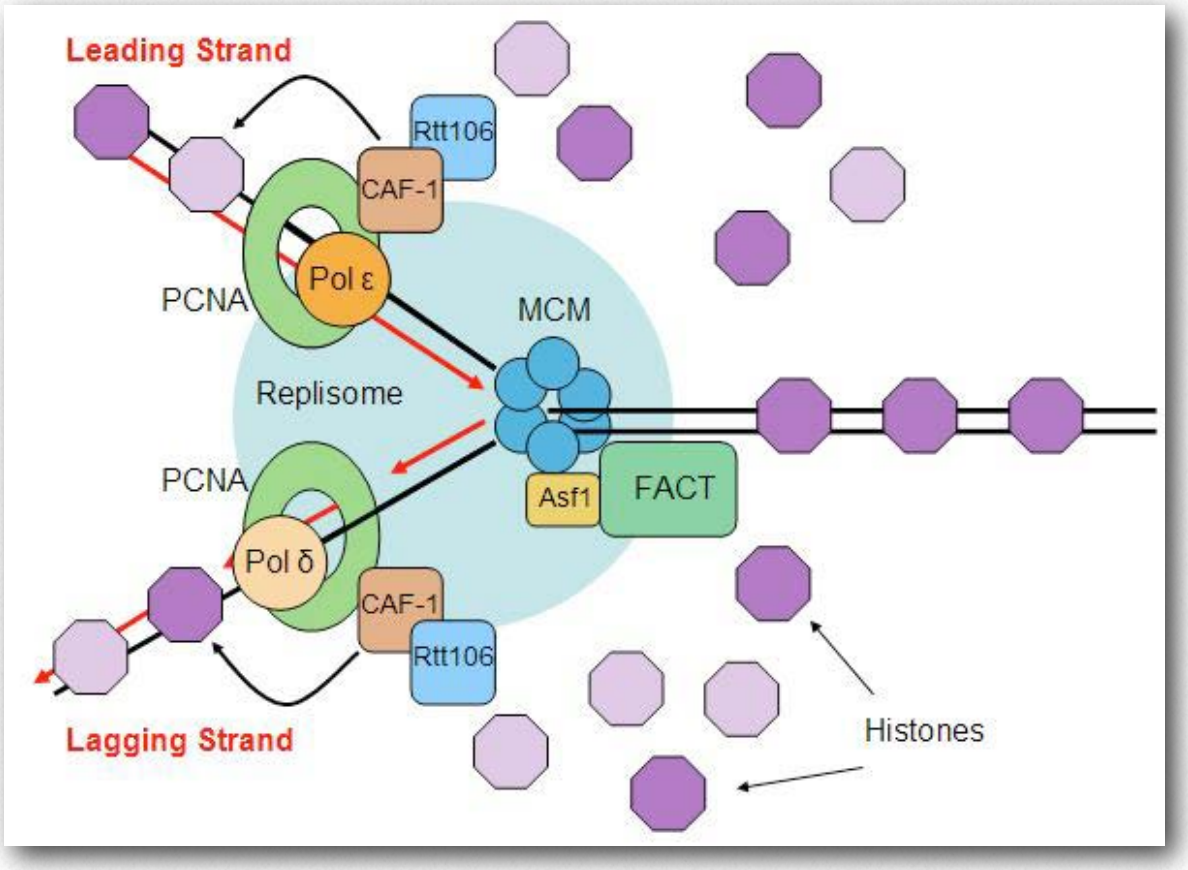

Figure 7.33 - Disruption of nucleosomes during DNA replication

Wikipedia

Disassembly and reassembly of nucleosomes

The events of replication have an additional twist in eukaryotes. Recall that DNA is found in eukaryotic cells as chromatin, a complex of the DNA with proteins. At its least condensed, chromatin looks like a string of beads, consisting of the DNA wrapped around histone cores to make nucleosomes. The nucleosome structure must be disrupted to make DNA available for replication and restored after replication is completed (Figure 7.33).

YouTube Lectures by Kevin HERE & HERE

Ahead of the replication fork, chromatin structure is disassembled by ATP-dependent chromatin remodeling complexes, allowing access to the DNA template. Once the new strands of DNA have been synthesized, both the original nucleosomes and new nucleosomes must be reassembled behind the replication fork. Since replication gives rise to two DNA molecules where there was one, twice the amount of histones is needed to package the DNA. Preparation for DNA replication, therefore, involves the synthesis of large amounts of histones to supply the need. Interestingly, it appears that newly synthesized DNA is packaged into nucleosomes using the original histones

that were displaced to allow the replication fork to pass, as well as newly synthesized histones.

We also know that post-translational modifications like acetylation, methylation or phosphorylation of the histones can regulate the degree to which a given region of the genome is accessible for use. One question that remains the subject of intense research is how these modifications are accurately passed on to the new nucleosomes.

Information Processing: DNA Repair

Safeguarding the genome

In the last section we considered the ways in which cells deal with the challenges associated with replicating their DNA, a vital process for all cells. It is evident that if DNA is the master copy of instructions for an organism, then it is important not to make mistakes when copying the DNA to pass on to new cells. Although proofreading by DNA polymerases greatly increases the accuracy of replication, there are additional mechanisms in cells to further ensure that newly replicated DNA is a faithful copy of the original, and also to repair damage to DNA during the normal life of a cell.

YouTube Lectures by Kevin HERE & HERE

DNA damage

All DNA suffers damage over time, from exposure to ultraviolet and other radiation, as well as from various chemicals in the environment (Figures 7.34 & 7.35). Even chemical reactions naturally occurring within cells can give rise to compounds that can damage DNA. As you already know, even minor changes in

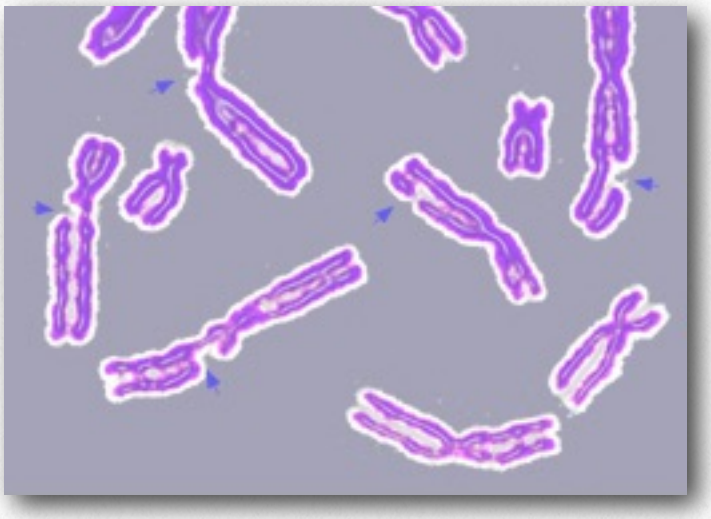

Figure 7.34 - Chromosome breaks

Wikipedia

DNA sequence, such as point mutations can sometimes have far-reaching consequences. Likewise, unrepaired damage caused by radiation, environmental chemicals or even normal cellular chemistry can interfere with the accurate transmission of information in DNA. Maintaining the integrity of the cell's "blueprint" is of vital importance and this is reflected in the numerous mechanisms that exist to repair mistakes and damage in DNA.

Post-replicative mismatch repair

We earlier discussed proofreading by DNA polymerases during replication. While proofreading significantly reduces the error rate, not all mistakes are fixed on the fly by DNA polymerases.

What mechanisms exist to correct the replication errors that are missed by the proofreading function of DNA polymerases? Errors that slip by proofreading during replication can be corrected by a mechanism called mismatch repair. While the error rate of DNA replication is about one in 10^7 nucleotides in the absence of mismatch repair, this is further reduced a hundred-fold to one in 10^9 nucleotides when mismatch repair is functional.

What are the tasks that a mismatch repair system faces?

It must:

- Scan newly made DNA to see if there are any mispaired bases (e.g., a G paired to a T)
- Identify and remove the region of the mismatch.
- Correctly fill in the gap created by the excision of the mismatch region.

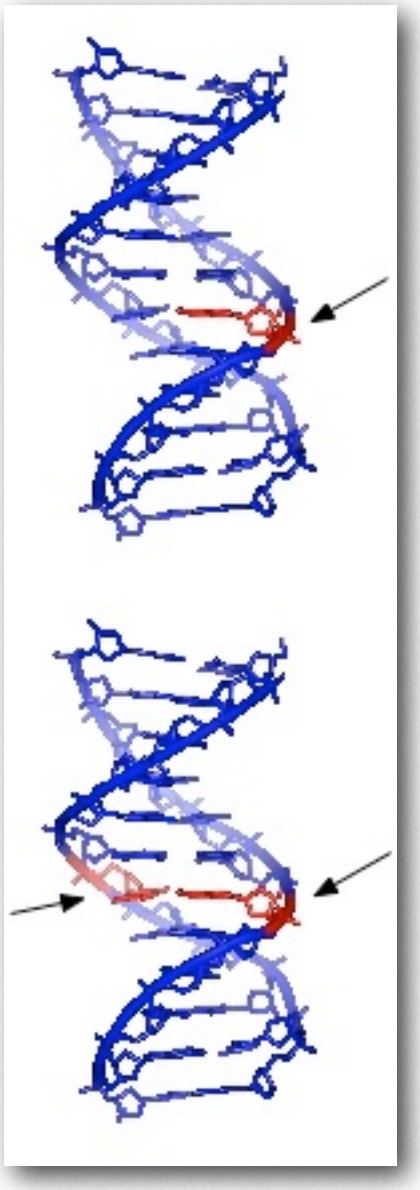

Figure 7.35 - Single- (top) and double-strand (bottom) damaged DNA

Wikipedia

Distinguishing strands

Importantly, the mismatch repair system must have a means to distinguish the newly made DNA strand from the template strand, if replication errors are to be fixed correctly. In other words, when the mismatch repair system encounters an A-G mispair, for example, it must know whether the A should

be removed and replaced with a C or if the G should be removed and replaced with a T.

But how does the mismatch repair system distinguish between the original and the new strands of DNA? In bacteria, the existence of a system that methylates the DNA at GATC sequences is the solution to this problem. *E.coli* has an enzyme, DNA adenine methylase (Dam) that adds methyl groups on the to adenines in GATC sequences in DNA (Figure 7.36). Newly replicated DNA has not yet undergone methylation and thus, can be distinguished from the template strand, which is methylated.

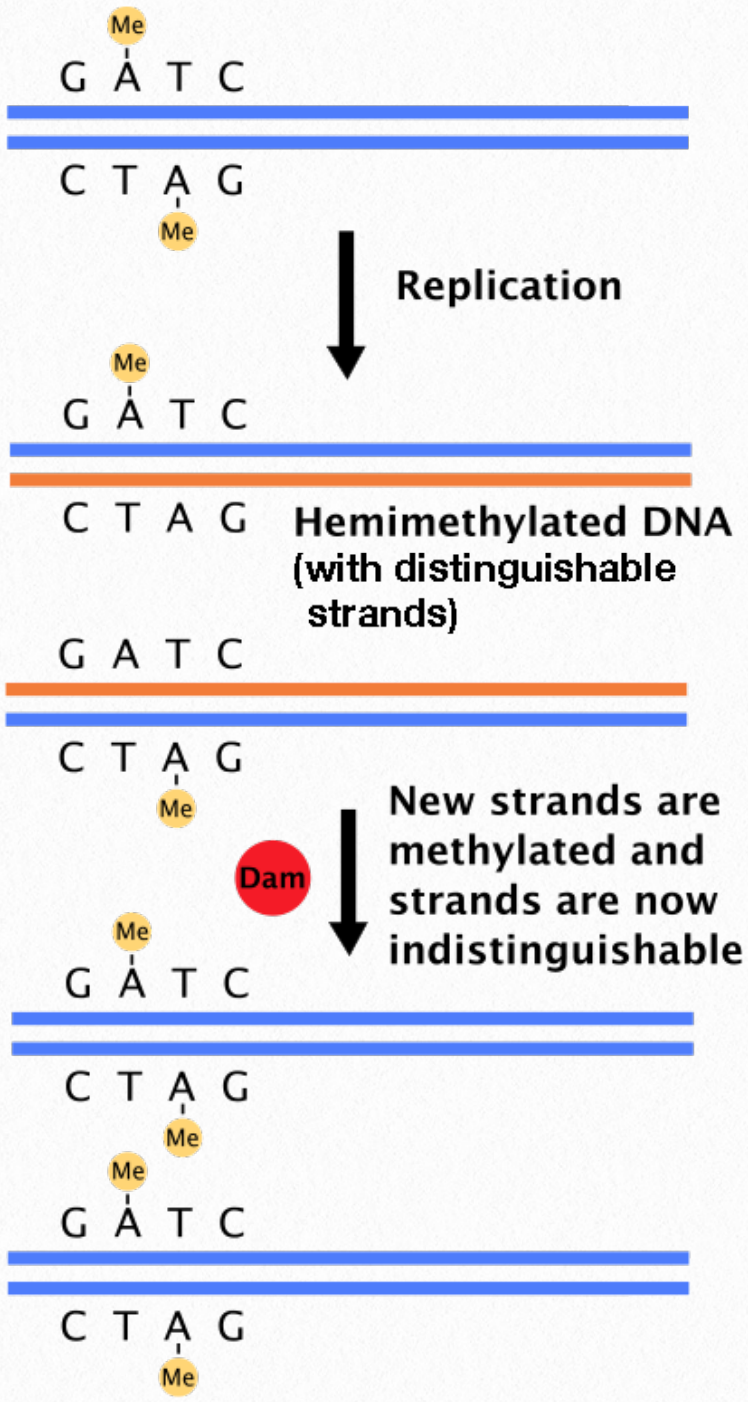

Figure 7.36- Dam methylase adds methyl groups at GATC sequences

The mismatch repair proteins selectively replace the strand lacking methylation, thus ensuring that it is mistakes in the newly made strand that are removed and replaced. Because methylation is the criterion that enables the mismatch repair system to choose the strand that is repaired, the bacterial mismatch repair system is described as being *methyl-directed*.

Mismatch repair genes

Mismatch repair has been well studied in bacteria, and the proteins involved have been identified. In *E.coli*, mismatch repair proteins are encoded by a group of genes collectively known as the mut genes. Important components of the mismatch repair machinery are the proteins MutS, MutL and MutH (Figure 7.37).

MutS acts to recognize the mismatch, while MutL and MutH are recruited to the mismatch site by the binding of MutS. MutH is an endonuclease that cuts the newly synthesized and, as yet, unmethylated DNA strand at a GATC. This activates a DNA helicase and an exonuclease that help unwind and remove the region containing the mismatch.

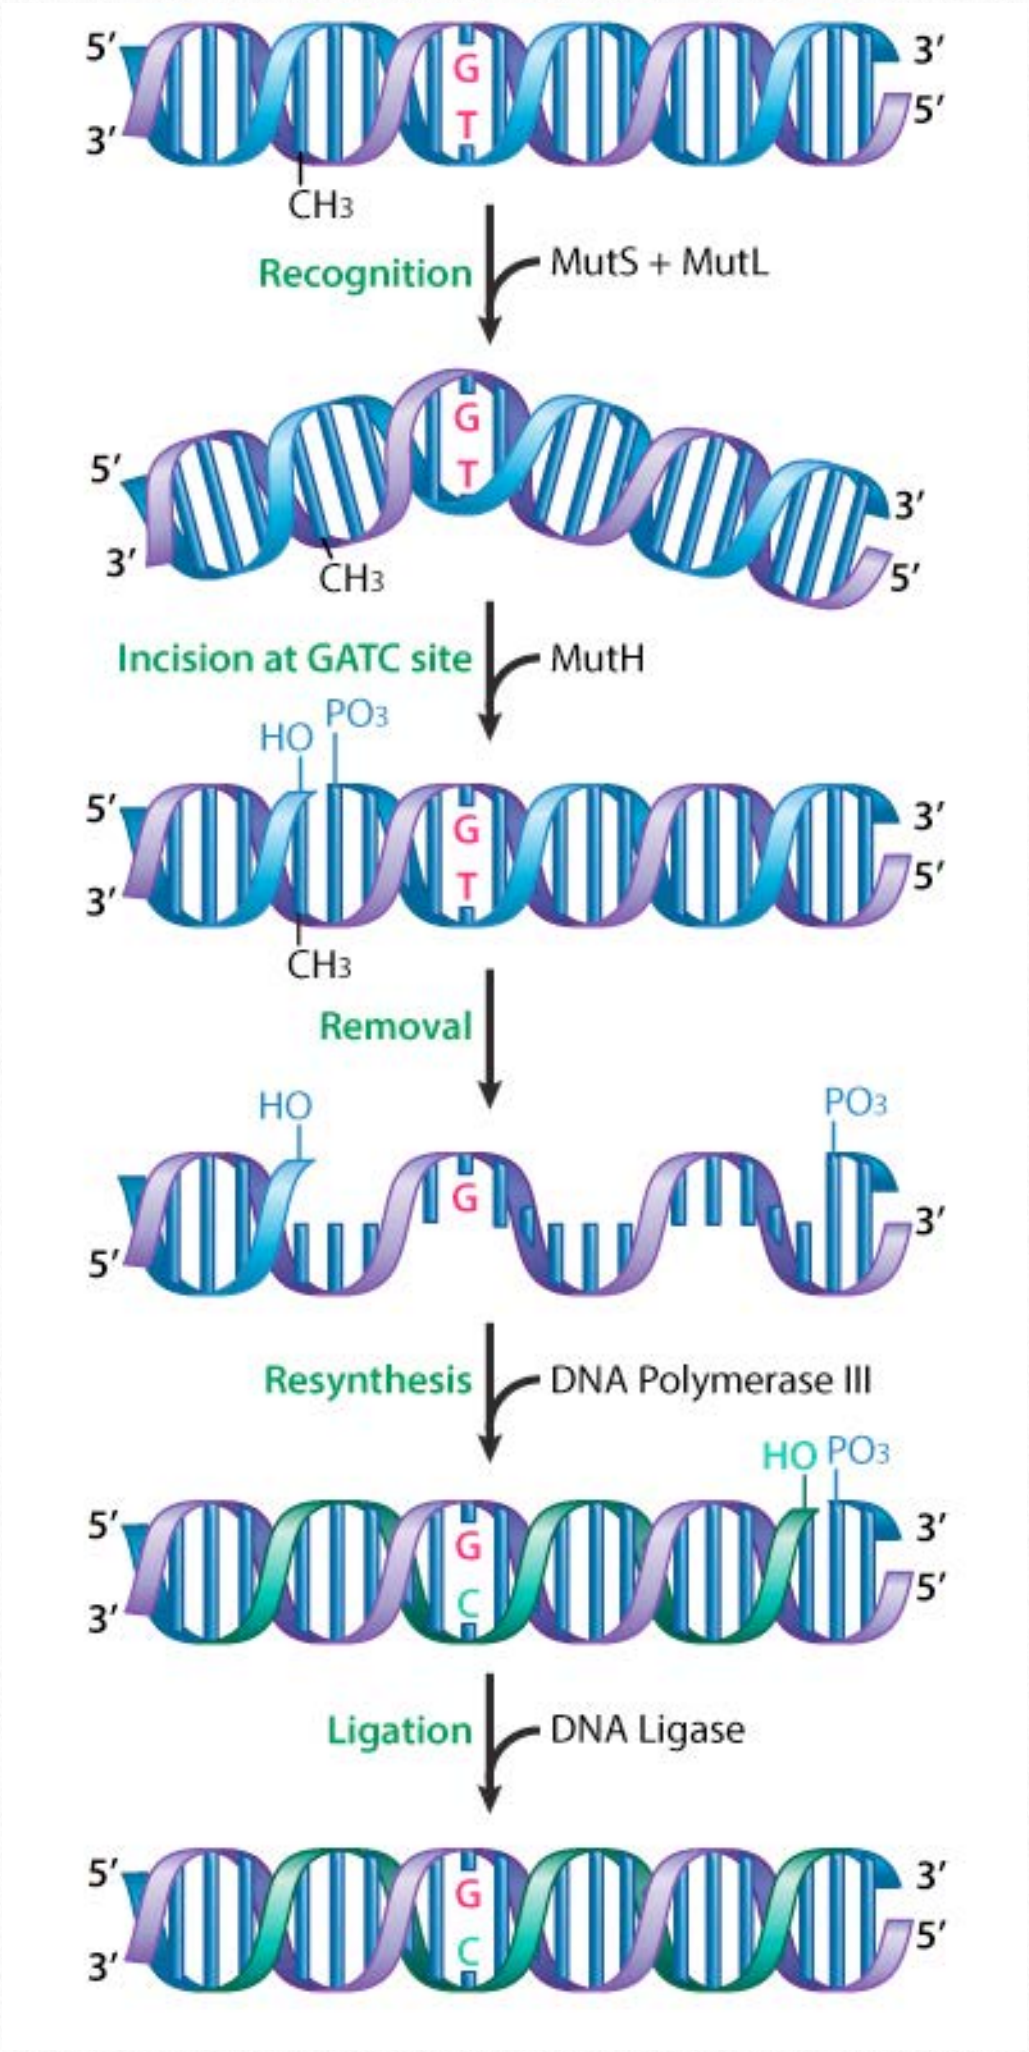

Figure 7.37 - Mismatch repair in *E. coli*

Image by Aleia Kim

DNA polymerase III fills in the gap, using the opposite strand as the template, and ligase joins the ends, to restore a continuous strand.

Eukaryotes also have a mismatch repair system that repairs not only single base mismatches but also insertions and deletions. Homologs to the *E. coli* MutS and MutL have been identified in other organisms, including humans: hMSH1 and hMSH2 (human MutS homolog 1 and 2) are homologous to MutS, while hMLH 1 is homologous to MutL. These, together with additional proteins, carry out mismatch repair in eukaryotic cells.

DNA methylation is not used by eukaryotic cells as a way to distinguish the new strand from the template, and it is not yet completely understood how the mismatch repair system in eukaryotes "knows" which strand to repair. There is evidence that the newly made DNA may be recognized by the fact that it is nicked, or discontinuous. This suggests that discontinuity resulting from Okazaki fragments that have not yet been joined together may permit the new strand to be distinguished from the old, continuous template strand.

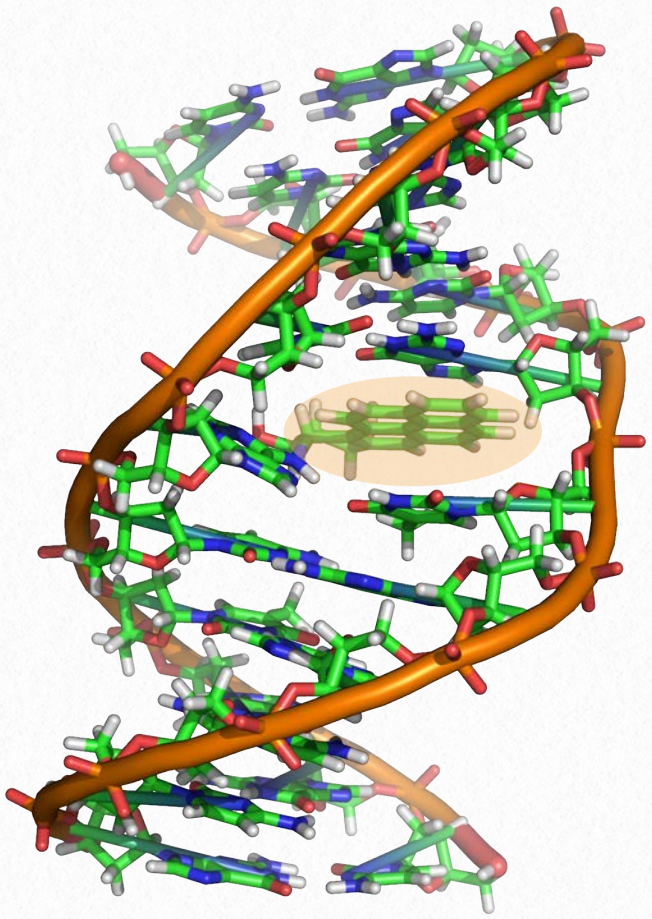

Figure 7.38 - DNA adducted to benz-o-pyrene (highlighted in orange)

Repairing damage to DNA

In the preceding section we looked at mistakes made when DNA is copied, where the wrong base is inserted during synthesis of the new strand. But even DNA that is not being replicated can get damaged or mutated. These sorts of damage are not associated with DNA replication, rather they can occur at any time.

What causes damage to DNA?

Some major causes of DNA damage are:

YouTube Lectures by Kevin HERE & HERE

a. Radiation (e.g., UV rays in sunlight and in tanning booths, or ionizing radiation)

b. Exposure to damaging chemicals, such as nitrosamines or polycyclic aromatic hydrocarbons, in the environment (see Figure 7.38)

c. Chemical reactions within the cell (such as the deamination of cytosine to give uracil, or the methylation of guanine to produce methylguanine).

This means the DNA in your cells is vulnerable to damage simply from normal sorts of actions, such as walking outdoors, being in traffic, or from the chemical transformations occurring in every cell as part of its everyday activities. (Naturally, the damage is much worse in situations where exposure to radiation or damaging chemicals is greater, such as when people use tanning beds, or smoke, regularly.)

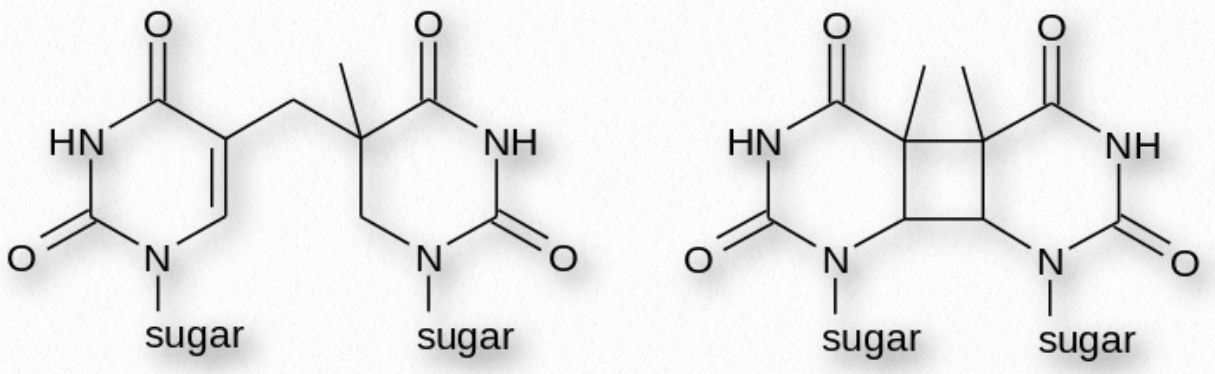

Figure 7.39 - Possible chemical structures of a pyrimidine dimer - 6-4PP (left) and CPD (right)

Wikipedia

Types of damage

What kinds of damage do these agents cause? Radiation can cause different kinds of damage to DNA.

Sometimes, as with much of the damage done by UV rays, two adjacent pyrimidine bases in the DNA will be cross-linked to form cyclobutane pyrimidine dimers or CPDs (see Figure 7.39). Note that these are two neighboring pyrimidine bases on the same strand of DNA. UV exposure can also lead to the formation of another type of lesion, known as a (6-4) photoproduct or 6-4PP (Figure 7.39). Ionizing radiation can cause breaks in the DNA backbone, in one or both strands.

Molecules like benzopyrene, found in automobile exhaust, can attach themselves to bases, forming bulky DNA adducts in which large chemical groups are linked to bases in the DNA. Damage like pyrimidine dimers, 6-4PPs or chemical adducts can physically distort the DNA helix, causing DNA and RNA polymerase to stall when they attempt to copy those regions of DNA (Figure 7.40).

Chemical reactions occurring within cells can cause cytosines in DNA to be deaminated to uracil. Other sorts of damage in this category include the formation of oxidized bases like 8-oxo-guanine or alkylated bases like O^6-methylguanine. These do not actually change the physical structure of the DNA helix, but they can cause problems because uracil and 8-oxo-guanine pair with different bases than the original cytosine or guanine, leading to mutations on the next round of replication. O^6-methylguanine similarly can form base pairs with thymine instead of cytosine.

Removing damage

Cells have several ways to remove the sorts of damage described above. The first of these is described as direct reversal. Many organisms (though, unfortunately for us, not humans) can repair UV damage like CPDs and 6-4PPs

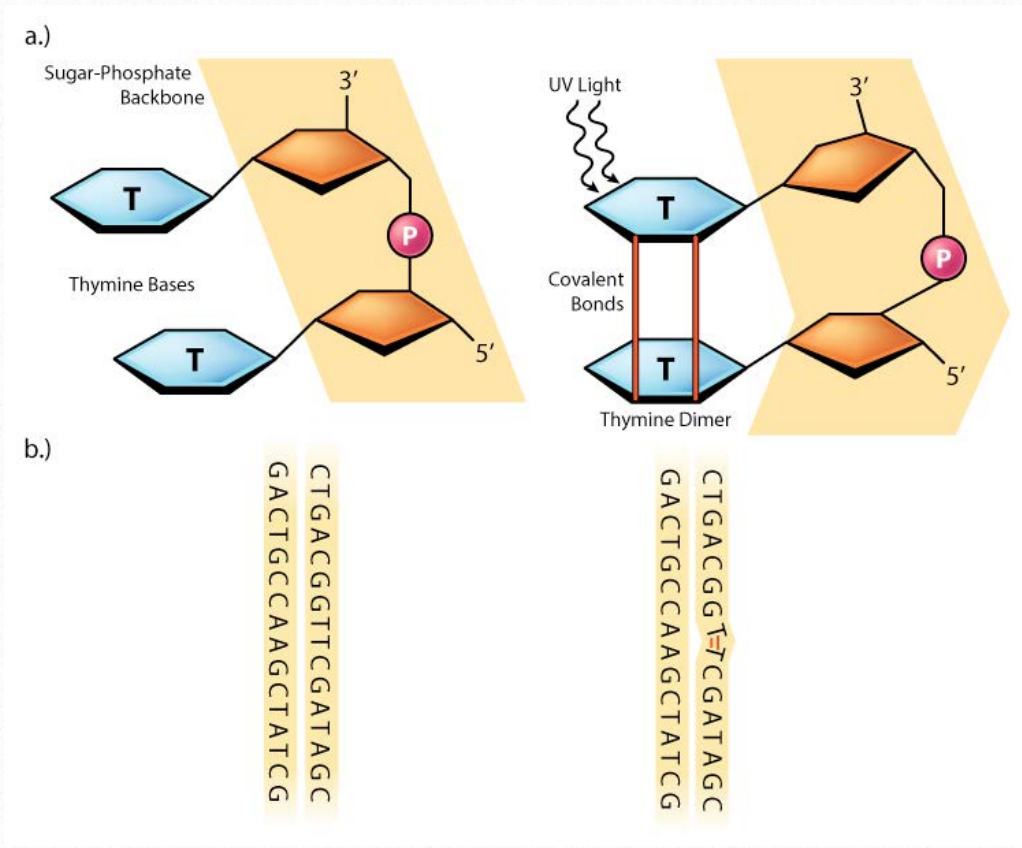

Figure 7.40- Thymine dimers distort the DNA helix

Aleia Kim

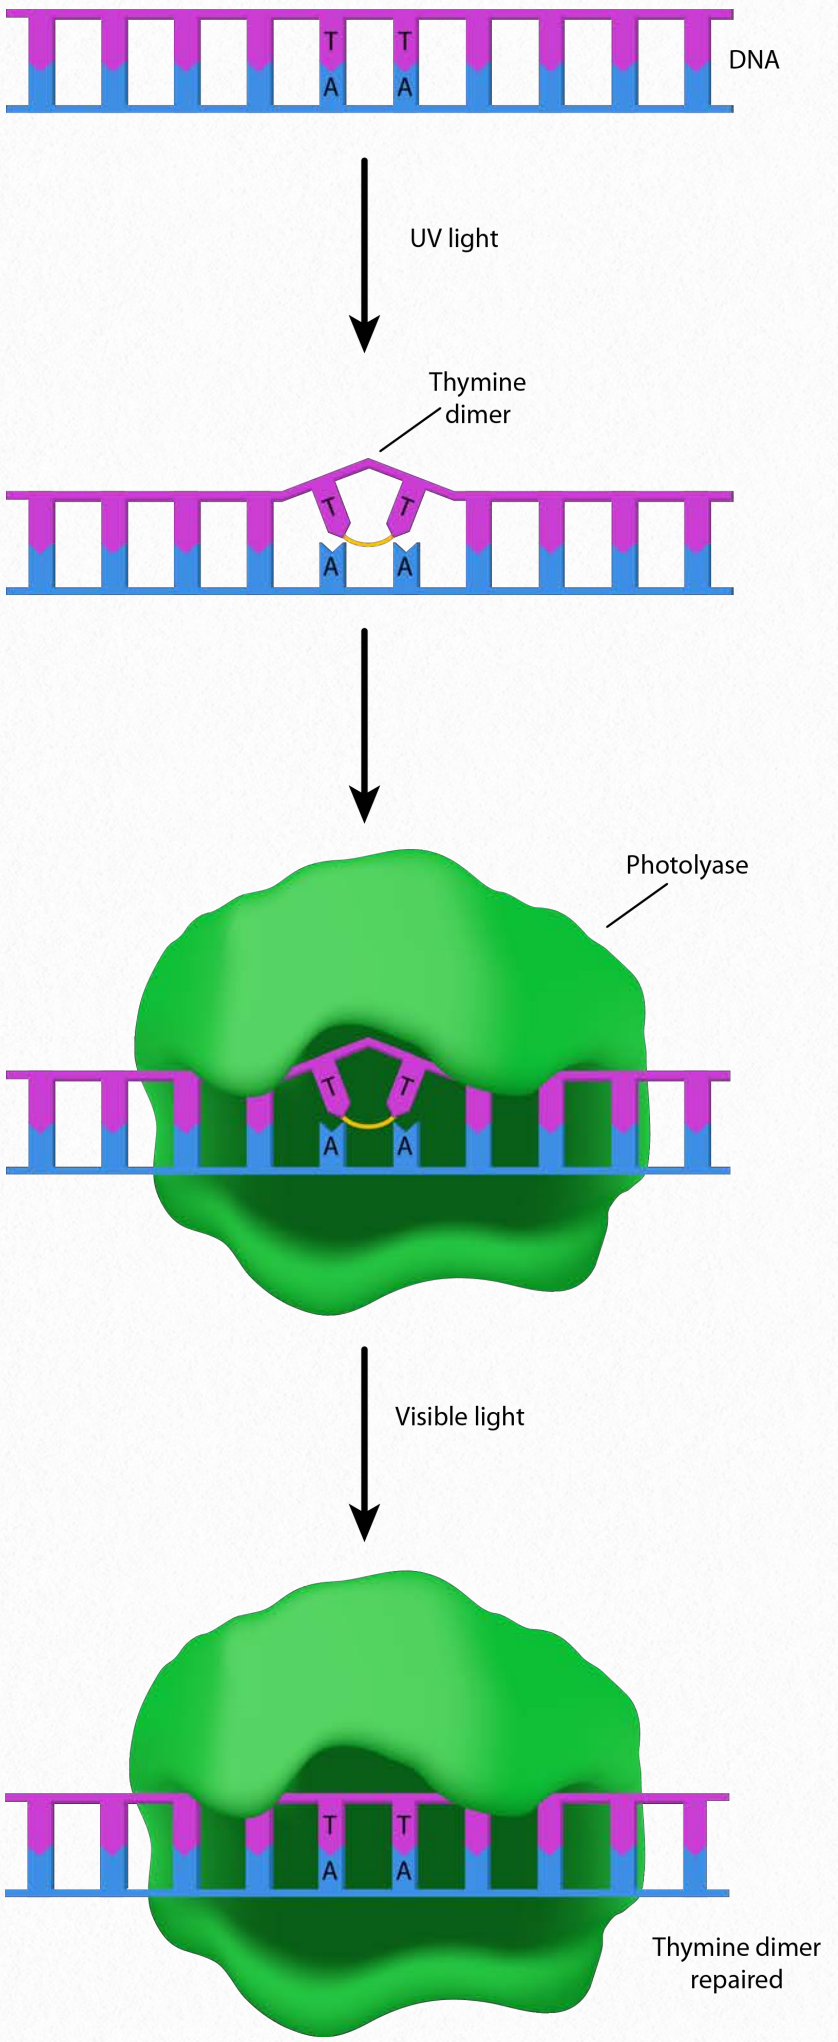

Figure 7.41- Direct repair of thymine dimers by photolyase

Pehr Jacobsen

because they possess enzymes called photolyases (photo=light; lyase=breakdown enzyme - Figure 7.41). Photolyases work through a process called photoreactivation, and use blue light energy to catalyze a photochemical reaction that breaks the aberrant bonds in the damaged DNA and returns the DNA to its original state.

Suicide enzyme

O^6-methylguanine in DNA can also be removed by direct reversal, with the help of the enzyme O^6-methylguanine methyltransferase. This is a very unusual enzyme that removes the methyl group from the guanine and transfers it onto a cysteine residue in the enzyme. The addition of the methyl group to the cysteine renders the enzyme non-functional.

As you know, most enzymes are catalysts that remain unchanged over the course of the reaction, permitting a single enzyme molecule to repeatedly catalyze a reaction. Because the O^6-methylguanine methyltransferase does not fit this description, it is sometimes not regarded as a true enzyme. It has also been called a suicide enzyme, because the enzyme “dies” as a result of its own activity.

Excision repair

Excision repair is another common strategy. Excision repair is a general term for the cutting out and re-synthesizing of the damaged region of a DNA. There are several different

kinds of excision repair, but they all involve excising the portion of the DNA that is damaged, followed by repair synthesis using the other strand as template, and finally, ligation to restore continuity to the repaired strand. Cells possess several different kinds of excision repair, each geared to specific kinds of DNA damage. Between them, these repair systems deal with the wide variety of insults to the genome.

Nucleotide excision repair

Nucleotide excision repair (NER) fixes damage such as the formation of chemical adducts, as well as UV damage. Both chemical adducts and the formation of CPDs or 6,4 photoproducts can cause significant distortion of the DNA helix. NER proteins act to cut the damaged strand on either side of the lesion. A short portion of the DNA strand containing the damage is then removed and a DNA polymerase fills in the gap with the appropriate nucleotides. Nucleotide excision repair has been extensively studied in bacteria.

In *E. coli*, recognition and excision of the damage is carried out by a group of proteins encoded by the uvrABC and uvrD genes. The protein products of the uvrA, uvrB and uvrC genes function together as the so-called UvrABC excinuclease. The damage is initially recognized and bound by a complex of the UvrA and UvrB proteins. Once the complex is bound, the UvrA dissociates, leaving the UvrB attached to the

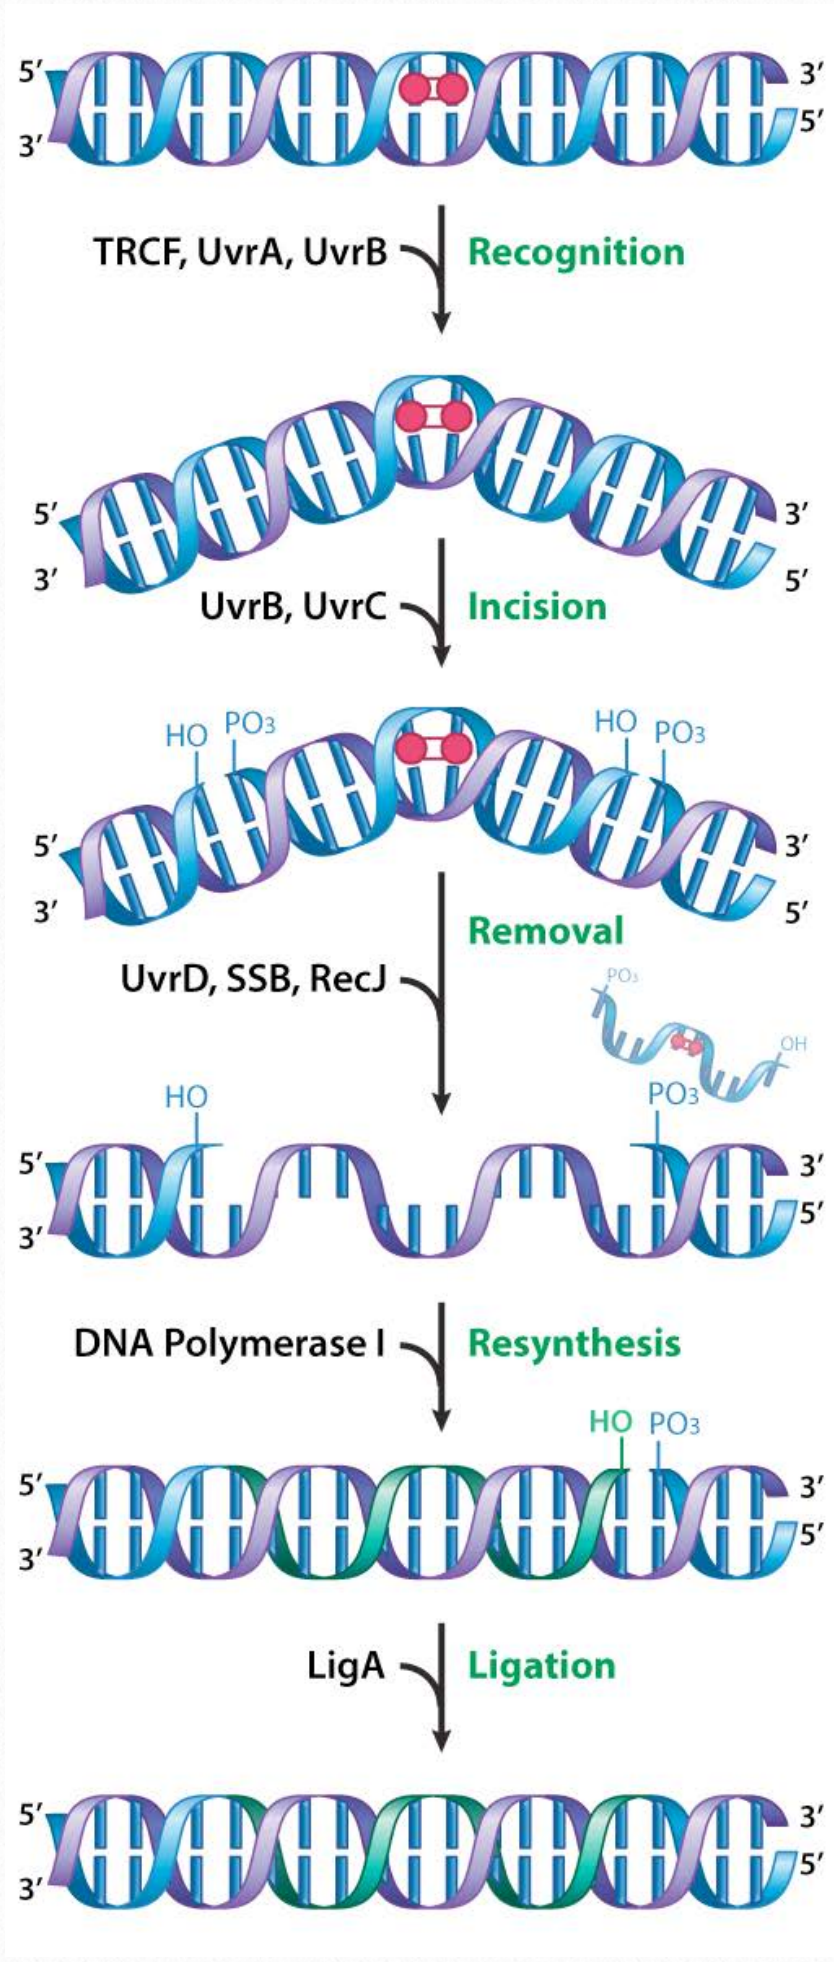

Figure 7.42 - Nucleotide excision repair
Aleia Kim

DNA, where it is then joined by the UvrC protein.

Strand nicking

It is the complex consisting of UvrB and C that acts to cut the phosphodiester backbone on either side of the damage, creating nicks in the strand about 12-13 nucleotides apart. A helicase encoded by uvrD then unwinds the region containing the damage, displacing it from the double helix together with UvrBC. The gap in the DNA is filled in by DNA polymerase, which copies the undamaged strand, and the nick is sealed with the help of DNA ligase.

Nucleotide excision repair is also an important pathway in eukaryotes. It is particularly important in the removal of UV damage in humans, given that we lack photolyases. A number of proteins have been identified that function in ways similar to the Uvr proteins.

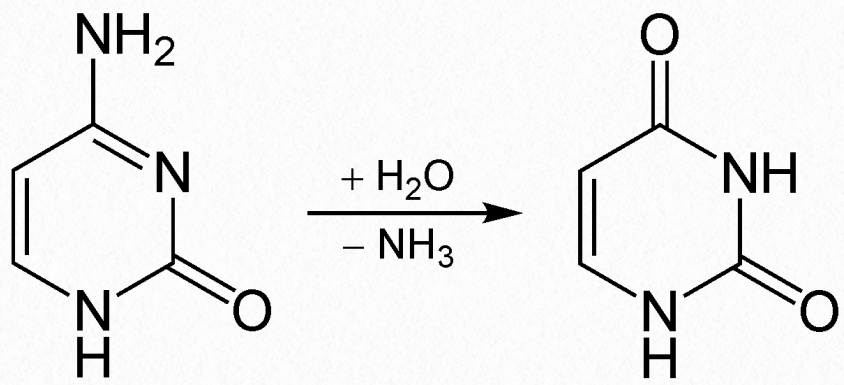

Figure 7.43 - Spontaneous hydrolysis of cytosine to form uracil

The importance of these proteins is evident from the fact that mutations in the genes that encode them can lead to a number of genetic diseases, like Xeroderma pigmentosum, or XP. People with XP are extremely sensitive to UV exposure, because the damage caused by it cannot be repaired, leaving them at a much higher risk of developing skin cancer.

YouTube Lectures by Kevin HERE & HERE

Two repair modes

Nucleotide excision repair operates in two modes, one known as global genomic repair and the other as transcription-coupled repair. While the function of both is to remove helix-destabilizing damage like cyclobutane pyrimidine dimers or chemical adducts, the way in which the lesions are detected differs.

In global genomic repair, damage is identified by surveillance of the entire genome for helix distorting lesions. In the case of transcription-coupled repair, the stalling of the RNA polymerase at a site of DNA damage is the indicator that activates this mode of nucleotide excision repair.

Base excision repair

Base excision repair (BER) is a repair mechanism that deals with situations like the deamination of cytosine to uracil (Figure 7.43) or the methylation of a purine base. These changes do not typically distort

the structure of the DNA helix, unlike chemical adducts or UV damage.

In base excision repair a single damaged base is first removed from the DNA, followed by removal of a region of the DNA surrounding the missing base. The gap is then repaired.

Uracil-DNA glycosylase

The removal of uracil from DNA is accomplished by the enzyme uracil-DNA glycosylase that can recognize uracil in DNA and break the glycosidic bond between the uracil and the sugar in the nucleotide (Figure 7.44). The removal of the base leaves a gap called an apyrimidinic site (AP site) because, in this case, uracil, a pyrimidine was removed. It is important to remember that at this point the backbone of the DNA is still intact, and the removal of a single base simply creates a gap like a tooth that has been knocked out.

The formation of the AP site triggers the activity of an enzyme known as an AP endonuclease that cuts the DNA backbone 5' to the AP site. In the remaining steps, a DNA polymerase binds to the nick, then using its exonuclease and polymerase activities, replaces the sequence in this region. Depending on the situation, a single nucleotide may be replaced (short patch BER) or a stretch of several nucleotides may be removed and replaced (long patch BER). Finally, as always, DNA ligase acts to seal the nick in the DNA.

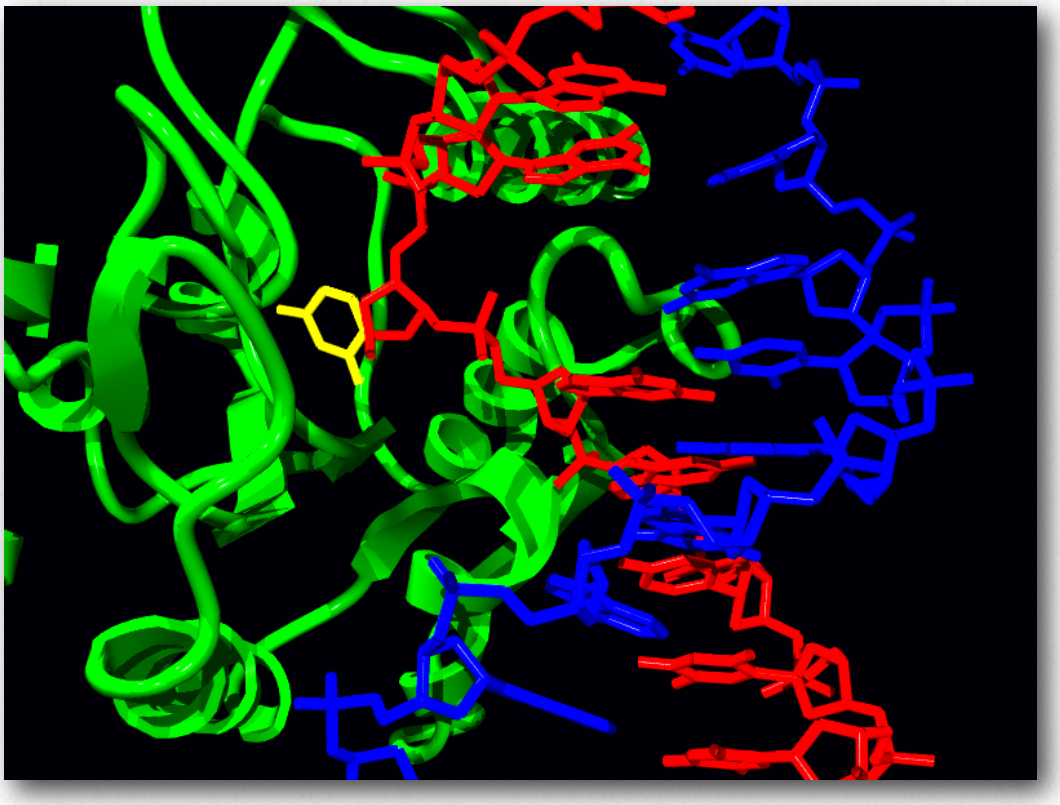

Figure 7.44 - Base excision repair by uracil-DNA glycosylase. The yellow uracil base has been "flipped" out of the DNA helix for excision

Repair of double-strand breaks

While all the repair mechanisms discussed so far fixed damage on one strand of DNA using the other, undamaged strand as a template, these mechanisms cannot repair damage to both strands. What happens if both strands are damaged? Ionizing radiation, exposure to certain chemicals, or reactive oxygen species generated in the cell can lead to double-strand breaks (DSBs) in DNA.

DSBs are a potentially lethal form of damage that, in addition to blocking replication and transcription,

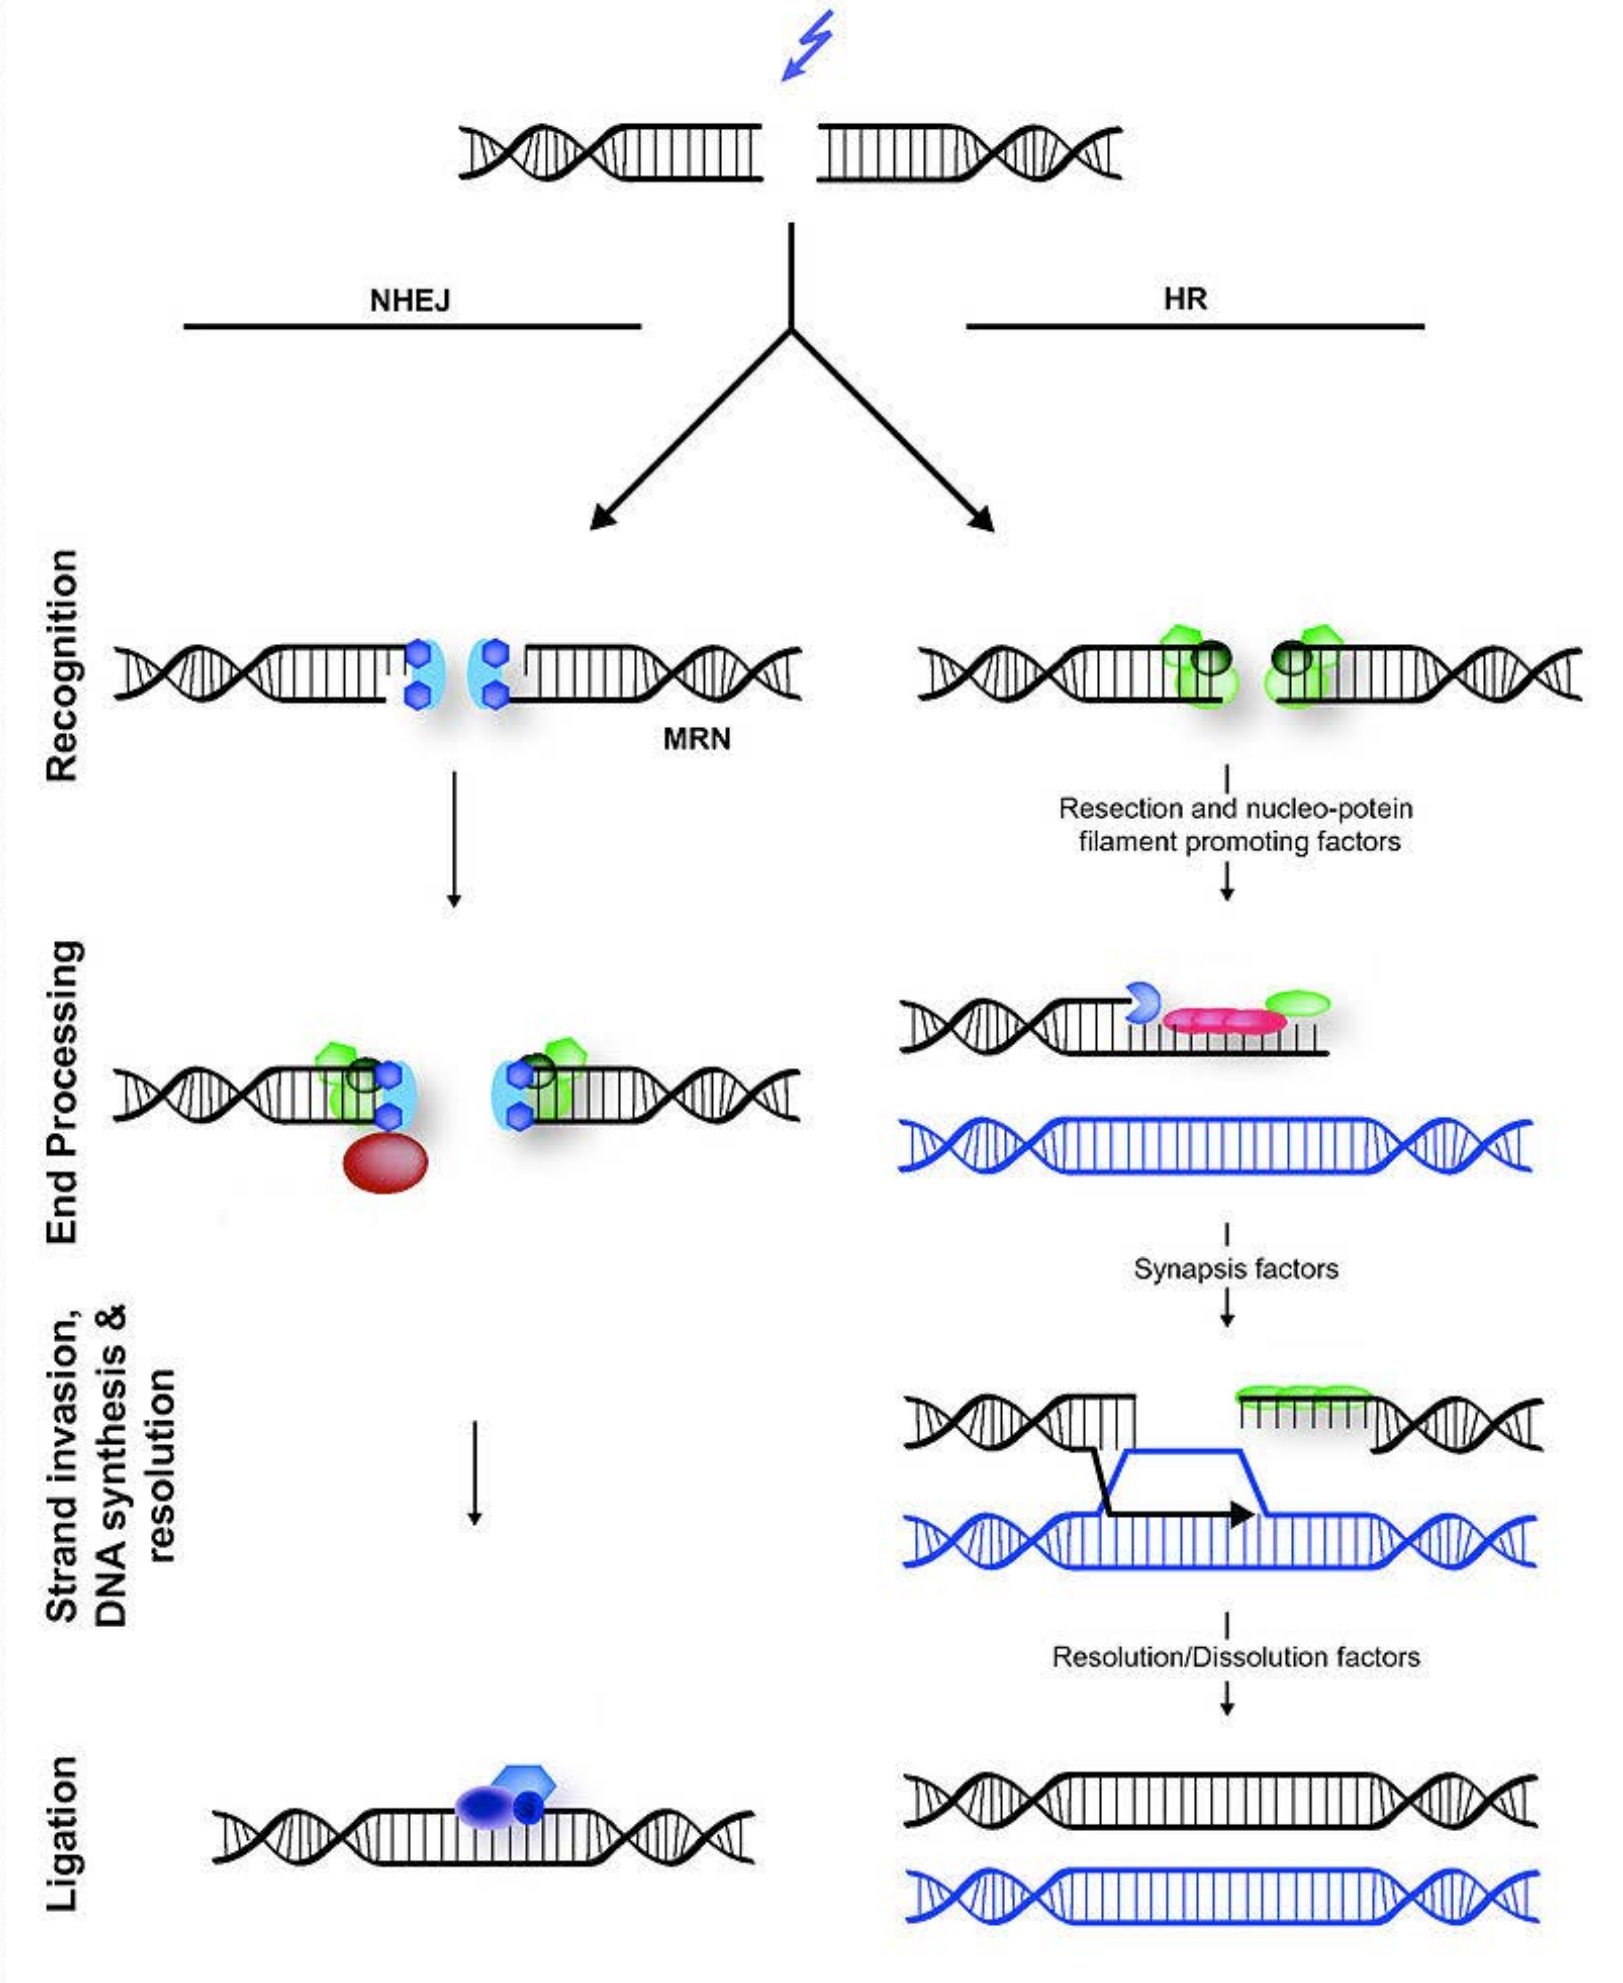

Figure 7.45 - Non-homologous end joining (left) versus homologous recombination (right)

Wikipedia

can also lead to chromosomal translocations, where part of one chromosome gets attached to a piece of another chromosome.

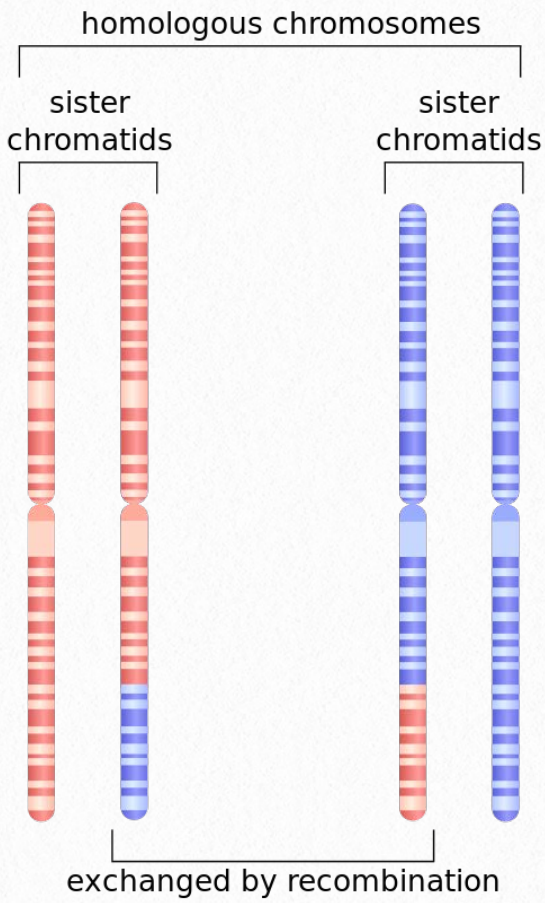

Figure 7.46 - Result of homologous recombination

Wikipedia

Two different cellular mechanisms exist that help repair DSBs (Figure 7.45), homologous recombination (HR) and non-homologous end joining (NHEJ).

Homologous recombination repair commonly occurs in the late S and G_2 phases of the cell, when each chromosome has been replicated and information from a sister chromatid can be used as a template to achieve error-free repair. Note that in contrast to excision repair, where the damaged strand was removed and the undamaged sister strand

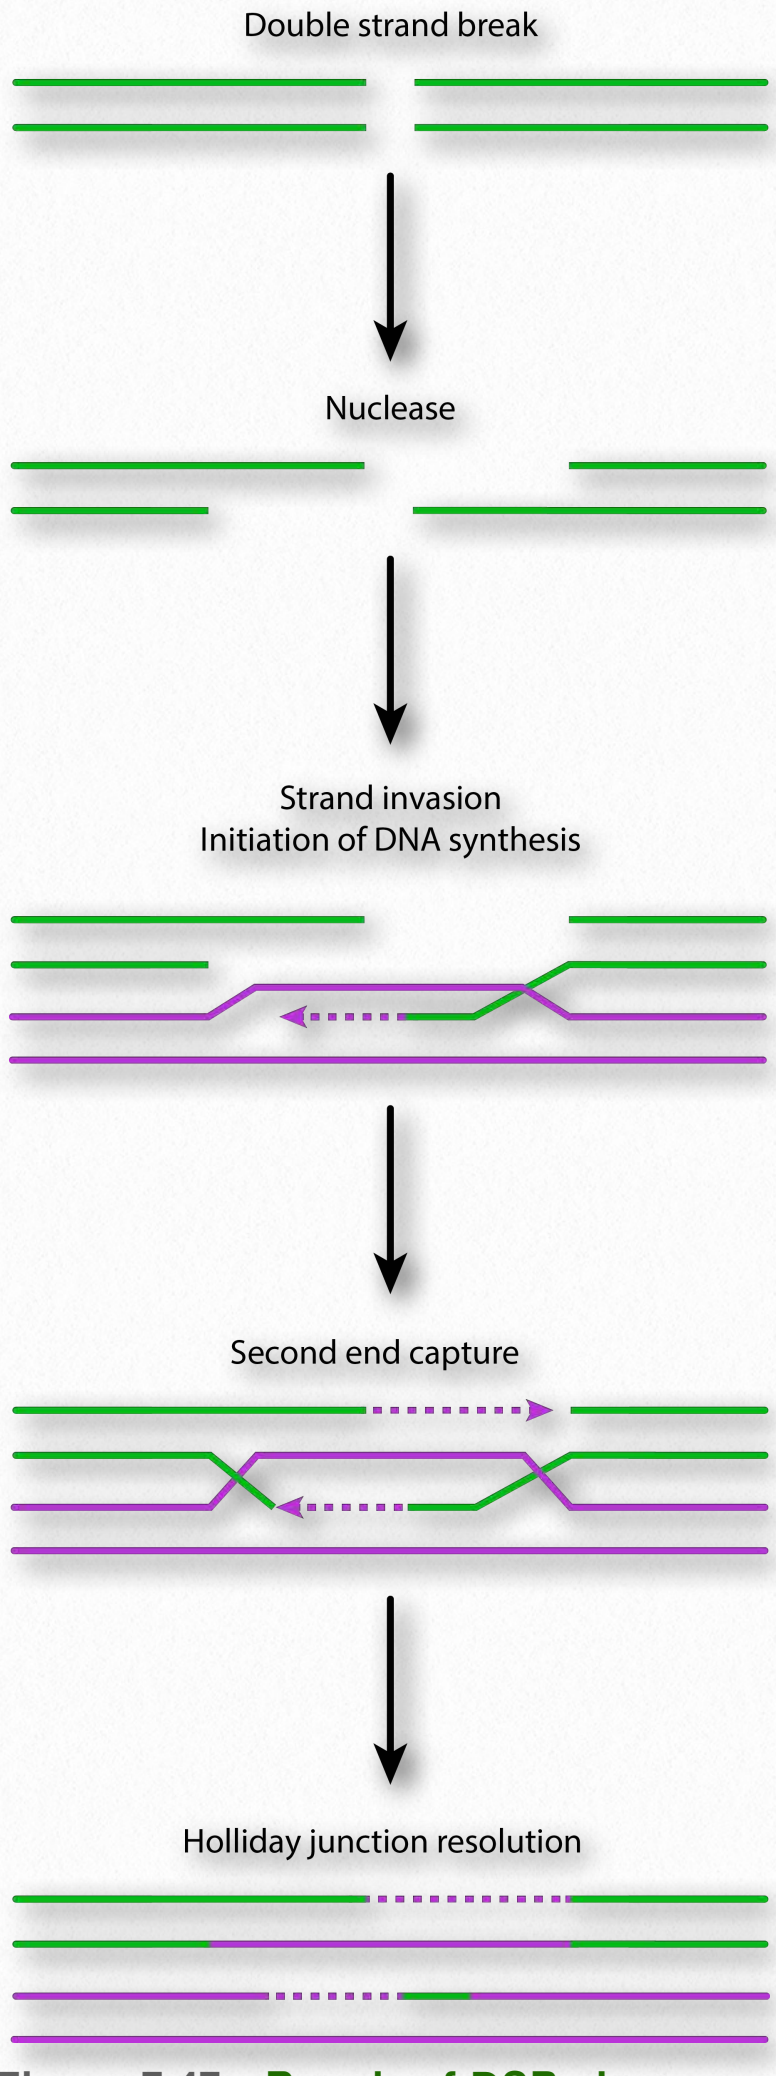

Figure 7.47 - Repair of DSBs by homologous recombination

Image by Pehr Jacobson

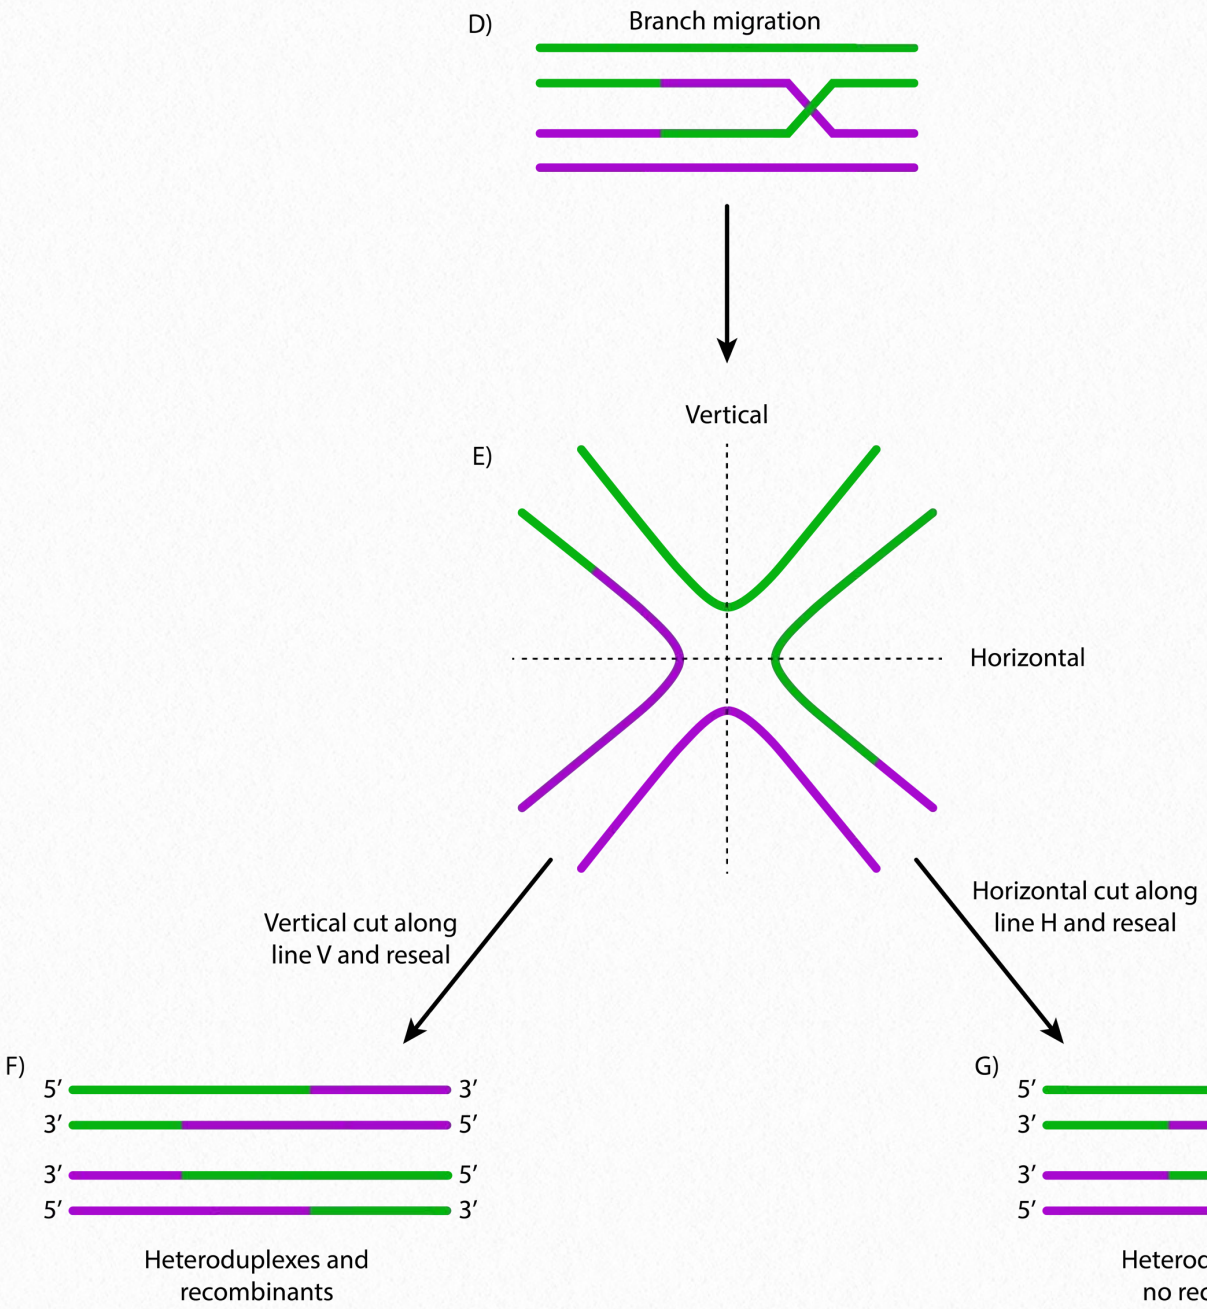

Figure 7.48 - Resolution of Holliday Junctions

Image by Pehr Jacobsen

served as the template for filling in the damaged region, HR must use the information from another DNA molecule, because both strands of the DNA are damaged in DSBs.

Nuclease action

Detection of the double-strand break triggers nuclease activity that chews back one strand on each end of the break. This results in the production of single-stranded 3' overhangs on each end. These single-stranded ends are bound by several proteins, creating a nucleoprotein filament that can then "search" for homologous (matching) sequences on a sister chromatid.

When such sequences are found, the nucleoprotein filament invades the undamaged sister chromatid, forming a crossover. This creates heteroduplexes made up of DNA strands from different chromatids. Strand invasion (Figure 7.47) is followed by branch migra-

tion, during which the Holliday junction moves along the DNA, extending the heteroduplex away from the original site of the crossover (Figure 7.48). In *E. coli*, branch migration depends on the activity of two proteins, RuvA and RuvB. The resulting recombination intermediate can be resolved, with the help of RuvC to give complete, error-free strands.

Non-homologous end joining

In contrast to homologous recombination, Non-homologous end joining (NHEJ) is error-prone. It does not use or require a homologous template to copy, and works by simply chewing back the broken ends of DSBs and ligating them together. Not surprisingly, NHEJ introduces deletions in the DNA as a result.

Translesion DNA synthesis

As we have seen, cells have a variety of mechanisms to help safeguard the integrity of the information in DNA. One measure of last resort is translesion DNA synthesis, also known as bypass synthesis. Translesion synthesis occurs when a DNA polymerase encounters DNA damage on the template strand, but instead of stalling or skipping past the damage, replication switches to an error-prone mode, ignoring the template and incorporating random nucleotides into the new strand. In *E.coli*, translesion synthesis is dependent on the activities of proteins encoded by the umuC and umuD genes. Under the appropriate conditions (see SOS response, below) UmuC and UmuD are activated to begin bypass synthesis. Being error-prone, translesion synthesis gives rise to many mutations.

Figure 7.49 -Lex A repressor, N-terminal domain

The SOS response

Named for standard SOS distress signals, the term "SOS repair" refers to a cellular response to UV damage. When bacterial cells suffer extensive damage to their DNA as a result of UV exposure, they turn on the coordinated expression of a large number of genes that are necessary for DNA repair. These include the uvr genes needed for nucleotide excision repair and recA, which is involved in homologous recombination. In addition to these mechanisms, which can carry out error-free repair, the SOS response can also induce the expression of translesion polymerases encoded by the dinA, dinB and umuCD genes.

How are all these genes induced in a coordi-

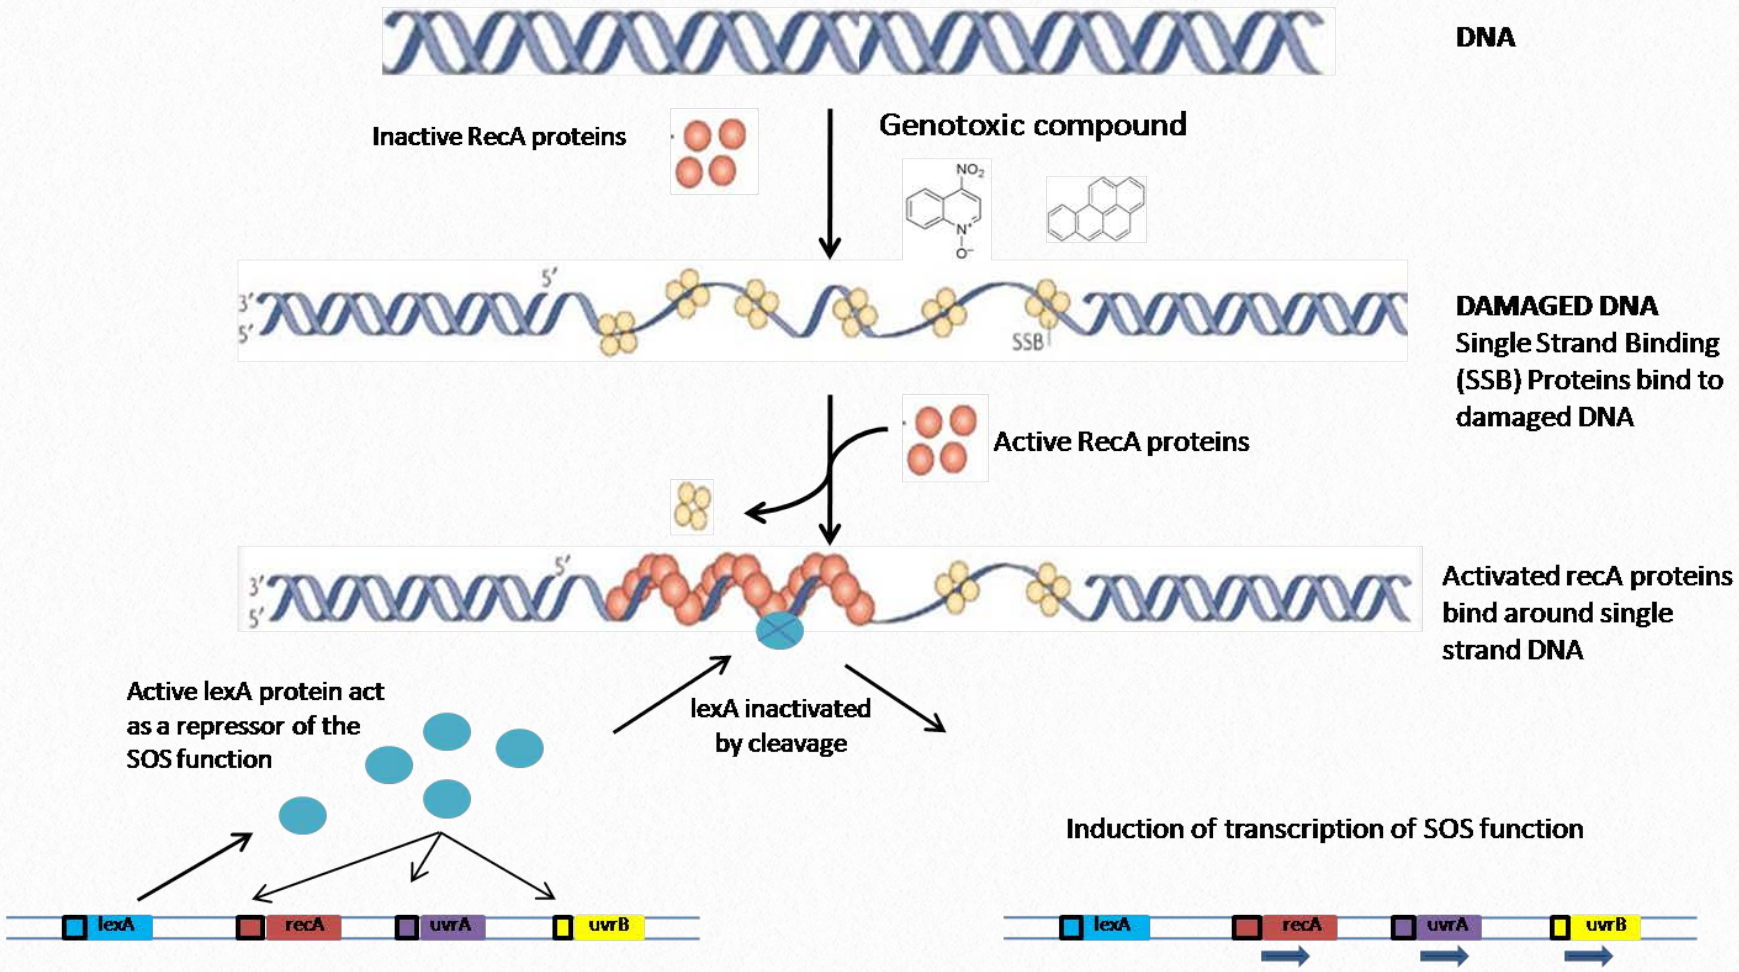

Figure 7.50 - Activation of SOS genes by lexA in *E. coli*

nated way following UV damage? All of the genes induced in the SOS response are regulated by two components. The first is the presence of a short DNA sequence upstream of their coding region, called the SOS box. The second is a protein, the LexA repressor (Figure 7.49), that binds to the SOS box and prevents transcription of the downstream genes. Expression of the genes requires the removal of LexA from its binding site. How is this achieved?

When exposure to radiation results in DNA breaks, the presence of single-stranded regions triggers the activation and binding of RecA proteins to the single-stranded region, creating a nucleoprotein filament. The interaction of the RecA with the LexA repressor leads to autocleavage of the repressor, allowing the downstream gene(s) to be expressed (Figure 7.50).

YouTube Lectures by Kevin HERE & HERE

The genes controlled by the LexA repressor, as mentioned earlier, encode proteins that are necessary for accurate DNA repair as well as error-prone translesion synthesis. The various genes involved in DNA repair are induced in a specific order. In the initial stages, the repair genes that are derepressed are for nucleotide excision repair, followed by homologous recombination, both error-free mechanisms for repair. If the damage is too

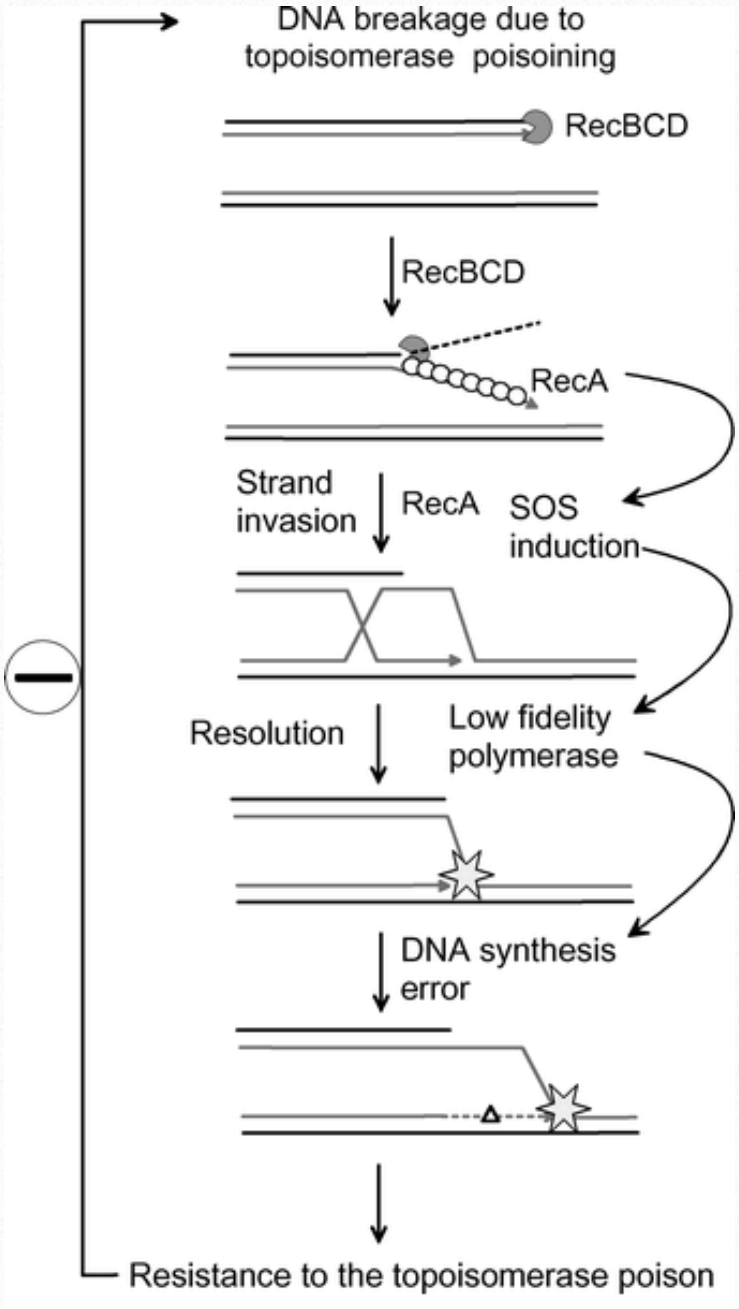

Figure 7.51 - A proposed mechanism of evolved bacterial antibiotic resistance

Wikipedia

extensive to be repaired by these systems, error-prone repair mechanisms may be brought into play as a last resort.

SOS response and antibiotic resistance

The increased mutation rate in the SOS response may play a role in the acquisition of antibiotic resistance in bacteria (Figure 7.51).

An example is the development of resistance to topoisomerase poisons like the fluoroquinolone family of drugs. Fluoroquinolones inhibit the ability of topoisomerases to religate the ends of their substrates after nicking them to allow overwound DNA to relax. This results in accumulation of strand breaks that can trigger the SOS response. As a consequence of error-prone DNA synthesis by low fidelity polymerases during the SOS response, there is a large increase in the number of mutations. While some mutations may be lethal to the bacteria, others can contribute to the rapid development of drug resistance in the population.

Information Processing: Transcription

In the preceding sections, we have discussed the replication of the cell's DNA and the mechanisms by which the integrity of the genetic information is carefully maintained. What do cells do with this information? How does the sequence in DNA control what happens in a cell? If DNA is a giant instruction book containing all of the cell's "knowledge" that is copied and passed down from generation to generation, what are the instructions for? And how do cells use these instructions to make what they need?

YouTube Lectures by Kevin
HERE & HERE

Information flow

You have learned in introductory biology courses that genes, which are instructions for making proteins, are made of DNA. You also know that information in genes is copied into temporary instructions called messenger RNAs that direct the synthesis of specific proteins. This description of flow of information from DNA to RNA to protein is often called the central dogma of molecular biology and is a good starting point for

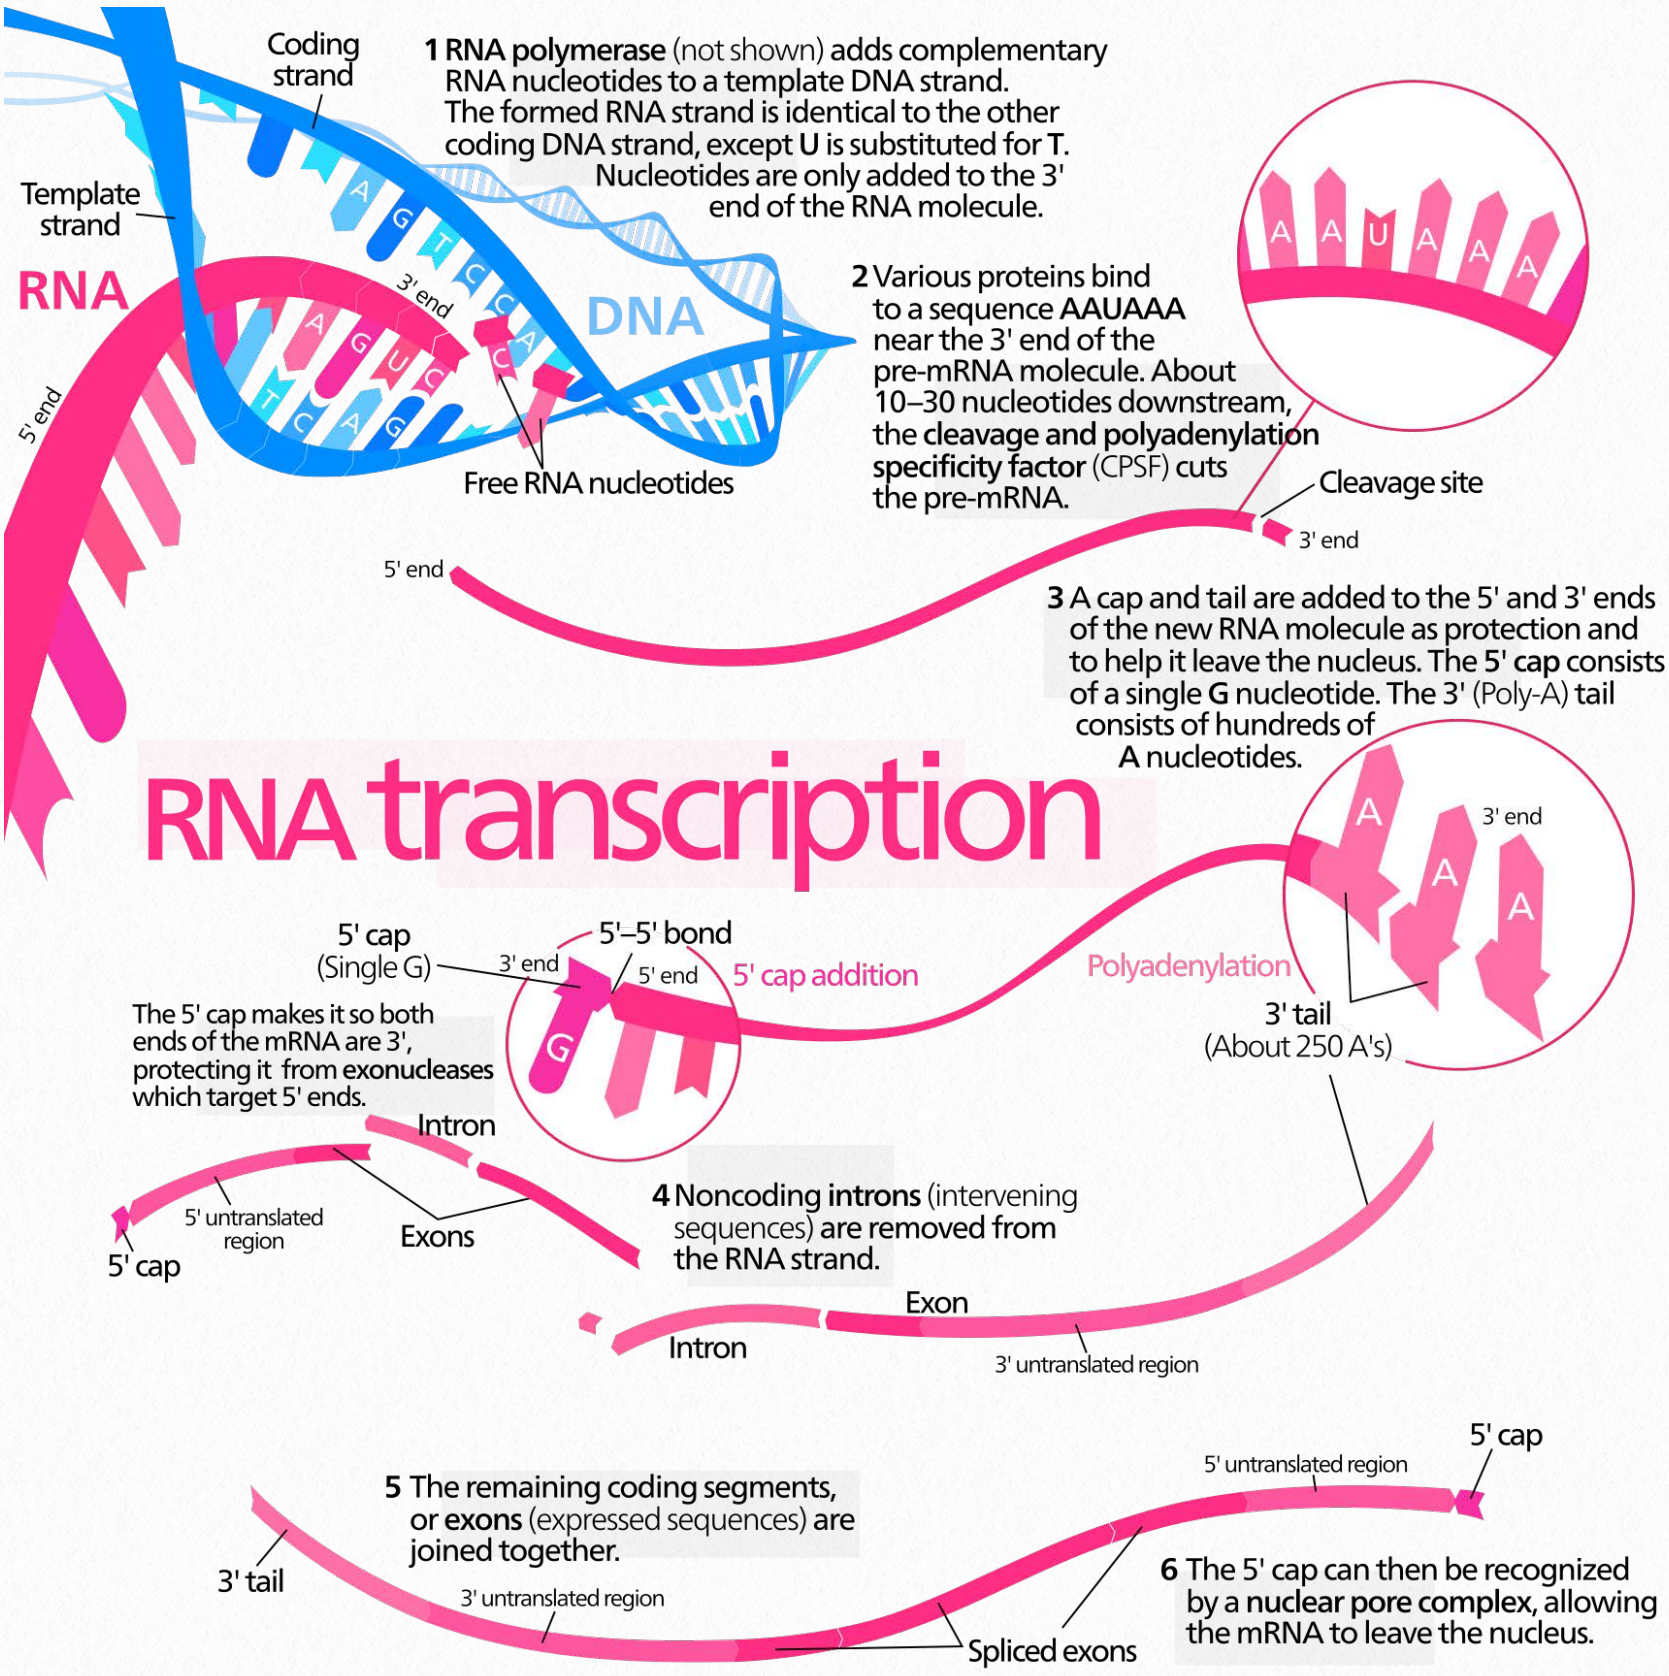

Figure 7.52 - Overview of eukaryotic transcription

Wikipedia

an examination of how cells use the information in DNA.

Consider that all of the cells in a multicellular organism have arisen by division from a single fertilized egg and therefore, all have the same DNA. Division of that original fertilized egg produces, in the case of humans, over a trillion cells, by the time a baby is produced from that egg (that's a lot of DNA replica-

tion!). Yet, we also know that a baby is not a giant ball of a trillion identical cells, but has the many different kinds of cells that make up tissues like skin and muscle and bone and nerves. How did cells that have identical DNA turn out so different?

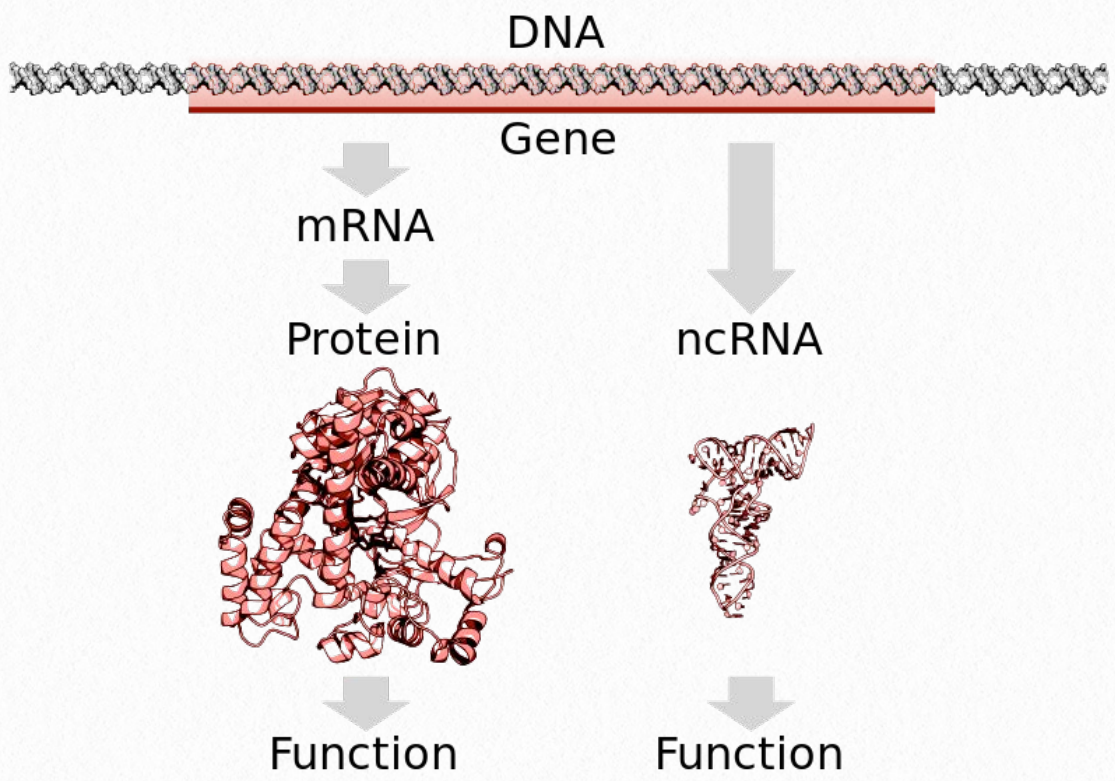

Figure 7.53 - Transcripts may code for protein or may be functional as RNAs

Wikipedia

The answer lies in gene expression, which is the process by which the information in DNA is used. Although all the cells in a baby have the same DNA, each different cell type uses a different subset of the genes in that DNA to direct the synthesis of a distinctive set of RNAs and proteins. The first step in gene expression is transcription, which we will examine next (Figure 7.52).

Transcription

Transcription is the process of copying information from DNA sequences into RNA sequences. This process is also known as DNA-dependent RNA synthesis. When a sequence of DNA is transcribed, only one of the two DNA strands is copied into RNA. We will consider what determines which strand of DNA is copied into RNA, later on.

But, apart from copying one, rather than both strands of DNA, how is transcription different from replication of DNA? DNA replication serves to copy all the genetic material of the cell and occurs before a cell divides, so that a full copy of the cell's genetic information can be passed on to the daughter cell. Transcription, by contrast, copies short stretches of the coding regions of DNA to make RNA. Different genes may be copied into RNA at different times in the cell's life cycle. RNAs are, essentially, temporary copies of the information in DNA and different sets of instructions are copied for use at different times and in different cell types.

Cells make several different kinds of RNA:

- mRNAs that code for proteins
- rRNAS that form part of ribosomes

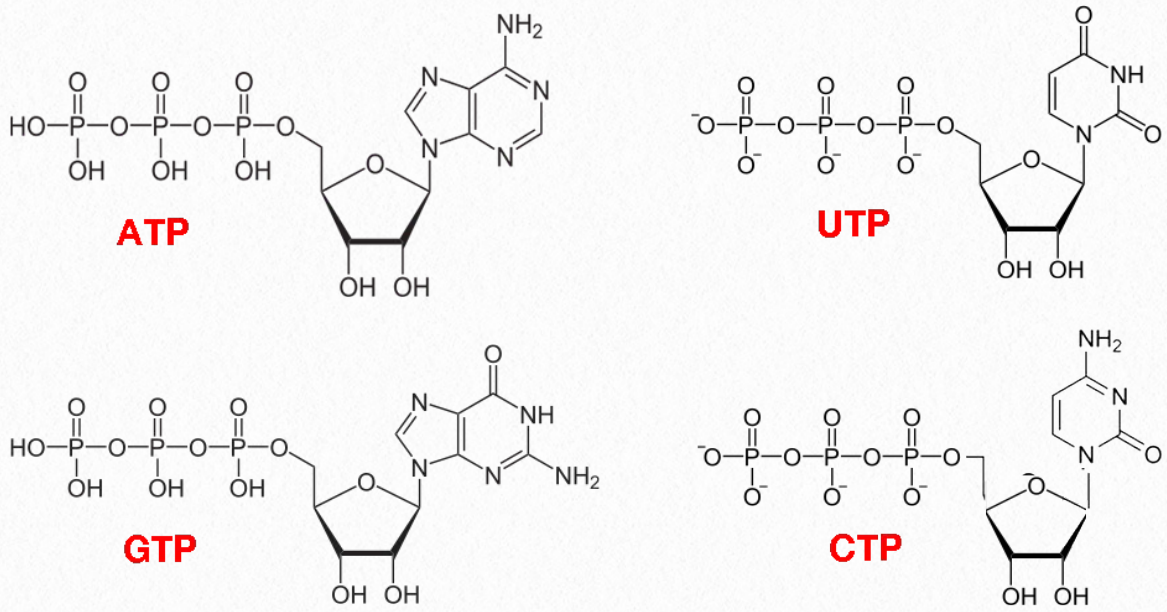

Figure 7.54 - The four ribonucleotides for making RNA

- tRNAs that serve as adaptors between mRNA and amino acids during translation

- Small RNAs that regulate gene expression, including miRNAs and siRNAs

- Other small RNAs that have a variety of functions, including the small nuclear RNAs that are part of the splicing machinery.

- Long noncoding RNAs (lnc RNAs - Figure 7.53)

Building an RNA strand is very similar to building a DNA strand. This is not surprising, knowing that DNA and RNA are very similar molecules. Transcription is catalyzed by the enzyme RNA Polymerase. "RNA polymerase" is a general term for an enzyme that makes RNA. There are several different kinds of RNA polymerases in eukaryotic cells, while in prokaryotes, a single type of RNA polymerase is responsible for all transcription.

RNA synthesis

Like DNA polymerases, RNA polymerases synthesize new strands only in the 5' to 3' direction, but because they are making RNA, they use ribonucleotides (i.e., RNA nucleotides - Figure 7.54) rather than deoxyribonucleotides. Ribonucleotides are joined in exactly the same way as deoxyribonucleotides, i.e., the 3'OH of the last nucleotide on the growing chain is joined to the 5' phosphate on

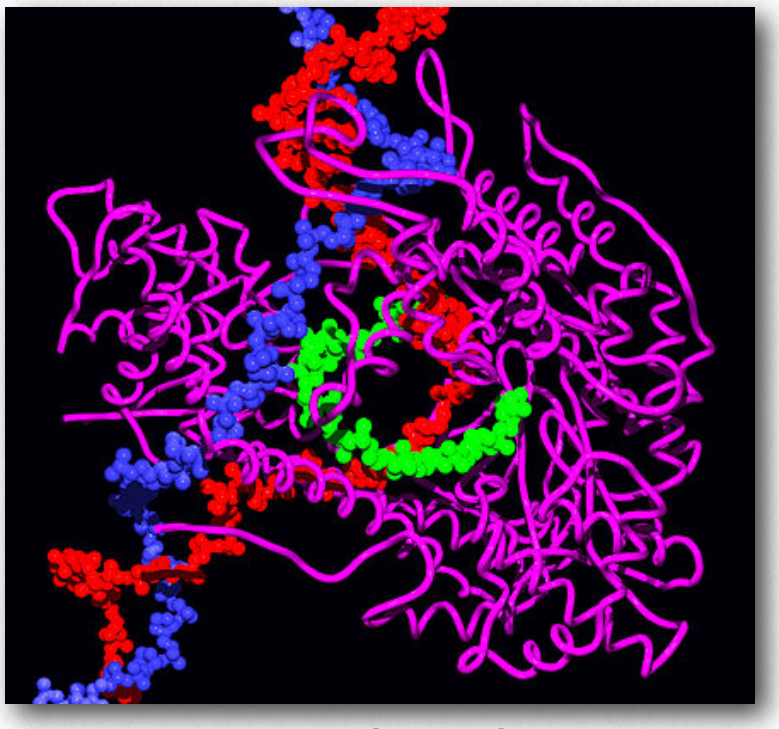

Figure 7.55 - RNA (green) being synthesized from DNA template (blue strand) by T7 RNA polymerase (purple). The non-template DNA strand is in red.

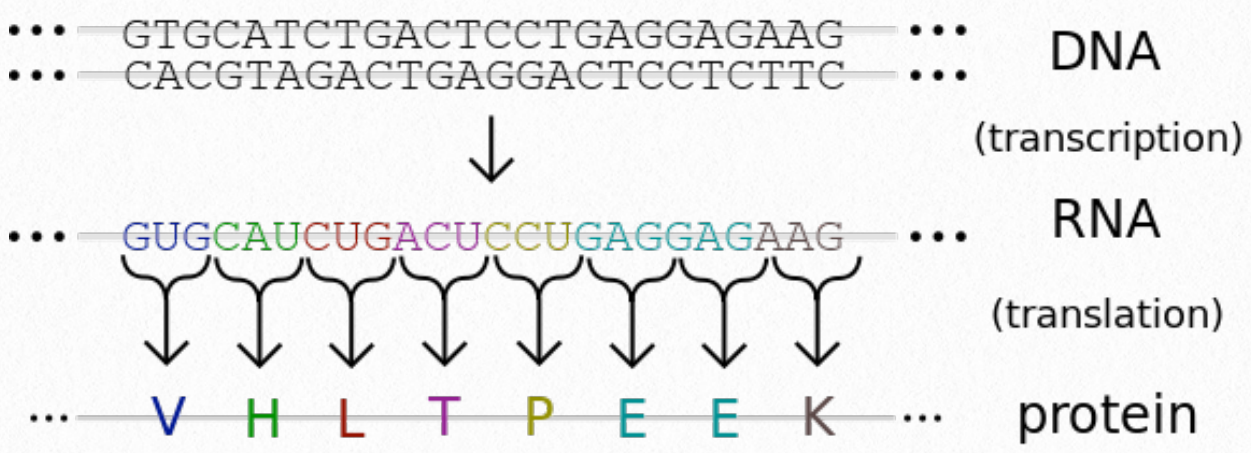

Figure 7.56 - Central dogma - DNA to RNA to protein Wikipedia

the incoming nucleotide to make a phosphodiester bond.

One important difference between DNA polymerases and RNA polymerases is that the latter do not require a primer to start making RNA. Once RNA polymerases are in the right place to start copying DNA, they just begin making RNA by joining together RNA nucleotides complementary to the DNA template.

Starting points

This, of course, brings us to an obvious question- how do RNA polymerases "know" where to start copying on the DNA?

Unlike the situation in replication, where every nucleotide of the parental DNA must eventually be copied, transcription, as we have already noted, only copies selected portions of the DNA into RNA at any given time. Consider the challenge here: in a human cell, there are approximately 6 billion base-pairs of DNA. Much of this is non-coding DNA, meaning that it will not need to be transcribed. The small percentage of the genome that is made up of coding sequences still amounts to between 20,000 and 30,000 genes in each cell. Of these genes, only a small number will need to be expressed at any given time.What indicates to an RNA polymerase where to start copying DNA to make a transcript?

Promoters

It turns out that patterns in the DNA sequence indicate where RNA polymerase should start and end transcription. These sequences are recognized by the RNA polymerase or by proteins that help RNA polymerase determine where it should bind the DNA to start transcription. A DNA sequence at which the RNA polymerase binds to start transcription is called a promoter. The DNA sequence that indicates the endpoint of transcription, where the RNA polymerase should stop adding nucleotides and dissociate from the template is known as a terminator sequence. The promoter and terminator, thus, bracket the region of the DNA that is to be transcribed.

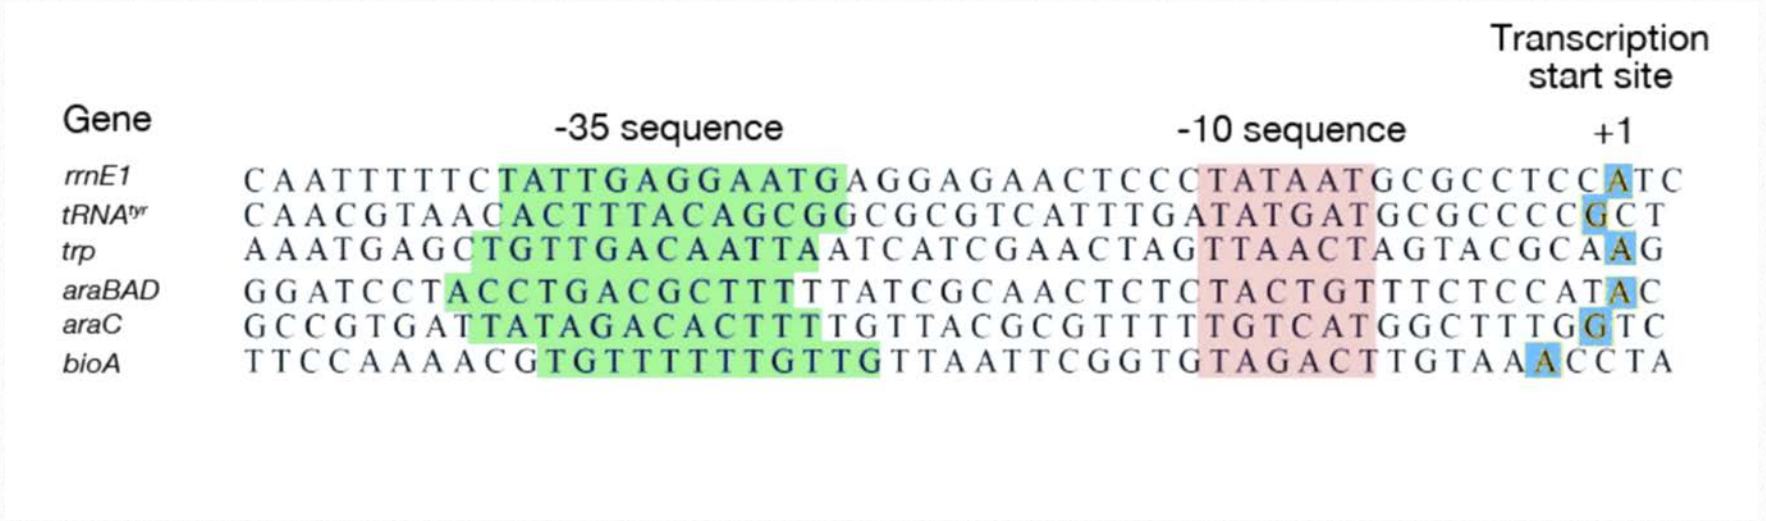

Figure 7.57 - Sequences upstream of transcription start site in several prokaryotic genes

Image by Martha Baker

A promoter is described as being situated upstream of the gene that it controls (Figure 7.57). What this means is that on the DNA strand that the gene is on, the promoter sequence is "before" the gene, or to put it differently, it is on the side of the gene opposite to the direction of transcription. Also notice that the promoter is said to "control" the gene it is associated with. This is because expression of the gene is dependent on the binding of RNA polymerase to the promoter sequence to begin transcription. If the RNA polymerase and its helper proteins do not bind at the promoter, the gene cannot be transcribed and it will therefore, not be expressed.

YouTube Lectures by Kevin HERE & HERE

What is special about a promoter sequence? In an effort to answer this question, scientists examined many genes and their surrounding sequences (Figure 7.57). Because the same RNA polymerase has to bind to many different promoters, it would be predicted that promoters would have some similarities in their sequences. As expected, common sequence patterns were seen to be present in many promoters.

We will first take a look at prokaryotic promoters.

When prokaryotic genes were examined, the following features commonly emerged:

- A transcription start site (this the base in the DNA across from which the first RNA nucleotide is paired), which, by convention, is denoted as +1.
- A -10 sequence: this is a 6 bp region centered about 10 bp upstream of the start site. The consensus sequence at this position is TATAAT. In other words, if you count back from the transcription start site, the se-

quence found at roughly -10 in the majority of promoters studied is TATAAT.

- A -35 sequence: this is a 6 bp sequence at about 35 basepairs upstream from the start of transcription. The consensus sequence at this position is TTGACA.

-10 Sequence

T	A	T	A	A	T
77%	76%	60%	61%	56%	82%

-35 Sequence

T	T	G	A	C	A
69%	70%	61%	56%	54%	54%

It is important to understand that each nucleotide in a consensus sequence is simply the one that appeared at that position in the majority of promoters examined, and does not mean that the entire consensus sequence is found in all promoters. In fact, few promoters have -10 and -35 sequences that exactly match the consensus. The box at the left shows the -10 and -35 sequences by percentage of occurrence of each base in the promoter.

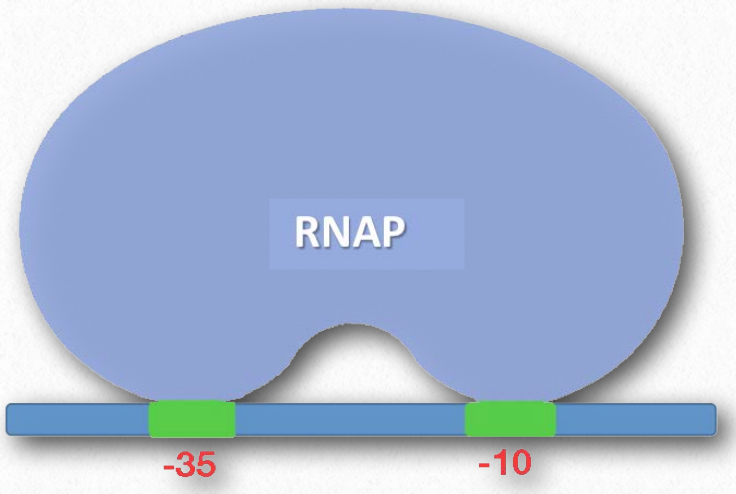

Figure 7.58 - RNA polymerase promoter binding

Wikipedia

Figure 7.59 - A bacterial RNA polymerase (α2ββ'and ω)

What is the significance of these sequences? It turns out that the sequences at -10 and -35 are necessary for recognition of the promoter region by RNA polymerase (Figure 7.58). The sequences at -10 and -35 may vary a little in individual promoters, as mentioned above, but the extent to which they are different is limited. It is only when the RNA polymerase has stably bound at the promoter that transcription can begin. The process by which the promoter is recognized and bound stably has been well studied for the RNA polymerase of *E. coli*.

Core polymerase and holoenzyme

The *E. coli* RNA polymerase is made up of a core enzyme of five subunits (α2ββ'and ω) and an additional subunit called the σ

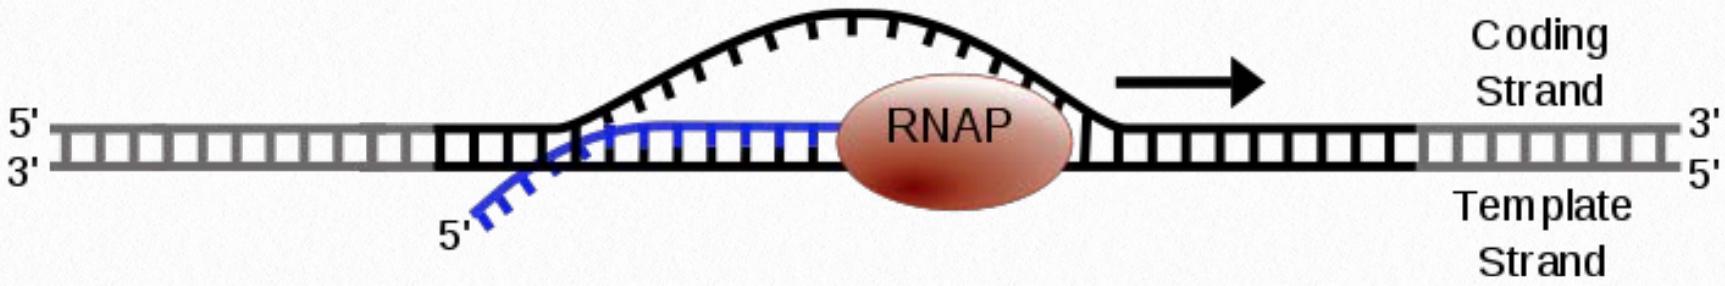

Figure 7.60 - Synthesis of RNA in the transcription bubble

(sigma) subunit. Together, the σ subunit and core polymerase make up what is termed the RNA polymerase holoenzyme. The core polymerase is the part of the RNA polymerase that is responsible for the actual synthesis of the RNA, while the σ subunit is necessary for binding of the enzyme at promoters to initiate transcription.

Loose association

The core polymerase and σ subunit are not always associated with each other. For the most part, the core polymerase is loosely associated with DNA, although it does not discriminate between promoters and other sequences in DNA, and the DNA strands are not opened up to allow transcription in this state. The role of the σ subunit is to reduce the affinity of the core polymerase for non-specific DNA sequences and to help the enzyme specifically bind to promoter sequences.

Holoenzyme binding

It is when the σ subunit associates with the core polymerase that the holoenzyme is able to bind specifically to promoter sequences. The initial binding of the holoenzyme at the promoter results in what is called a "closed" complex, meaning that the DNA template is still double-stranded and has not opened up to allow transcription. This closed complex is then converted to an "open" complex by the separation of the DNA strands to create a transcription bubble about 12-14 base-pairs long (Figure 7.60). The conversion of the closed complex to the open complex also requires the presence of the σ subunit.

Open complex & initiation

Once the open complex has formed, the DNA template can begin to be copied, and the core polymerase adds nucleotides complementary to one strand of the DNA. At this stage, known as initiation, the polymerase adds several nucleotides while still bound to the promoter, and without moving along the DNA template. Initially, short pieces of RNA a few nucleotides long may be made and released, without the polymerase leaving the promoter. Eventually, the enzyme makes the transition to the next stage, elongation, when

an RNA of 8-9 bases is made and the enzyme moves beyond the promoter region.

Elongation

Once elongation commences and the RNA polymerase is moving down the DNA template, the σ subunit is no longer necessary and may dissociate from the core enzyme. The core polymerase can move along the template, unwinding the DNA ahead of it to maintain a transcription bubble of 12-15 base-pairs and synthesizing RNA complementary to one of the strands of the DNA. As already mentioned, an RNA chain, complementary to the DNA template, is built by the RNA polymerase by the joining of the 5' phosphate of an incoming ribonucleotide to the 3'OH on the last nucleotide of the growing RNA strand. Behind the RNA polymerase, the DNA template is rewound, displacing the newly made RNA from its template strand.

Termination

As mentioned earlier, a sequence of nucleotides called the terminator is the signal to the RNA polymerase to stop transcription and dissociate from the template. Some terminator sequences, known as intrinsic terminators, allow termination by RNA polymerase without the help of any additional factors, while others, called rho-dependent terminators, require the assistance of a protein factor called rho (ρ).

How does the sequence of the terminator cause the RNA polymerase to stop adding nucleotides and release the transcript?

To understand this, it is useful to know that the terminator sequence precedes the last nucleotide of the transcript. In other words, the terminator is part of the end of the sequence that is transcribed (Figure 7.61).

Intrinsic terminators

In intrinsic terminators, this sequence in the RNA has self-complementary regions that can base-pair with each other to form a hairpin structure that contains a GC-rich run in the “stem” of the hairpin. This hairpin is fol-

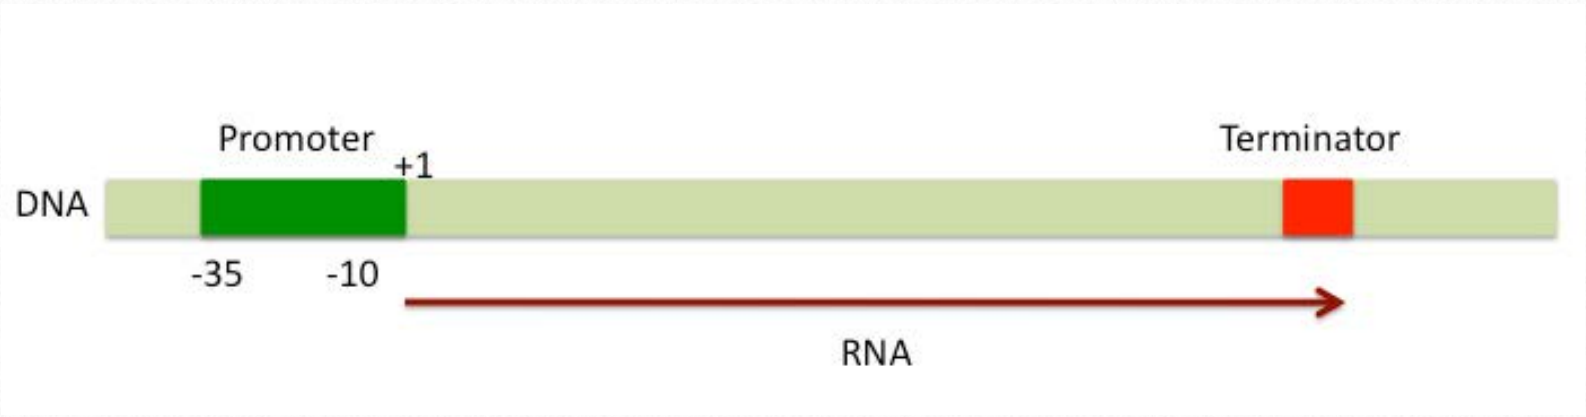

Figure 7.61 - Promoter and Terminator sequences determine where transcription starts and ends.

lowed by a single-stranded region that is rich in U's (Figure 7.62). The secondary structure formed by the folding of the end of the RNA into the hairpin causes the RNA polymerase to pause. Meanwhile, the run of U's at the end of the hairpin permits the RNA-DNA hybrid in this region to come apart, because the base-pairing between A's in the DNA template and the U's in the RNA is relatively weak. This allows the transcript to be released from the DNA template and from the RNA polymerase.

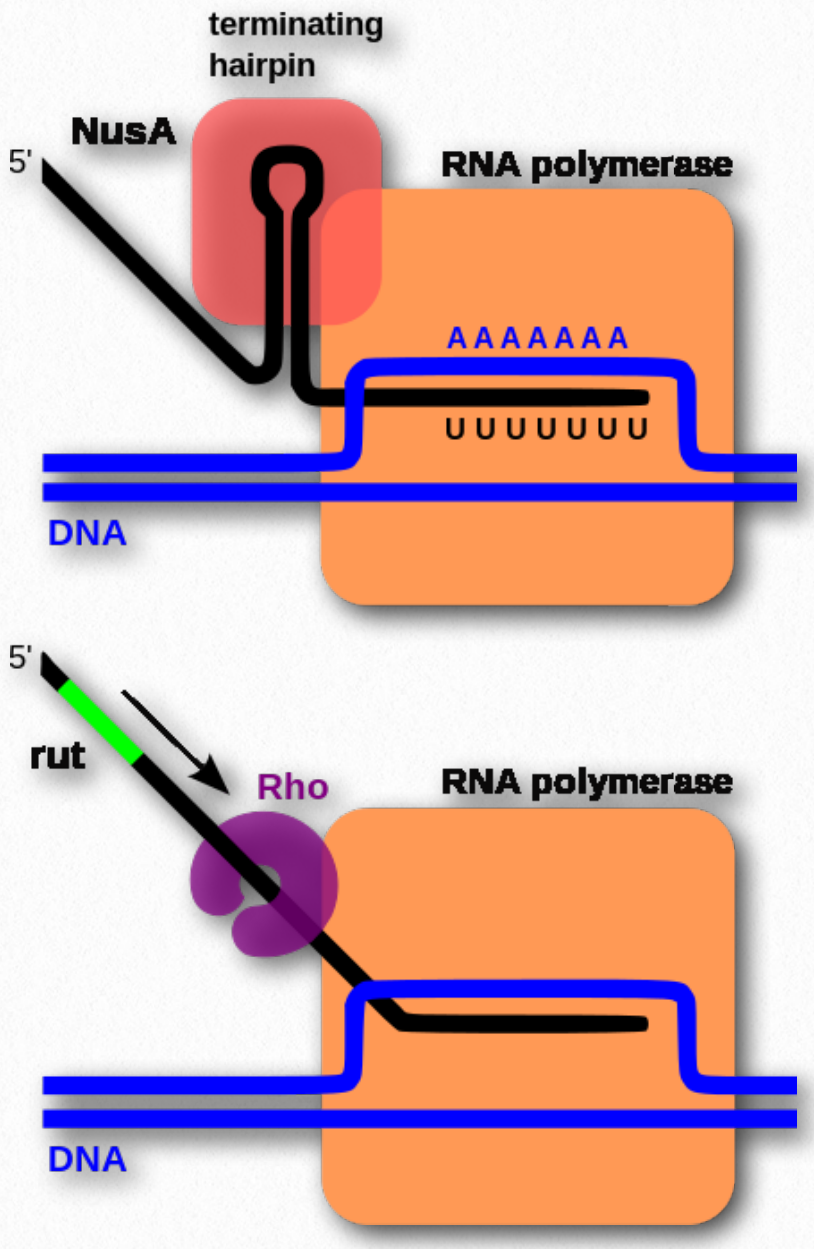

Figure 7.62 Transcription termination by intrinsic (top) and rho-dependent (bottom) mechanisms

Wikipedia

Rho-dependent termination

In the case of rho-dependent termination, an additional protein factor, rho, is necessary. Rho is a helicase that can separate the transcript from the template it is paired with. As in intrinsic termination, rho-dependent termination requires the formation of a hairpin structure in the RNA that causes pausing of the RNA polymerase. Meanwhile, rho binds to a region of the transcript called the rho utilization site (rut) and moves along the RNA till it reaches the paused RNA polymerase. It then acts on the RNA-DNA hybrid, releasing the transcript from the template.

Coupled transcription and translation

In prokaryotes, which lack a nucleus, the DNA is not separated from the rest of the cell in a separate compartment, so the mRNA is immediately available to the translation machinery, as the transcript is coming off the template DNA. Indeed, in prokaryotic cells, translation of the mRNA can begin before the entire gene has been transcribed. Ribosomes can assemble at the 5' end of the transcript, as it is displaced from the template, while the 3' end of the gene is still being copied. The lag time between transcrip-

tion and translation is thus, very short in prokaryotes.

Transcription in eukaryotes

Although the process of RNA synthesis is the same in eukaryotes as in prokaryotes, there are some additional considerations in eukaryotes. One is that in eukaryotes, the DNA template exists as chromatin, where the DNA is tightly associated with histones and other proteins. The "packaging" of the DNA must therefore be opened up to allow the RNA polymerase access to the template in the region to be transcribed (Figure 7.63). The restructuring of chromatin to allow access to regions of DNA is thus an important factor in determining which genes are expressed.

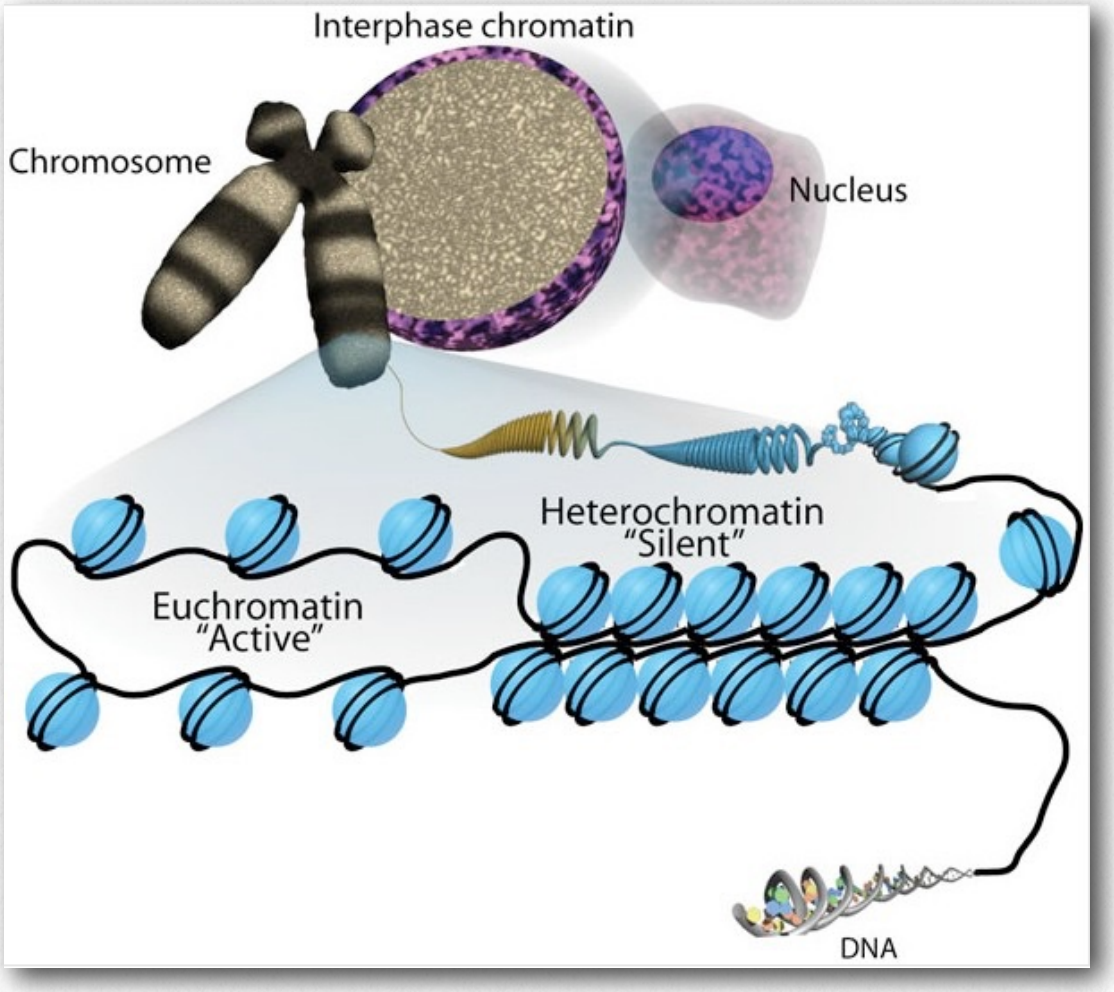

Figure 7.63 - Eukaryotic DNA is complexed with proteins in chromatin

Wikipedia

YouTube Lectures by Kevin HERE & HERE

Multiple RNA polymerases

A second difference is that eukaryotes have multiple RNA polymerases, not just one as in bacterial cells. The different eukaryotic polymerases transcribe different classes of genes. For example, RNA polymerase I transcribes the ribosomal RNA genes, while RNA polymerase III copies tRNA genes. The RNA polymerase we will focus on most is RNA polymerase II, which transcribes protein-coding genes to make mRNAs.

All three eukaryotic RNA polymerases need additional proteins to help them get transcription started. In prokaryotes, RNA polymerase by itself can initiate transcription (the σ subunit is a subunit of the RNA polymerase, not an entirely separate protein). The additional proteins needed by eukaryotic RNA polymerases are referred to as transcription factors. We will see below that there are various categories of transcription factors.

Transcription and translation are de-coupled

Finally, in eukaryotic cells, transcription is separated in space and time from translation. Transcription happens in the nucleus, and the RNAs produced are processed further before they are sent into the cytoplasm. Protein synthesis (translation) happens in the cytoplasm. As noted earlier, in prokaryotic cells, mRNAs can be translated as they are coming off the DNA template, and because there is no nuclear envelope, transcription and protein synthesis occur in a single cellular compartment. A representative eukaryotic gene, depicted in Figure 7.64 shows that transcription starts some 25 bp downstream of the TATA box, and creates a transcript that begins with a 5' untranslated region (5'UTR) followed by the coding region which may include multiple introns and ending in a 3' untranslated region or 3'UTR (Figure 7.64). As detailed below, the initial transcript is further processed before it is used.

Eukaryotic promoters

Like genes in prokaryotes, eukaryotic genes also have promoters that determine where transcription will begin. As with prokaryotes, there are specific sequences in the promoter regions that are recognized and bound by proteins involved in the initiation of transcription. We will focus primarily on the genes encoding proteins that are transcribed by RNA polymerase II. Such promoters commonly have a TATA box, a sequence similar to the -10 sequence in prokaryotic promoters. The TATA box is a sequence about 25-35 basepairs upstream of the start of transcription (+1). (Some eukaryotic promoters lack TATA boxes, and have, instead, other recognition sequences, known as DPE, or downstream promoter elements.) Interestingly, the TATA box is not directly recognized and bound by RNA polymerase II. Instead, this sequence is bound by other proteins that, together with the RNA polymerase, form the transcription initiation complex.

Eukaryotic promoters also have, in addition, several other short stretches of sequences, that affect transcription, within about 100 to 200 base-pairs upstream of the transcription start site. These sequences, which are sometimes called upstream elements or

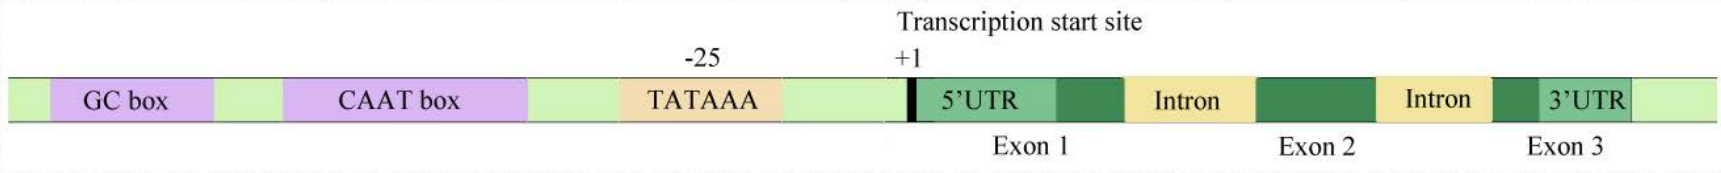

Figure 7.64 - Region surrounding the transcriptional start site in eukaryotic DNA

promoter-proximal upstream elements, are bound by activator proteins that interact with the transcription complex that forms at the TATA box. Examples of such upstream elements are the CAAT box and the GC box (Figure 7.64).

Making transcripts in eukaryotes

We noted earlier that all eukaryotic RNA polymerases need additional proteins to bind promoters and start transcription. The proteins that help eukaryotic RNA polymerases find promoter sites and initiate RNA synthesis are termed general transcription factors. We will focus on the transcription factors that assist RNA polymerase II, the enzyme that transcribes protein-coding genes. These transcription factors are named TFIIA, TFIIB and so on (TF= transcription factor, II=RNA polymerase II, and the letters distinguish individual transcription factors).

Transcription by RNA polymerase II requires the general transcription factors and the RNA polymerase to form a complex, at the TATA box, called the basal transcription complex or transcription initiation complex (Figure 7.65).

This is the minimum requirement for any gene to be transcribed. The first step in the formation of this complex is the binding of the TATA box by a transcription factor, TFIID. TFIID is made up of several proteins, one of which is called the TATA Binding Protein or TBP. Binding of the TBP causes the DNA to bend at this spot and take on a structure that is suitable for the binding of additional transcription factors and RNA polymerase.

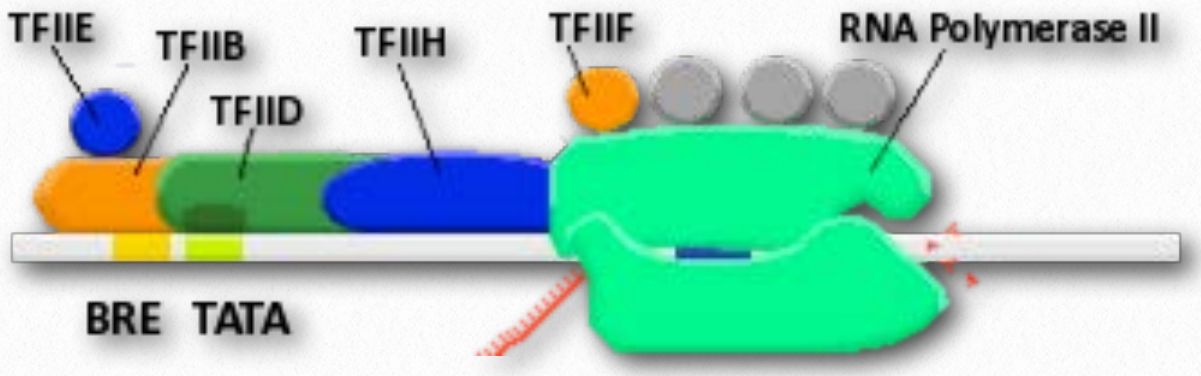

Figure 7.65 - Transcription pre-initiation complex in eukaryotes

Wikipedia

Interestingly, the binding of the TBP is a necessary step in forming a transcription initiation complex even when the promoter lacks a TATA box. The order of binding of additional proteins after binding of the TBP, as determined through *in vitro* experiments, appears to be TFIIB, followed by TFIIF and RNA polymerase II, then TFIIE. The final step in the assembly of the basal transcription complex is the binding of a general transcription factor called TFIIH. Some evidence suggests that following the binding of the TBP to DNA, the rest of the proteins in the initiation complex may assemble as a very large

The Student's Guide to a Perfect Transcript

Pol II's so smart, now let me see
It makes a transcript, one, two, three,
From a billion base pairs can it find
The one promoter it must bind?

I need some help, I hear it plead,
This DNA I cannot read
I cannot see where I must start
'Til TFIIs have done their part.

When TATA's bound by TBP
That sends a signal out, you see
Once DNA has made a bend
More TFIIs will soon attend.

When B arrives, it clears a place
For RNA polymerase
And F and E soon join the fun
TFIIH, the final one.

The last one is a special case
It moonlights as a helicase
And sends Pol II upon its way
To make a brand new RNA.

How does it do that, you may ask
A phosphate does the crucial task
Added on to CTD,
That's how the H sets Pol II free.

And Pol II goes its merry way
There soon will be some RNA
Then introns must be all excised
As RNA is capped and spliced.

Then PolyA polymerase
Will add a couple hundred As
For my own transcript, I can say
That all I want is one more A

Verse by Indira Rajagopal

complex that then binds directly to the DNA. In any case, the presence of all of these general transcription factors and RNA Polymerase II bound at the promoter is necessary for the initiation of transcription.

As in prokaryotic transcription, once the RNA polymerase binds, it can begin to assemble a short stretch of RNA. This must be followed by promoter clearance, in order to move down the template and elongate the transcript. This requires the action of TFIIH. TFIIH is a multifunctional protein that has helicase activity (i.e., it is capable of opening up a DNA double helix) as well as kinase activity. The kinase activity of TFIIH adds phosphates onto the C-terminal domain (CTD) of the RNA polymerase II. This

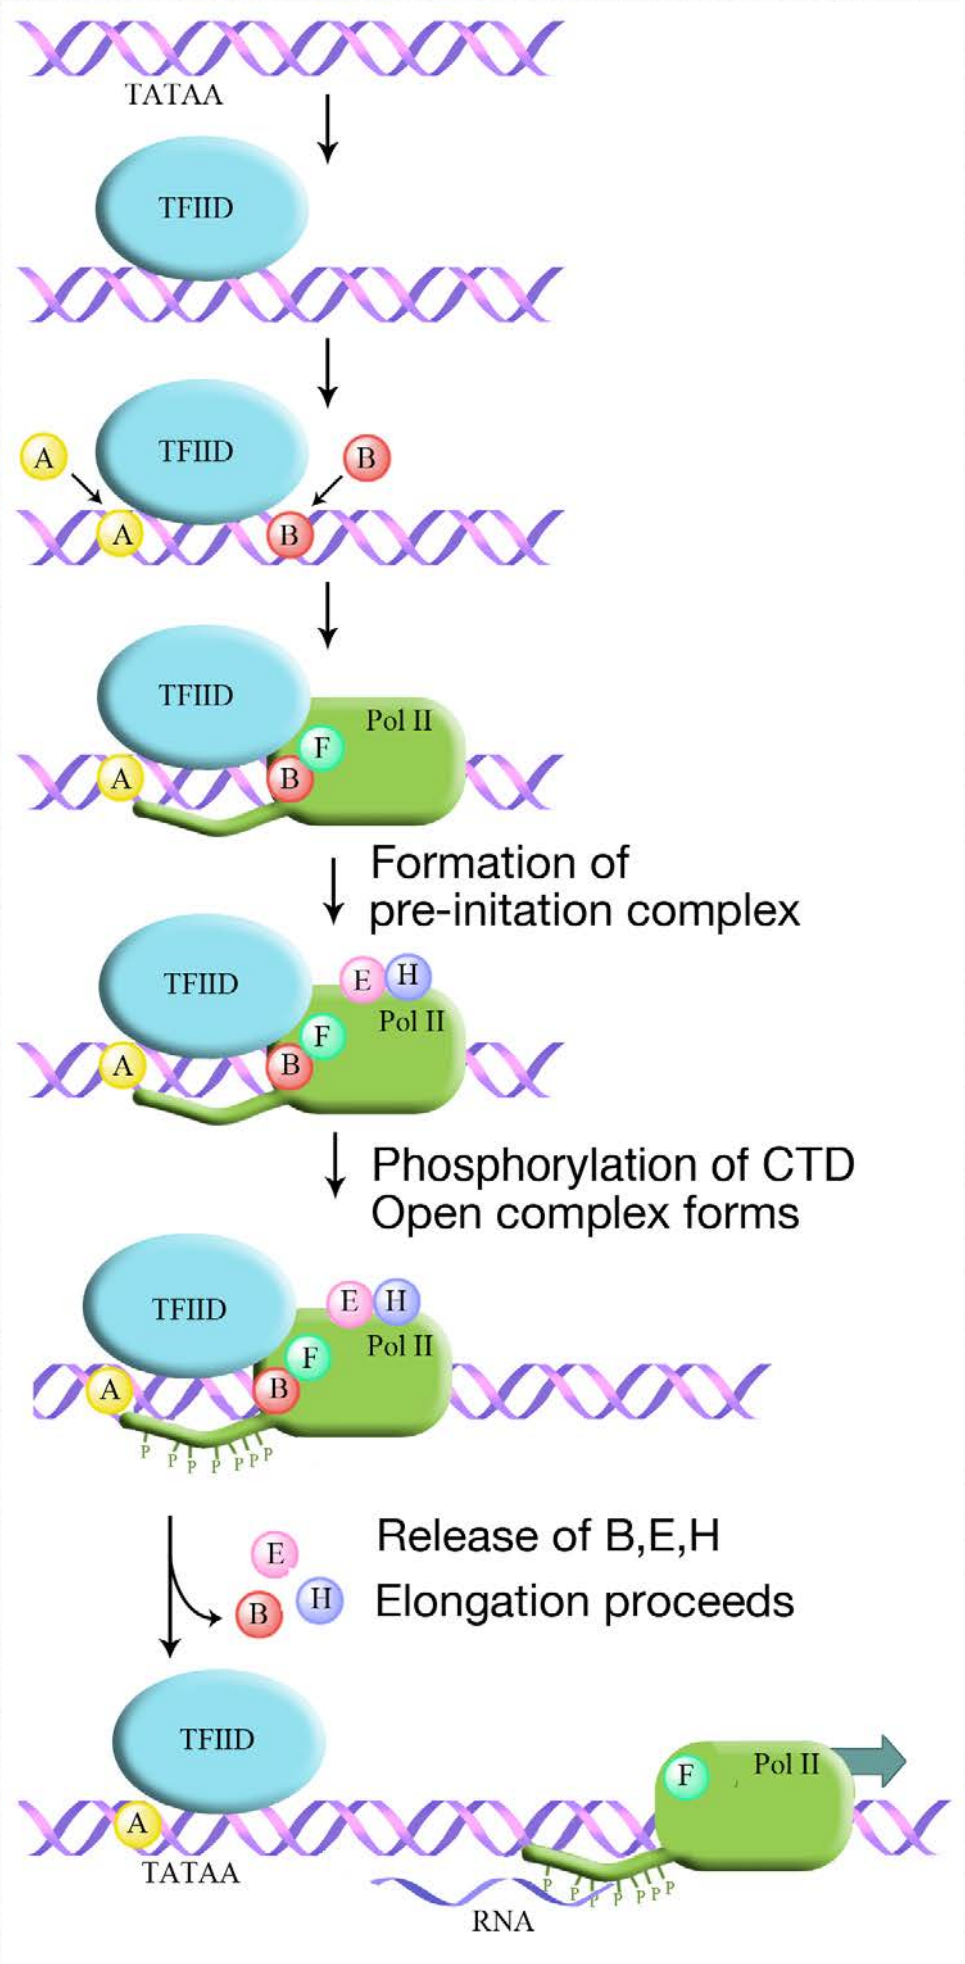

Figure 7.66 - Assembly of the basal transcription complex and transcription initiation

phosphorylation appears to be the signal that releases the RNA polymerase from the basal transcription complex and allows it to move forward on the template, building the new RNA as it goes (Figure 7.66).

Termination of transcription is not as well understood as it is in prokaryotes. Termination does not occur at a fixed distance from the 3' end of mature RNAs. Rather, it seems to occur hand in hand with the processing of the 3' end of the primary transcript. The polyadenylation signal in the 3' untranslated region of the transcript appears to play a role in RNA polymerase pausing, and subsequent release of the completed primary transcript. Recognition of the polyadenylation signal triggers the binding of proteins involved in 3'end processing and termination.

Central Dogma Zen

To the tune of "*Those Were the Days, My Friend*"
Metabolic Melodies Website HERE

Once upon a time a cell decided
The time was ripe for it to split in two
Had to copy cellular instructions
For the daughter cell would need them too.

Bring in a helicase
Unzip the DNAs
To ease the stress a gyrase joins the fray
Strands must be held apart
SSBs do their part
And primase builds a primer RNA.

Sliding clamp comes in behind clamp loader
dNTPs floating all around
In the wings a replicase is waiting
For the chance to start another round.

Polymerase, my friend
Starts at the 3' end
It puts a T across from every A
A G across from C
Perfect simplicity
The leading strand is made in just this way.

The lagging strand is made in little pieces
Okazaki fragments, you recall
Pol I fills the gaps that lie between them
Ligase comes in next and joins them all.

Blueprints can't have mistakes
That's why polymerase
Corrects its work
With exonuclease
Proofreading one by one
Till all its work is done
Hurray for D-N-A polymerase!

An organism's cellular construction
With blueprints for the things they have to do
Requires converting DNA instructions
To ribopolymers, oh yes it's true

Because they've been bestowed
With a genetic code
The RNAs provide the cell with means
To link amino A's
In most directed ways
Inside the protein-making cell machines

If "*coli*" cells don't have galactosidase
And lactose should appear inside its food
The lac repressor leaves the operator
'Cause otherwise metabolism's screwed

Polymerase unwinds
The DNAs it binds
Adjacent to the start site where it docks
Unravels A's and T's
With such amazing ease
At the promoter's little TATA box

The process moves along without much trouble
While making RNA inside the cell
It all occurs inside transcription bubbles
Where bases get linked anti-parallel

mRNA then roams
To find some ribosomes
Subunits large and small bind near the end
The A-U-G's in place
Inside the P site space
Initiation you can comprehend

The mechanism shifts to elongation
Proceeding by three bases at a stretch
A GTP's required for translocation
Advancing 5 to 3 the whole complex

The process moves anon
Until a stop codon
Arrives and causes movement to suspend
Translation has to cease
A peptide gets released
And we have reached the central dogma's end

Information Processing: RNA Processing

So far, we have looked at the mechanism by which the information in genes (DNA) is transcribed into RNA. The newly made RNA, also known as the primary transcript is further processed before it is functional. Both prokaryotes and eukaryotes process their ribosomal and transfer RNAs.

mRNA processing

The major difference in RNA processing, however, between prokaryotes and eukaryotes, is in the processing of messenger RNAs. We will focus on the processing of mRNAs in this section. You will recall that in bacterial cells, the mRNA is translated directly as it comes off the DNA template. In eukaryotic cells, RNA synthesis, which occurs in the nucleus, is separated from the protein synthesis machinery, which is in the cytoplasm. The initial product of transcription of an mRNA is sometimes referred to as the pre-mRNA. After it has been processed and is ready to be exported from the nucleus, it is called the mature

YouTube Lectures by Kevin
HERE & HERE

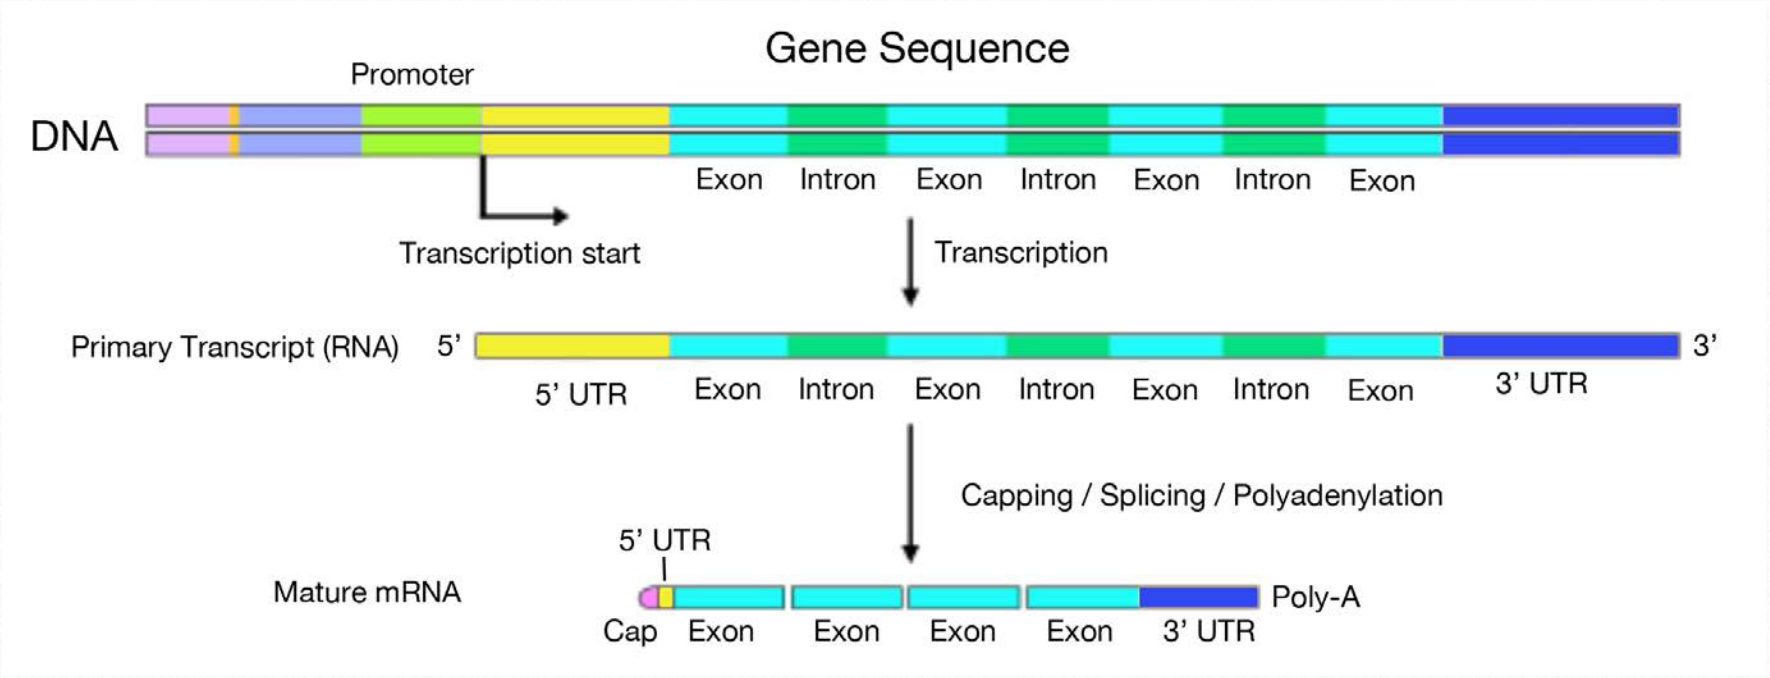

Figure 7.67 - Steps in processing of pre-mRNA

mRNA. The three main processing steps for mRNAs are (Figure 7.67):

- Capping at the 5' end
- Splicing to remove introns
- Addition of a polyA tail at the 3' end.

Although this description suggests that these processing steps occur post-transcriptionally, after the entire gene has been transcribed, there is evidence that processing occurs co-transcriptionally. That is, the steps of processing are occurring as the mRNA is being made. Proteins involved in mRNA processing have been shown to be associated with the phosphorylated C-terminal domain (CTD) of RNA polymerase II.

Capping

As might be expected, the addition of an mRNA cap at the 5' end is the first step in mRNA processing, since the 5'end of the RNA is the first to be made. Capping occurs once the first 20-30 nucleotides of the RNA

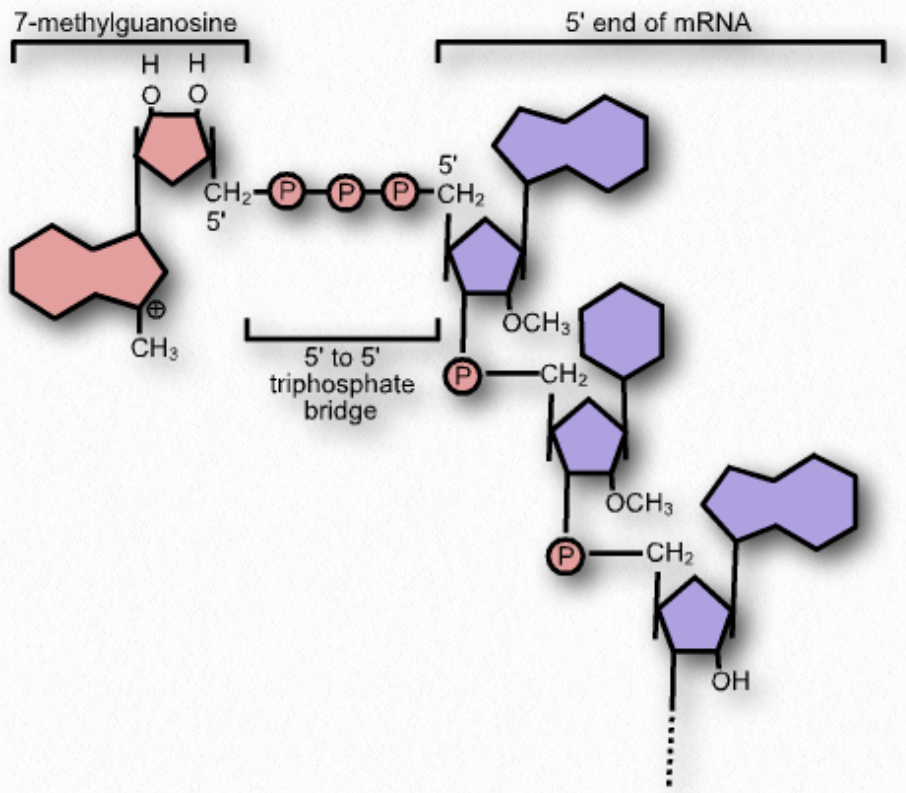

Figure 7.68 - 5' capping of eukaryotic mRNAs
Wikipedia

have been synthesized. The addition of the cap involves removal of a phosphate from the first nucleotide in the RNA to generate a diphosphate. This is then joined to a guanosine monophosphate which is subsequently methylated at N^7 of the guanine to form the 7mG cap structure (Figure 7.68). This cap is recognized and bound by a complex of proteins that remain associated with the cap till the mRNA has been transported into the cytoplasm. The cap protects the 5' end of the mRNA from degradation by nucleases and also helps to position the mRNA correctly on the ribosomes during protein synthesis.

mRNA is sent out of the nucleus to be used to direct protein synthesis.

Intron removal

Introns are removed from the pre-mRNA by the activity of a complex called the spliceosome. The spliceosome is made up of proteins and small RNAs that are associated to form protein-RNA enzymes called small nuclear ribonucleoproteins or snRNPs (pronounced snurps).

Splice junctions

The splicing machinery must be able to recognize splice junctions (i.e., where each exon ends and its associated intron begins) in order to correctly cut out the introns and join the exons to make the mature, spliced mRNA. What signals indicate exon-intron boundaries? The junctions between exons and introns are indicated by specific base sequences. The consensus sequence at the 5' exon-intron junction (also called the 5' splice site) is AG-

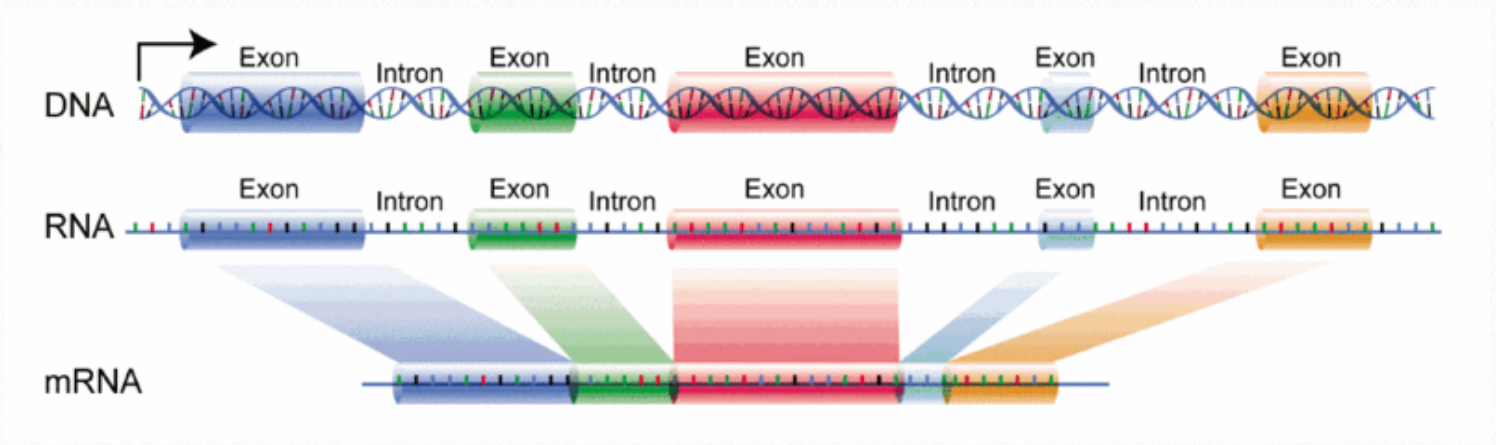

Figure 7.69 - Removal of introns from the primary transcript

Splicing

Eukaryotic genes have introns, noncoding regions that interrupt the gene. The mRNA copied from genes containing introns will also therefore have noncoding regions that interrupt the information in the gene. These noncoding regions must be removed (Figure 7.69) before the

Interactive Learning Module HERE

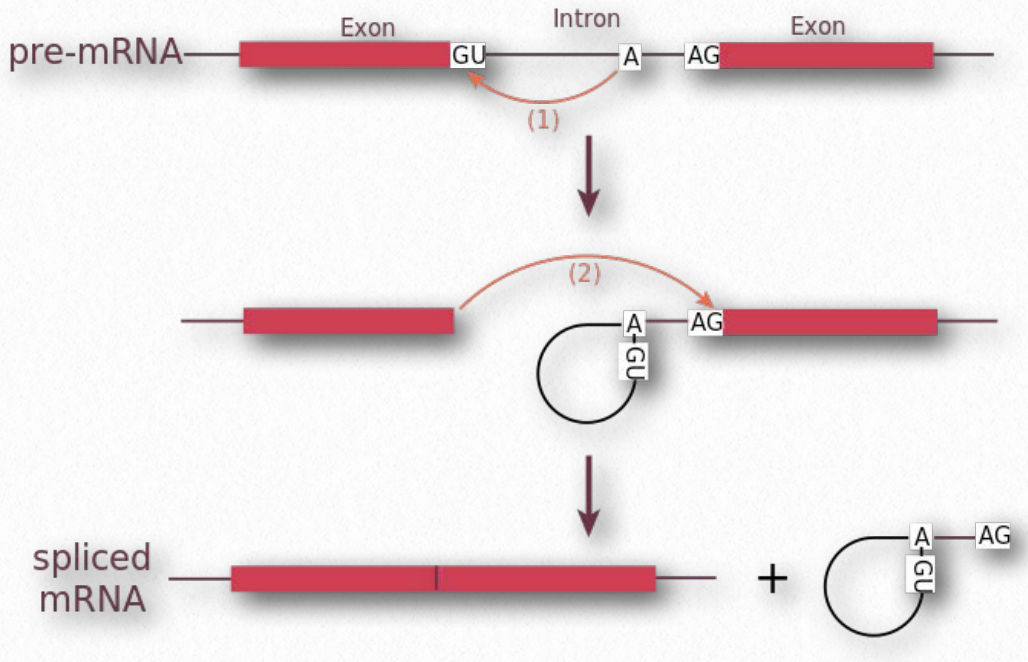

Figure 7.70 - Splicing of introns

Wikipedia

GURAGU. In this sequence, the intron starts with the second G (R stands for any purine). The 3' splice junction has the consensus sequence YAGRNNN, where YAG is within the intron, and RNNN is part of the exon (Y stands for any pyrimidine, and N for any nucleotide).

There is also a third important sequence within the intron, about a hundred nucleotides from the 3' splice site, called a branch point or branch site, that is important for splicing. This site is defined by the presence of an A followed by a string of pyrimidines. The importance of this site will be seen when we consider the steps of splicing.

Splicing mechanism

There are two main steps in splicing. The first step is the nucleophilic attack by the 2'OH of the branch point A on the 5' splice site (the junction of the 5' exon and the intron). As a result of a *trans*-esterification reaction, the 5' exon is released, and a lariat-shaped molecule composed of the 3' exon and the intron sequence is generated (Figure 7.70). In the second step, the 3' OH of the 5' exon attacks the 3' splice site, and the two exons are joined together, and the lariat-shaped intron is released.

Spliceosome

As mentioned earlier, splicing is carried out by a complex consisting of small RNAs and proteins. The five small RNAs crucial to this complex, U1, U2, U4, U5 and U6 are found associated with proteins, as snRNPs. These and many other proteins work together to facilitate splicing. Although many details remain to be worked out, it appears that components of the splicing machinery associate with the CTD of the RNA polymerase and that this association is important for efficient splicing. The assembly of the spliceosome requires the stepwise interaction of the various snRNPs and other splicing factors (Figure

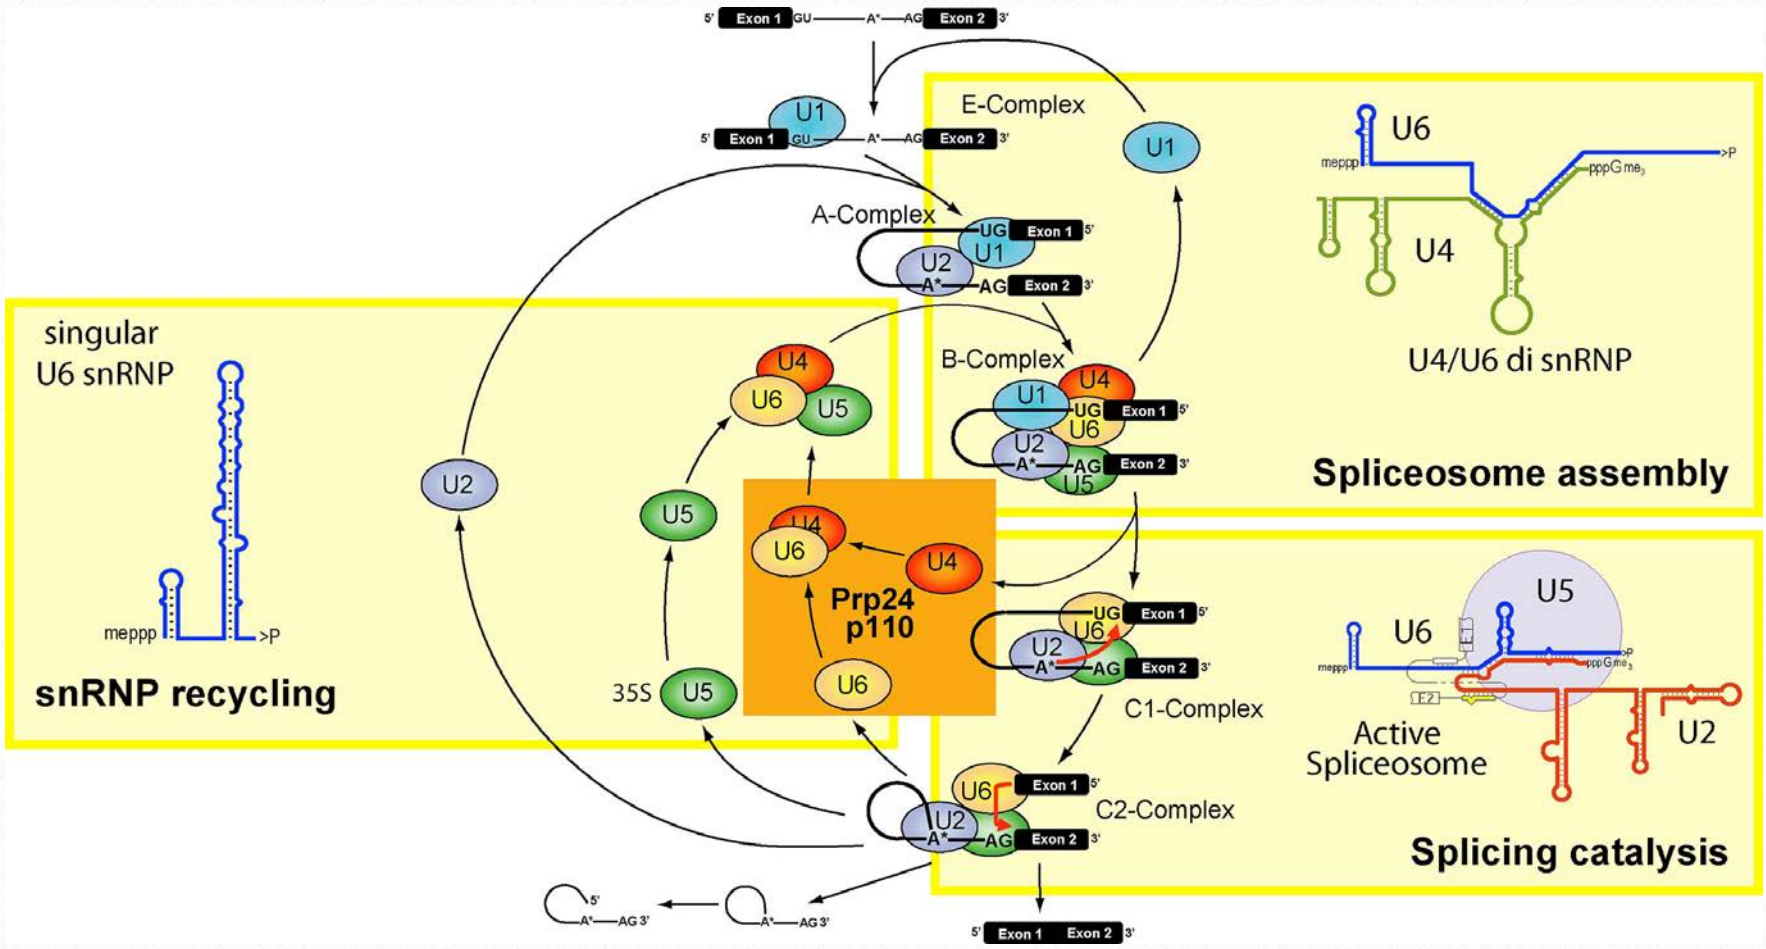

Figure 7.71 - Assembly of the spliceosome complex

Wikipedia

7.71). The initial step in this process is the interaction of the U1 snRNP with the 5' splice site. Additional proteins such as U2AF (AF = associated factor) are also loaded onto the pre-mRNA near the branch site. This is followed by the binding of the U2 snRNA to the branch site.

Next, a complex of the U4/U6 and U5 snRNPs is recruited to the spliceosome to generate a pre-catalytic complex. This complex undergoes rearrangements that alter RNA-RNA and protein-RNA interactions, resulting in displacement of the U4 and U1 snRNPs and the formation of the catalytically active spliceosome. This complex then carries out the two splicing steps described earlier.

YouTube Lectures by Kevin HERE & HERE

Alternative splicing

On average, human genes have about 9 exons each. However, the mature mRNAs from a gene containing nine exons may not include all of them. This is because the exons in a pre-mRNA can be spliced together in different combinations to generate different mature mRNAs. This is called alternative splicing, and allows the production of many different proteins using relatively few genes, since a single RNA with many exons can, by combining different exons dur-

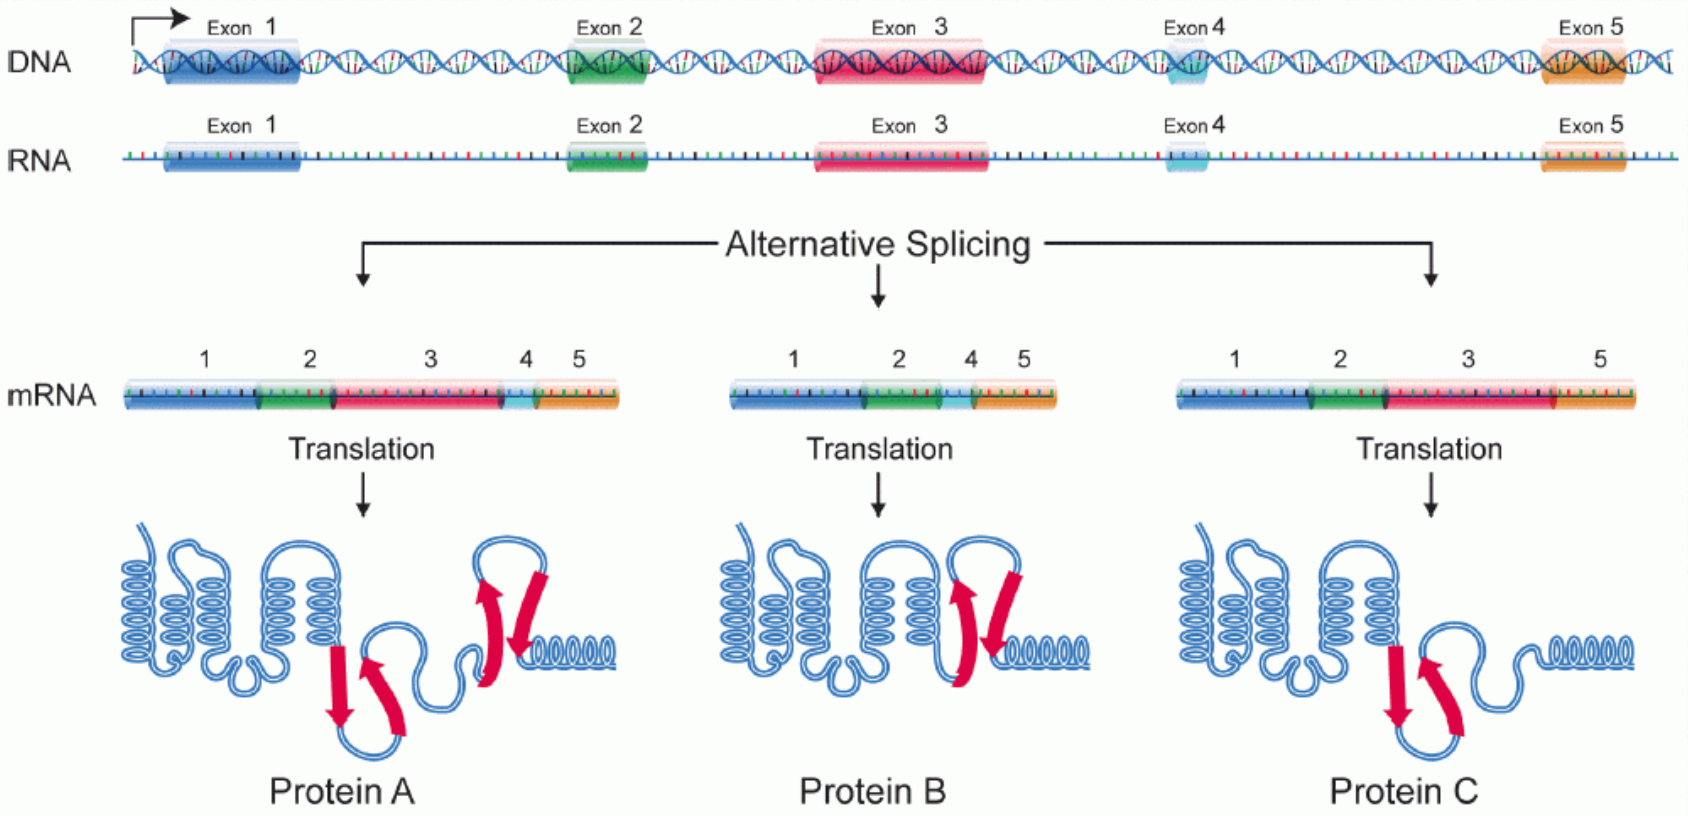

Figure 7.72 - Alternative splicing leads to different forms of a protein from the same gene sequence

ing splicing, create many different protein coding messages. Because of alternative splicing, each gene in our DNA gives rise, on average, to three different proteins. Alternative splicing allows the information in a single gene to be used to specify different proteins in different cell types or at different developmental stages (Figure 7.72).

Polyadenylation

The 3' end of a processed eukaryotic mRNA typically has a "poly(A) tail" consisting of about 200 adenine-containing nucleotides. These residues are added by a template-independent enzyme, poly(A)polymerase, following cleavage of

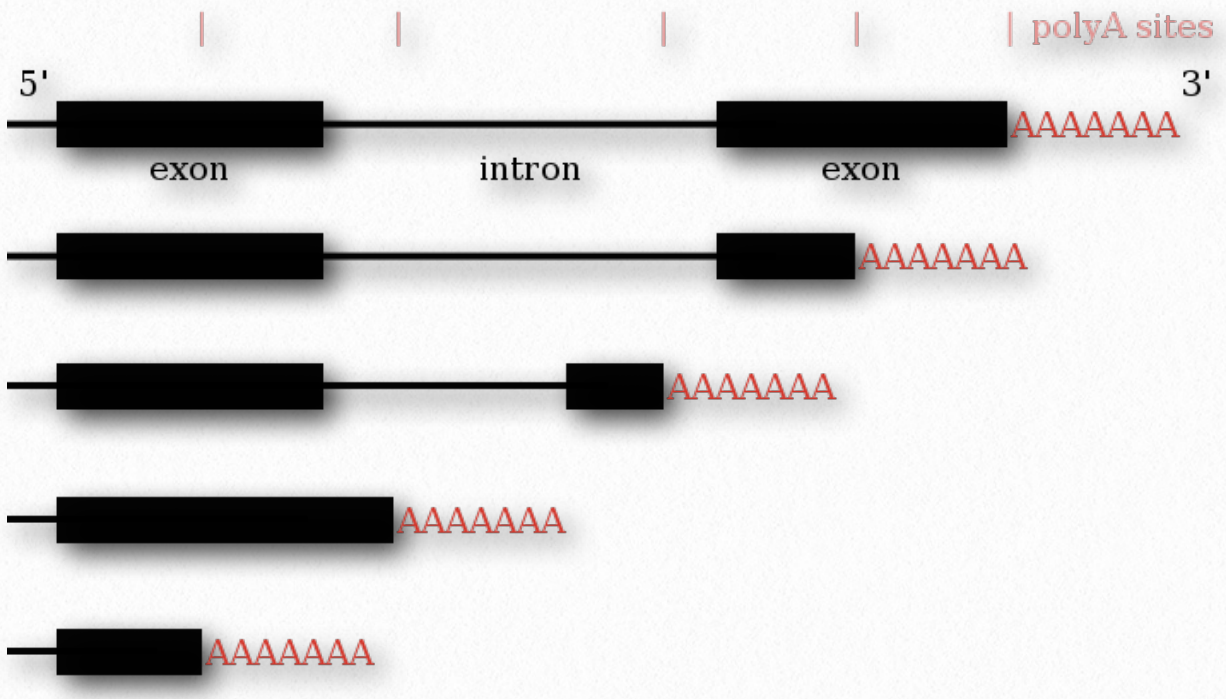

Figure 7.73 - Alternative poly-adenylation sites for a gene

the RNA at a site near the 3' end of the new transcript. Components of the polyadenylation machinery have been shown to be associated with the CTD of the RNA polymerase, showing that all three steps of pre-mRNA processing are tightly linked to transcription. There is evidence that the polyA tail plays a role in efficient translation of the mRNA, as well as in the stability of the mRNA. Like alternative splice sites, genes can have alternative polyA sites as well (Figure 7.73).

The cap and the polyA tail on an mRNA are also indications that the mRNA is complete (i.e., not defective). Once protein-coding messages have been processed by capping, splicing and addition of a poly A tail, they are transported out of the nucleus to be translated in the cytoplasm. Mature mRNAs are sent into the cytoplasm bound to export proteins that interact with the nuclear pore complexes in the nuclear envelope (Figure 7.74). Once the mature mRNA has been translocated to the cytoplasm, it is ready to be translated.

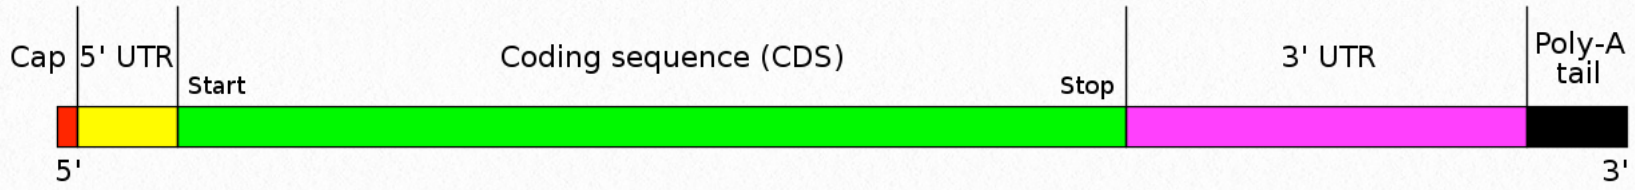

Figure 7.74 - Structure of a mature eukaryotic mRNA

RNA editing

In addition to undergoing the three processing steps outlined above, many RNAs undergo further modification called RNA editing. Editing has been observed in not only mRNAs but also in transfer RNAs and ribosomal RNAs. As the name suggests, RNA editing is a process during which the sequence of the transcript is altered post-transcriptionally. A well-studied example of RNA editing is the alteration of the sequence of the mRNA for apolipoprotein B (see also HERE). The editing results in the deamination of a cytosine in the transcript to form a uracil, at a specific location in the mRNA. This change converts the codon at this position, CAA, which encodes a glutamine, into UAA, a stop codon. The consequence of this is that a shorter version of the protein is made, when the edited transcript is translated. It is interesting that the editing of this transcript occurs

Interactive Learning Module HERE

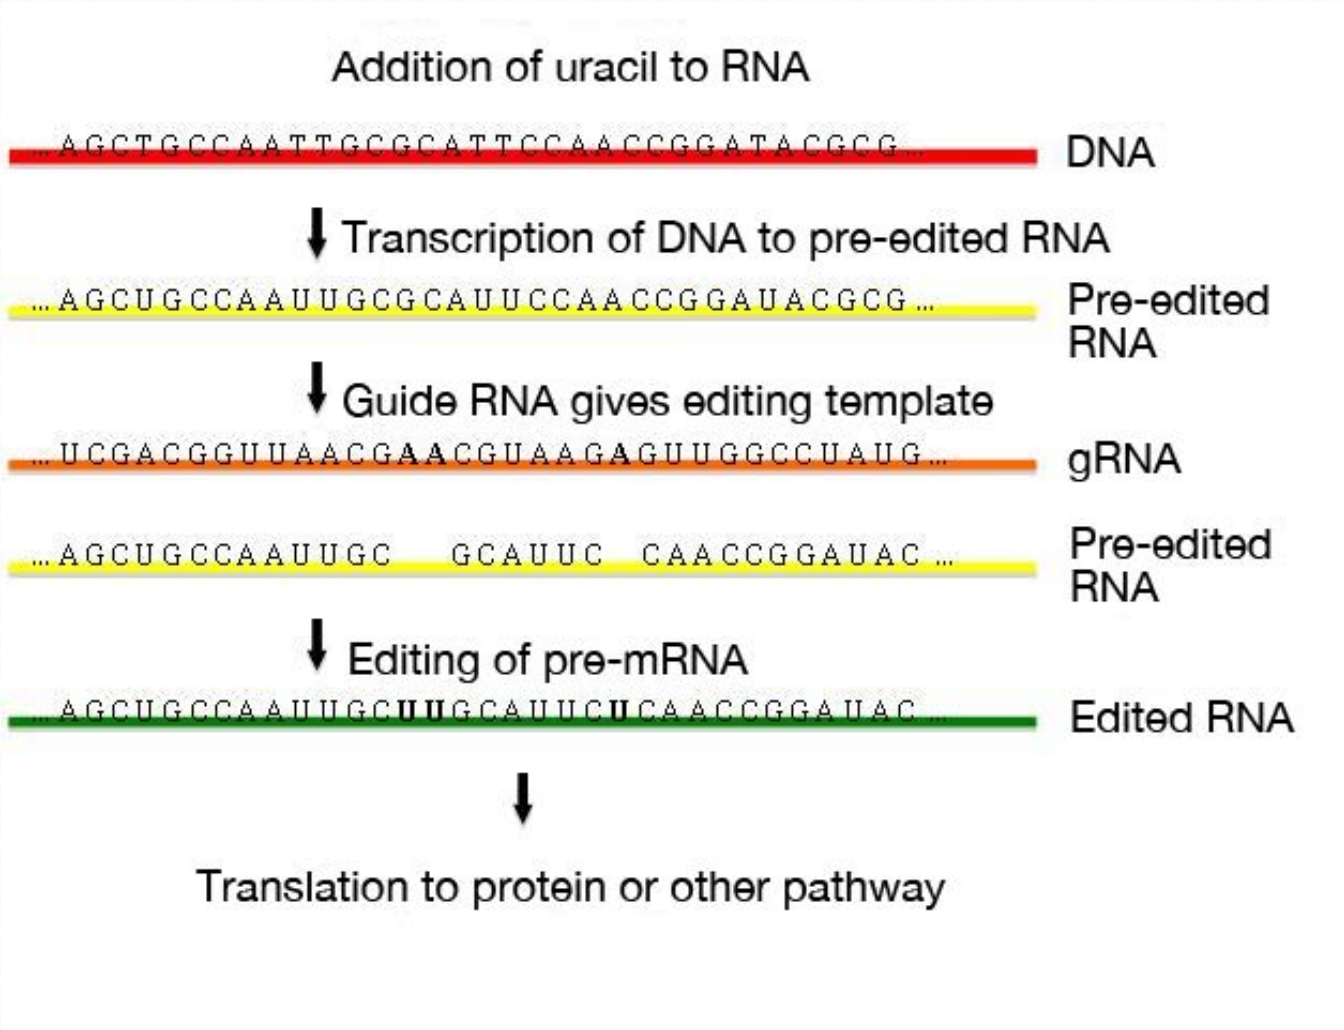

Figure 7.75 - Template guided - one mechanism of RNA editing

in intestinal cells but not in liver cells. Thus, the protein product of the apolipoprotein B gene is longer in the liver than it is in the intestine.

Insertion/deletion

Another kind of RNA editing involves the insertion or deletion of one or more nucleotides. One example of this sort of editing is seen in the mitochondrial RNAs of trypanosomes. Small guide RNAs indicate the sites at which nucleotides are inserted or deleted to produce the mRNA that is eventually translated (Figure 7.75).

The effect of either of these kinds of editing on the mRNA is that the encoded protein product is different, providing another point at which the product of expression of a gene can be controlled.

tRNA synthesis & processing

tRNAs are synthesized by RNA polymerase III, which makes precursor molecules called pre-tRNA that then undergo proc-

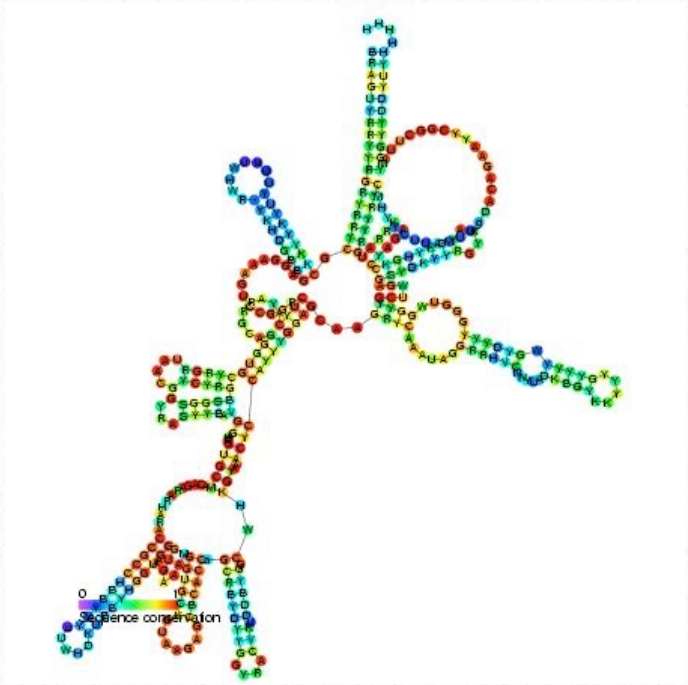

Figure 7.76 - Structure of the RNA component of ribonuclease P

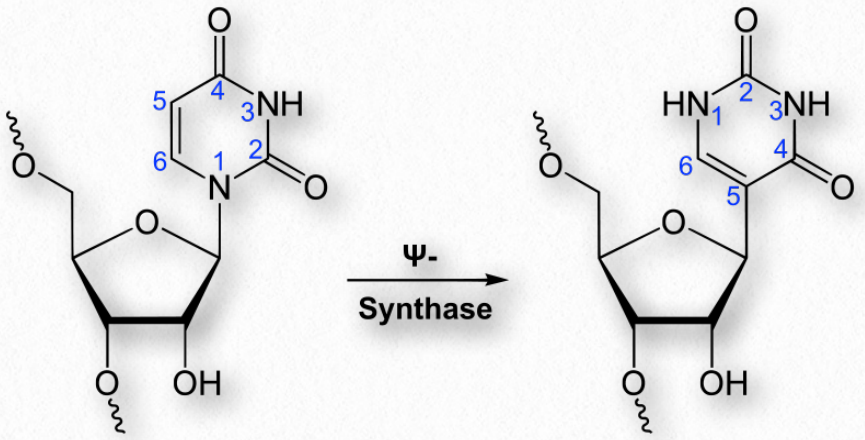

Figure 7.77 - Synthesis of pseudouridine from uridine

Wikipedia

essing to generate mature tRNAs. The initial transcripts contain additional RNA sequences at both the 5' and 3' ends. Some pre-tRNAs also contain introns. These additional sequences are removed from the transcript during processing.

The 5' leader sequence of the pre-tRNA (the additional nucleotides at the 5'-end) is removed by an unusual endonuclease called ribonuclease P (RNase P - Figure 7.76). RNase is a ribonucleoprotein complex composed of a catalytic RNA and numerous proteins. The 3' trailer sequence (extra nucleotides at the 3' end of the pre-tRNA) is later removed by different nucleases. All tRNAs must have a 3' CCA sequence that is necessary for the charging of the tRNAs with amino acids. In bacteria, this CCA sequence is encoded in the tRNA gene, but in eukaryotes, the CCA sequence is added post-transcriptionally by an enzyme called tRNA nucleotidyl transferase (tRNT).

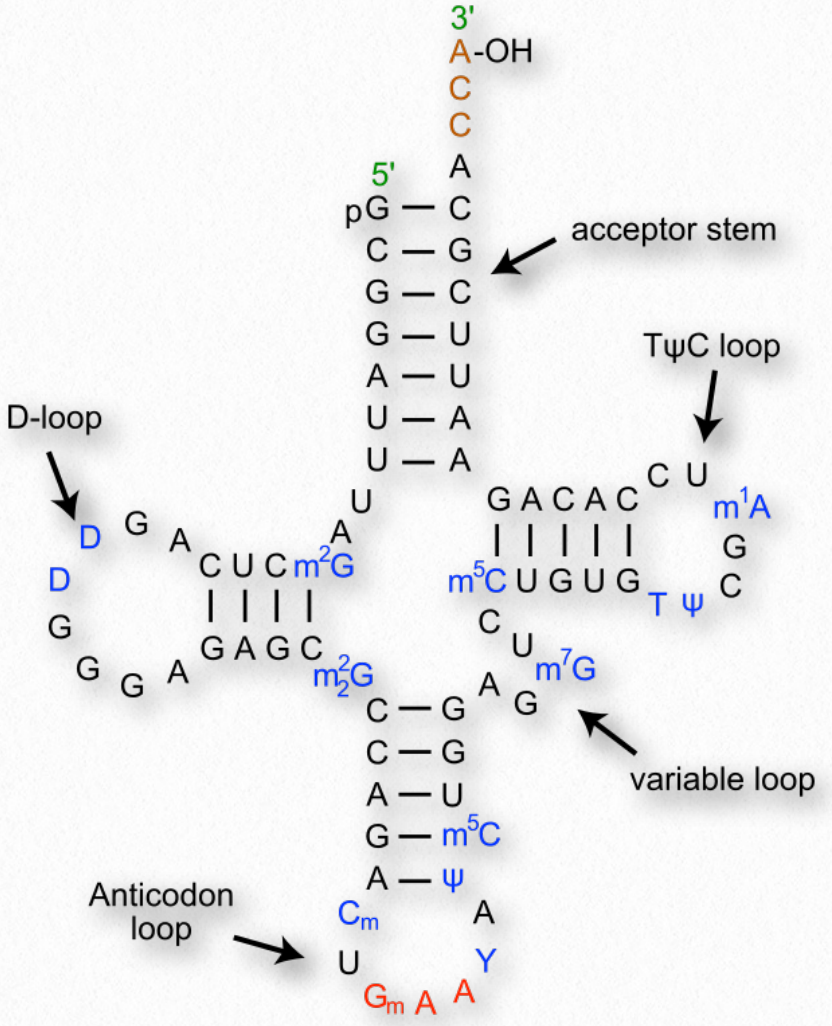

Figure 7.78 - Sequence of a mature tRNA

Wikipedia

Introns

As mentioned earlier, some tRNA precursors contain an intron located in the anticodon arm. In eukaryotes, this intron is typically found immediately 3' to the anticodon. The introns is spliced out with the help of a tRNA splicing endonuclease and a ligase.

Base modifications

Mature tRNAs contain a high proportion of bases other than the usual adenine (A), guanine (G), cytidine (C) and uracil (U). These unusual bases are produced by modifying the bases in the tRNA to form variants,

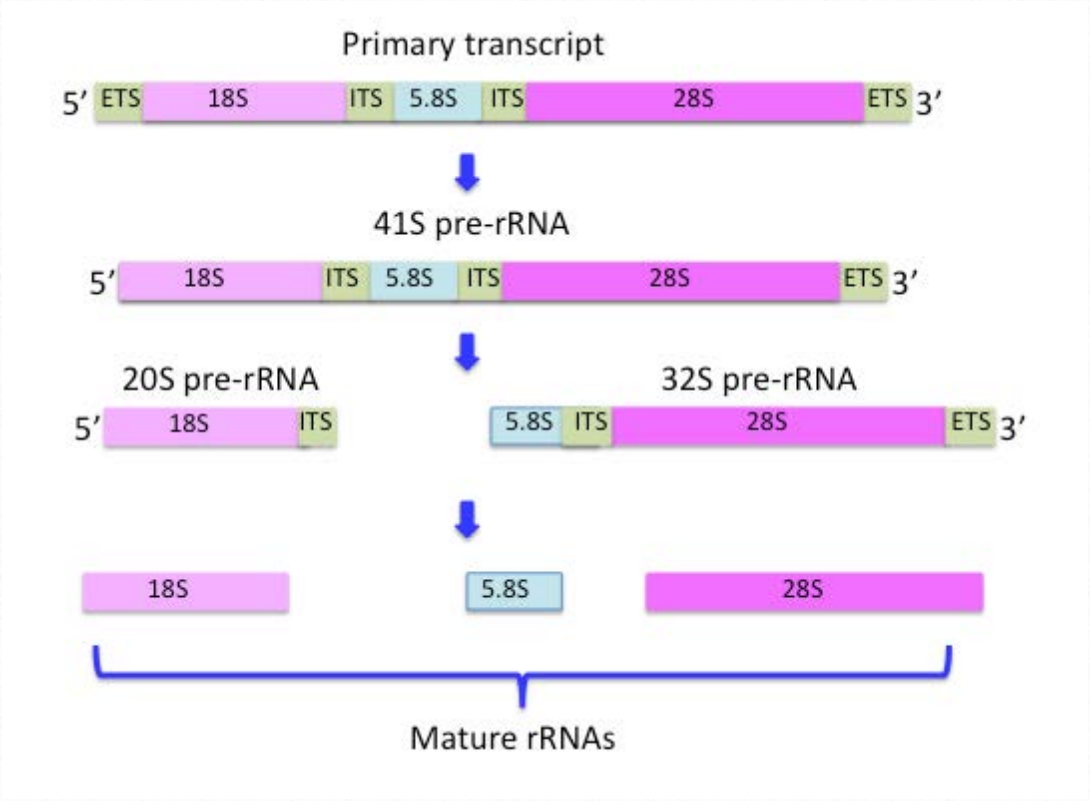

Figure 7.79 - Processing of ribosomal RNA

such as pseudouridine (Figure 7.77) or dihyrouridine. Modifications to the bases are introduced into the tRNA at the final processing step by a variety of specialized enzymes. Different tRNAs have different subsets of modifications at specific locations, often the first base of the anti-codon (the wobble position).

rRNA synthesis and processing

Cells contain many copies of rRNA genes (between 100 and 2000 copies are seen in mammalian cells). These genes are organized in transcription units separated by non-transcribed spacers. Each transcription unit contains sequences coding for 18S, 5.8S and 28S rRNA, and is transcribed by RNA polymerase I into a single long transcript (47S). The 5S rRNA is separately transcribed.

The sizes of ribosomal RNAs are, by convention, indicated by their sedimentation coefficients, which is a measure of their rate of sedimentation during centrifugation. Sedimentation is expressed in Svedberg units (hence the S at the end of the number) with larger numbers indicating greater mass.

The initial transcript contains 5' and 3' external transcribed spacers (ETS) as well as internal transcribed sequences (ITS). The primary transcript is first trimmed at both ends by nucleases to give a 45S pre-rRNA. Further processing of the pre-rRNA through cleavages guided by RNA-protein complexes containing snoRNAs (small nucleolar RNAs), gives rise to the mature 18S, 5.8S and 28S rRNAs (Figure 7.79). Ribosomal RNAs are also modified both on the ribose sugars and on the bases. Interestingly, methylation of ribose sugars is the major modification in rRNA. The modified base pseudouridine is also common in rRNA. Other modifications include base methylation, and acetylation. These modifications are thought to be important in modulating ribosome function.

Lyrics by Kevin Ahern

Information Processing: Translation

Translation is the process by which information in mRNAs is used to direct the synthesis of proteins. As you have learned in introductory biology, in eukaryotic cells, this process is carried out in the cytoplasm of the cell, by large RNA-protein machines called ribosomes. Ribosomes contain ribosomal RNA (rRNA) and proteins. The proteins and rRNA are organized into two subunits, a large and a small. Ribosomes function by binding to mRNAs and holding them in a way that allows the amino acids encoded by the RNA to be joined sequentially to form a polypeptide. Transfer RNAs are the carriers of the appropriate amino acids to the ribosome.

The genetic code

We speak of genes (i.e., DNA) coding for proteins and the central dogma, which states that DNA makes RNA makes protein. What does this actually mean? A code can be thought of as a system for storing or communicating information. A familiar ex-

tion, it conveys information that your bag should be sent to Portland, Oregon. To function well, such a set-up must have unique identifiers for each airport and people who can decode the identifiers correctly. That is, PDX must stand only for Portland, Oregon and no other airport. Also, luggage handlers must be able to correctly recognize what PDX stands for, so that your luggage doesn't land in Phoenix, instead.

How does this relate to genes and the proteins they encode?

Genes are first transcribed into mRNA, as we have already discussed. The sequence of an mRNA, copied from a gene, directly specifies the sequence of amino acids in the protein it encodes. Each amino acid in the protein is specified by a sequence of 3 bases called a codon in the mRNA (Figure 7.81). For example, the amino acid tryptophan is encoded by the sequence UGG on an mRNA. All of the twenty amino acids used to build proteins have, likewise, 3-base sequences that encode them.

Degeneracy

Given that there are 4 bases in RNA, the number of different 3-base combinations that are possible is 4^3, or 64. There are, however, only 20 amino acids that are used in building proteins in cells. This discrepancy in the number of possible codons and the actual number of amino acids they specify is explained by the fact that the same amino acid may be specified by more than one codon. In fact, with the exception of the amino acids methionine and tryptophan, all the other amino acids are encoded by multiple codons. Codons for the same amino acid are often related, with the first two bases the same and the third being variable. An example would be the codons for alanine: GCU, GCA, GCC and GCG all stand for alanine. This sort of re-

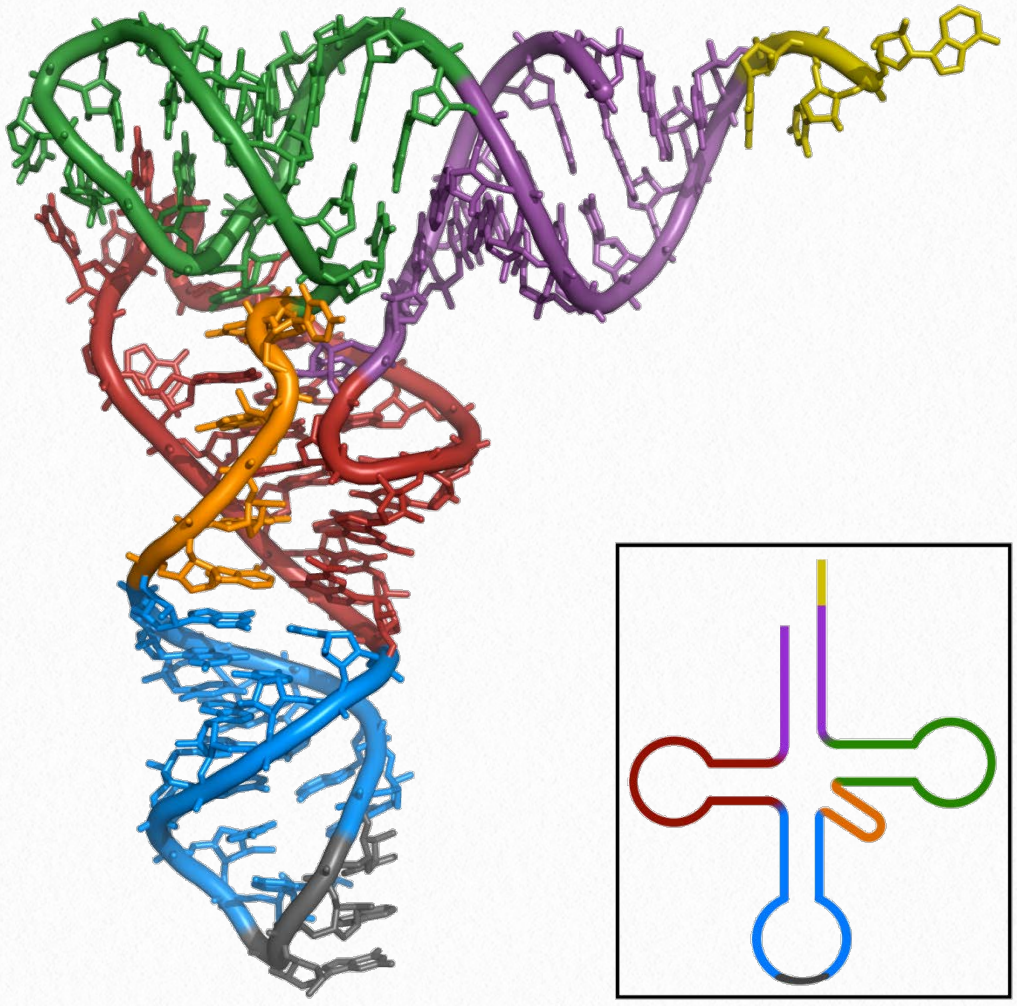

Figure 7.83 - tRNA - 3D projection (left) and 2D projection (inset)
Wikipedia

dundancy in the genetic code is termed degeneracy.

Stop and start codons

Three of the 64 codons are what are known as termination or stop codons, and as their name suggests, indicate the end of a protein coding sequence. The codon for methionine, AUG, is used as the initiation or start codon for the majority of proteins. This ingenious system is used to direct the assembly of a protein in the same way that you might string together colored beads in a particular order using instructions that used symbols like UGG for a red bead, followed by UUU for a green bead, CAC for yellow, and so on, till you came to UGA, indicating that you should stop stringing beads.

Translating the code

While the ribosomes are literally the factories that join amino acids together using the instructions in mRNAs, another class of RNA molecules, the transfer RNAs (tRNAs) are also needed for translation (Figure 7.83 and Interactive 7.1). Transfer RNAs are small RNA molecules, about 75-90 nucleotides long, that function to 'interpret' the instructions in the mRNA during protein synthesis. Transfer RNAs are extensively modified post-transcriptionally and contain a large number of unusual bases. The sequences of tRNAs have several self complementary regions, where the single-stranded tRNA folds on itself and base-pairs to form what is sometimes described as a clover leaf structure.

This structure is crucial to the function of the tRNA, providing both the sites for attachment of the appropriate amino acid and for recognition of codons in the mRNA. In terms of the bead analogy above, someone or something has to be able to bring a red bead in when the instructions indicate UGG, and a green bead when the instructions say UUU. This, then, is the function of the tRNAs. They must be able to bring the amino acid corre-

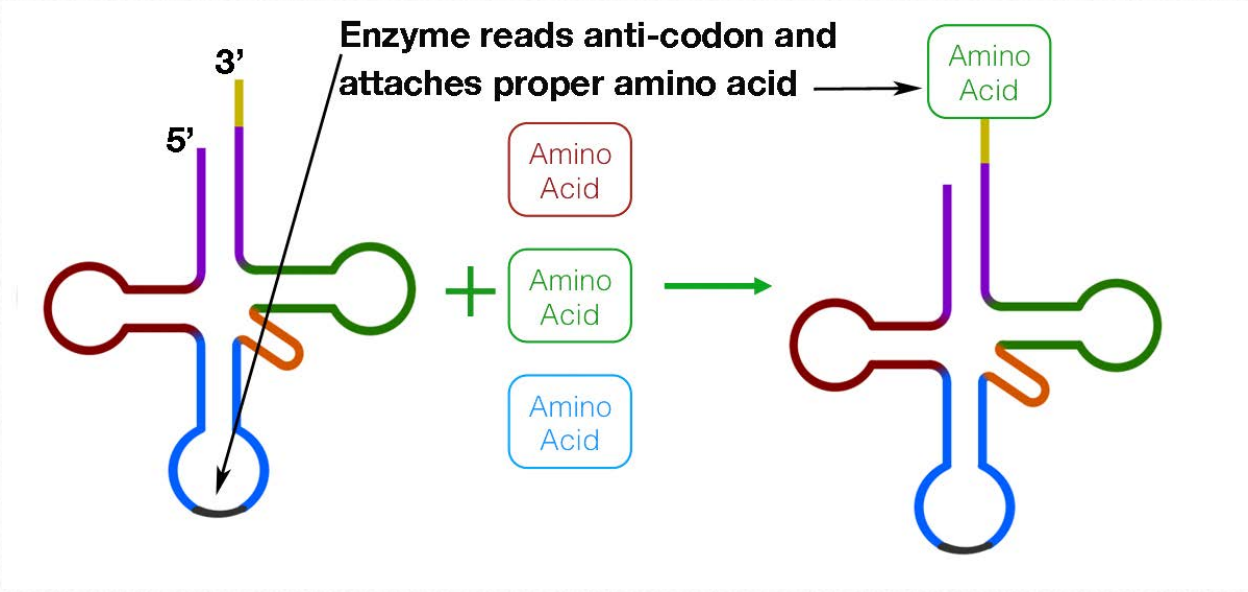

Figure 7.84 - Charging of a tRNA by aminoacyl tRNA synthetase

Wikipedia

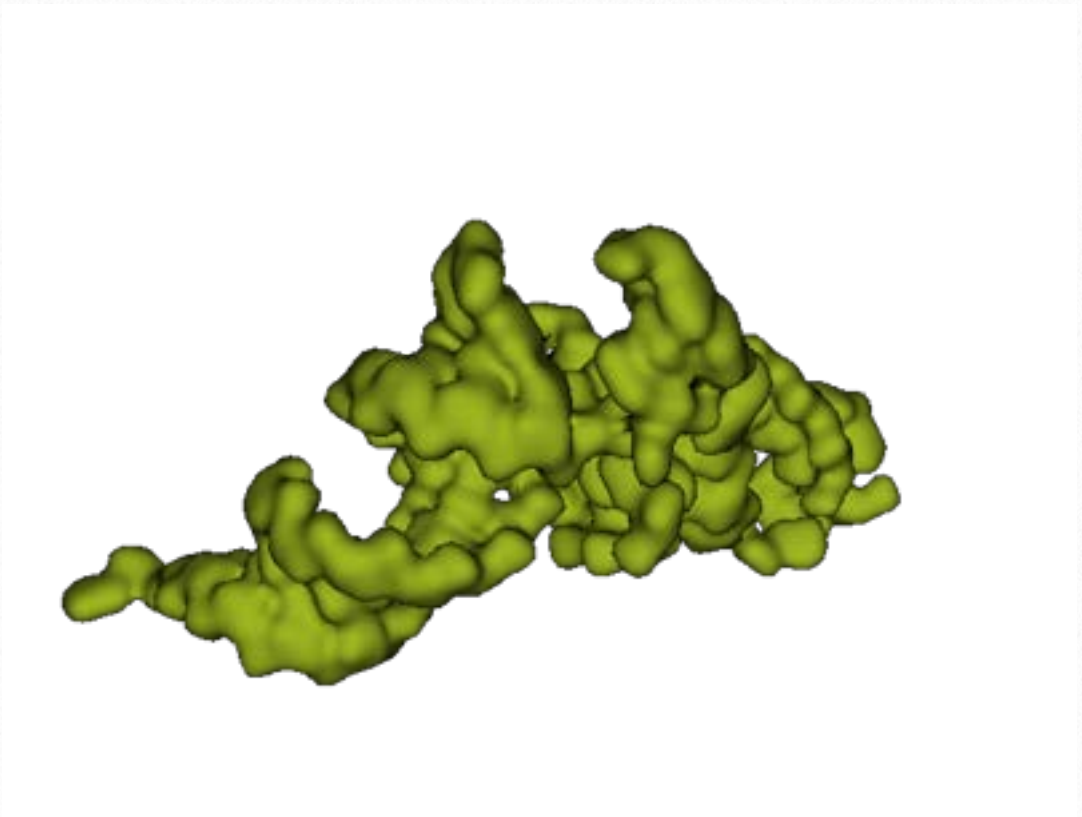
sponding to the instructions to the ribosome.

t-RNA specificity

A given transfer RNA is specific for a particular amino acid. It is linked covalently at its 3' end to the appropriate amino acid by an enzyme called aminoacyl tRNA synthetase. For example, there is a transfer RNA that is specific to the amino acid tryptophan, and a corresponding aminoacyl tRNA synthetase, called a tryptophanyl tRNA synthetase, that can attach the tryptophan specifically to this tRNA. Likewise, there is an aminoacyl tRNA synthetase specific for each amino acid. A tRNA with an amino acid attached to it is said to be *charged* (Figure 7.84). A pool of charged tRNAs is necessary to carry out protein synthesis. How do these tRNAs, carrying specific amino acids assist the ribosome in stringing together the correct amino acids, as specified by the sequence of the mRNA?

Codon recognition

As we already know, the amino acid sequence of the protein is determined by the order of the codons in the mRNA. We also have charged tRNAs carrying the various amino acids present. How are the amino acids attached to each other in the order indicated by the base se-



Interactive 7.1 - Phenylalanyl-tRNA

PDB

quence of the mRNA? This requires recognition of the codons on the mRNA by the appropriate charged tRNAs. The amino acid tryptophan, as we noted, is specified by the codon UGG in the mRNA. This codon must be recognized by a tRNA charged with tryptophan. Every tRNA has a a sequence of 3 bases, the anticodon, that is complementary to the codon for the amino acid it is carrying. When the tRNA encounters the codon for its amino acid on the messenger RNA, the anticodon will base-pair with the codon. For the tryptophan tRNA this is what it would look like:

YouTube Lectures by Kevin HERE & HERE

Sequence of tryptophan codon in mRNA:

5’ UGG 3’

Anticodon sequence in tryptophan tRNA:

5’ CCA 3’

Note that the sequences are both written, by convention, in the 5’ to 3’ direction. To base pair, though, they must be oriented in opposite directions (anti-parallel). The codon-anticodon basepair in the antiparallel orientation then would be:

5’ UGG 3’
3’ ACC 5’

The base-pairing of the anticodon on a charged tRNA with the codon on the mRNA is what brings the correct amino acids in to the ribosome to be added on to the growing protein chain (Figure 7.85).

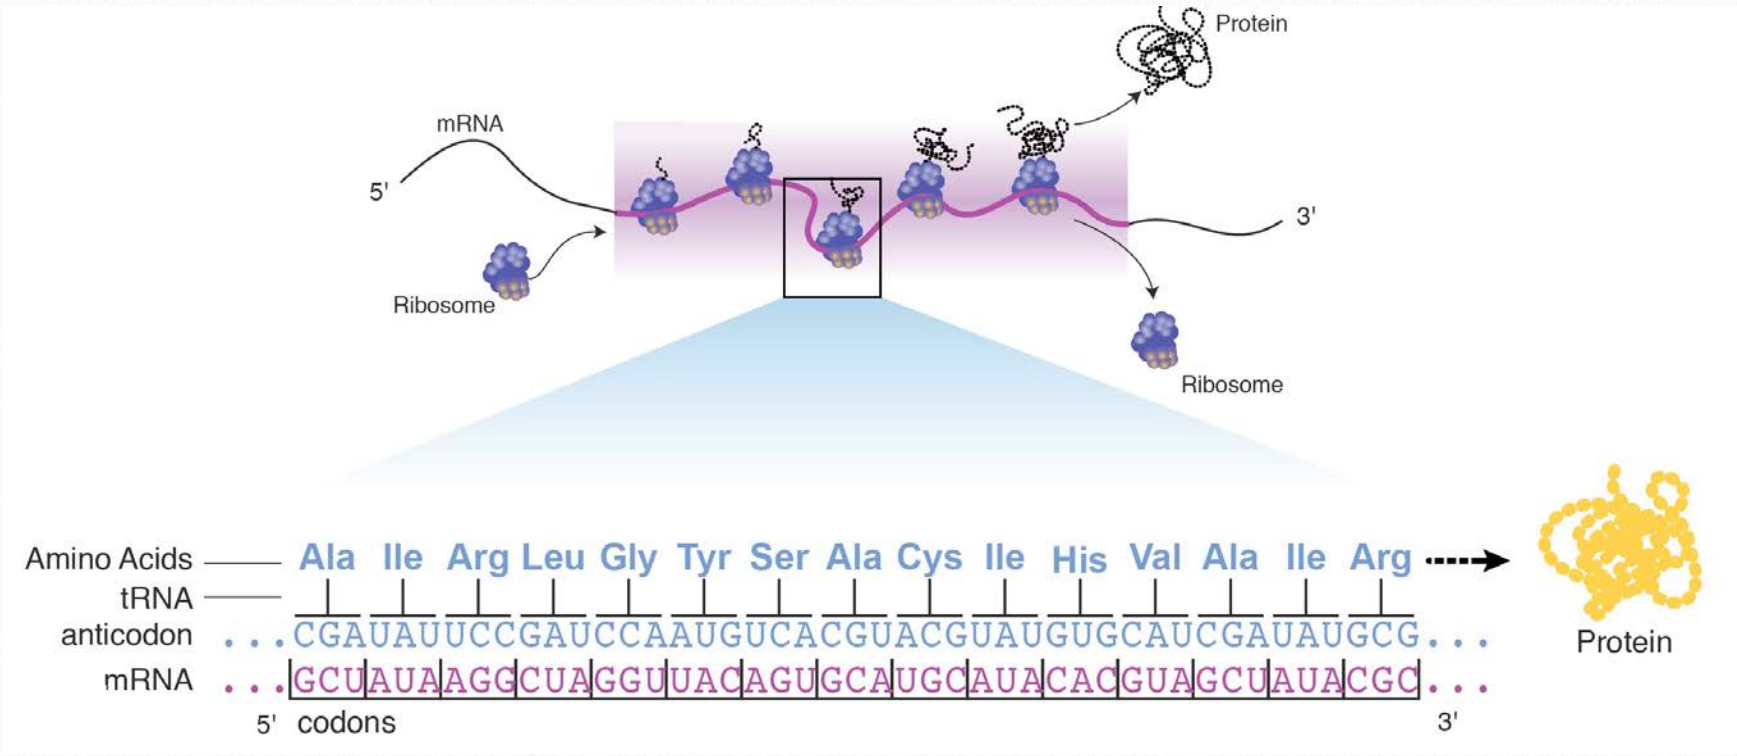


Figure 7.85 - Codons in mRNA pair with anticodons on tRNA to bring the appropriate amino acid to the ribosome for polypeptide assembly

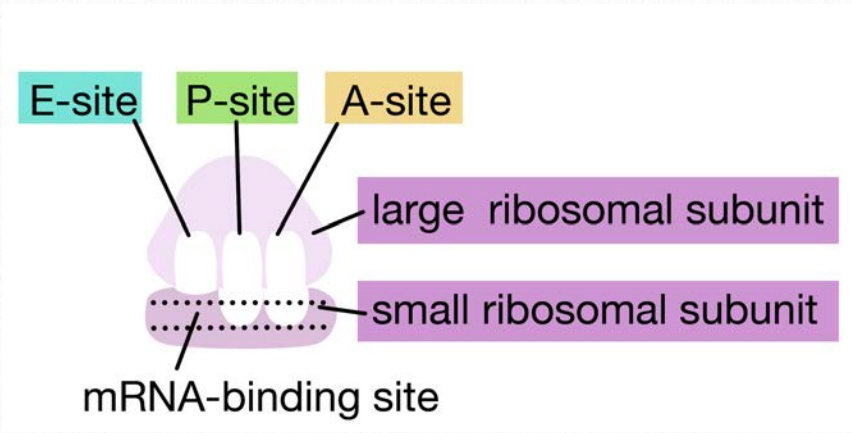

Figure 7.86 - The A, P, and E sites in a ribosome

Image by Martha Baker

Making a polypeptide

With an idea of the various components necessary for translation and how they work, we can now take a look at the process of protein synthesis. The main steps in the process are similar in prokaryotes and eukaryotes. As we already noted, ribosomes bind to mRNAs and facilitate the interaction between the codons in the mRNA and the anticodons on charged tRNAs.

Ribosomes have two sites (P-site and A-site) for binding and positioning charged tRNAs so each can form base pairs between their anticodon and a codon from the mRNA. The start codon (AUG) is positioned to base pair with the tRNA in the P-site (peptidyl site). Next, the charged tRNA complementary to the codon adjacent to the start codon binds and occupies the A-site (aminoacyl site) in the ribosome (Figure 7.86).

Interactive Learning Module HERE

At this point, the ribosome joins the amino acids carried on each tRNA by making a peptide bond. The bond between the amino acid and the tRNA in the P-site is broken and the dipeptide is joined to the tRNA on the A-site.

The initiator tRNA without its amino acid is then released, moving into a site known as the Exit or E-site, while the second tRNA carrying the dipeptide (and the codon it is base paired to) moves into the P-site. The A-site now is ready with a new codon for the next incoming charged tRNA.

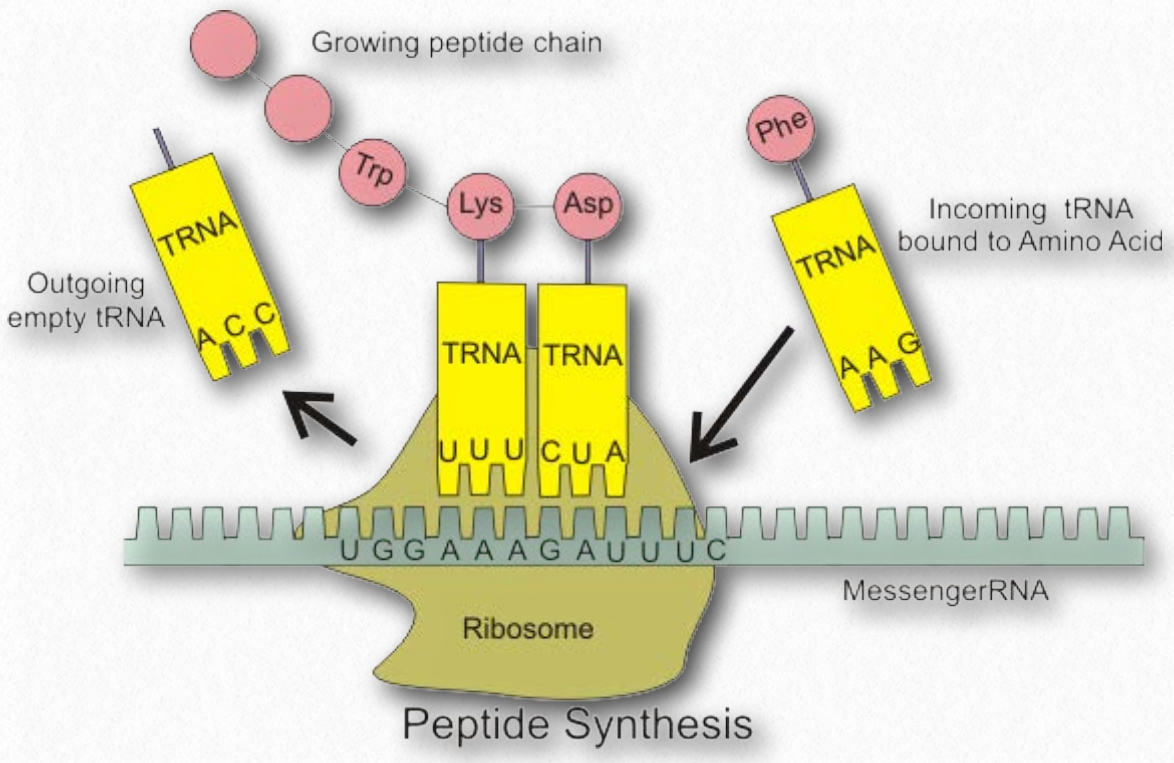

Figure 7.87 - Overview of elongation

Wikipedia

This process is repeated, with the ribosome moving on the mRNA one codon at a time, until the stop codon reaches the A-site. At this point, a release factor binds at the A-site, and helps to free the completed polypeptide from the ribosome. The ribosome then dissociates into the small and large subunits, once more.

rRNA Name	Prokaryotes	Eukaryotes	Function
5S	Large Subunit	Large Subunit	tRNA binding?

28S		Large Subunit	Peptide bond formation

Table 7.1 - Location and function of rRNAs.

Three steps

Having considered the steps of translation in broader terms, we can now look at them in greater detail. We will consider the three steps of translation (bel0w) individually.

Movie 7.1 - 30S ribosomal subunit

Wikipedia

- Initiation (binding of the ribosomal subunits to the transcript and initiator tRNA)
- Elongation (repeated addition of amino acids to the growing polypeptide, based on the sequence of the mRNA - Figure 7.87)
- Termination (release of the completed polypeptide and dissociation of the ribosome into its subunits).

We already know that processed mRNAs are sent from the nucleus to the cytoplasm in eukaryotic cells, while in prokaryotic cells, transcription and translation occur in a single cellular compartment. The small and large subunits of ribosomes, each composed of characteristic rRNAs and proteins, are found in the cytoplasm and assemble on mRNAs to form complete ribosomes that carry out translation. Both prokaryotic

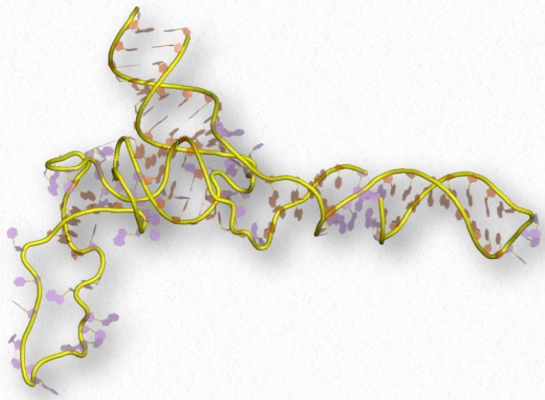

Figure 7.88 - Structure of 5S rRNA

and eukaryotic ribosomal subunits are made up of one or more major rRNAs together with a large number of ribosomal proteins. The small subunits of prokaryotic cells are called the 30S ribosomal subunits, while their counterparts in eukaryotes are the 40S subunits. The large ribosomal subunits in prokaryotes are the 50S subunits, while those in eukaryotic cells are 60S. These differences reflect the larger mass of eukaryotic ribosomes. The rRNA components of ribosomes are important for the recognition of the 5' end of the mRNA, and also play a catalytic role in the formation of peptide bonds.

Initiation

Messenger RNAs have non-coding sequences both at their 5' and 3' ends, with the actual protein-coding region sandwiched in between these untranslated regions (called the 5' UTR and 3' UTR, respectively). The ribosome must be able to recognize the 5' end of the mRNA and bind to it, then determine where the start codon is located. It is important to note that both in prokaryotes and eukaryotes, ribosomes assemble at the 5' end of the transcript by the stepwise binding of the small and large subunits. The small subunit first binds to the mRNA at specific sequences in the 5' UTR. The large subunit then binds to the complex of the mRNA and small subunit, to form the complete ribosome.

Initiator tRNA

Initiation also requires the binding of the first tRNA to the ribosome. As we have noted earlier, the initiation, or start codon is usually AUG, which codes for the amino acid methionine. Thus, the initiator tRNA is one that carries methionine and is designated as $tRNA^{met}$ or methionyl $tRNA^{met}$. In bacteria, the methionine on the initiator tRNA is modified by the addition of a formyl group, and is designated $tRNA^{fmet}$. The initiator tRNA carrying methionine to the AUG is different from the tRNAs that carry methionine

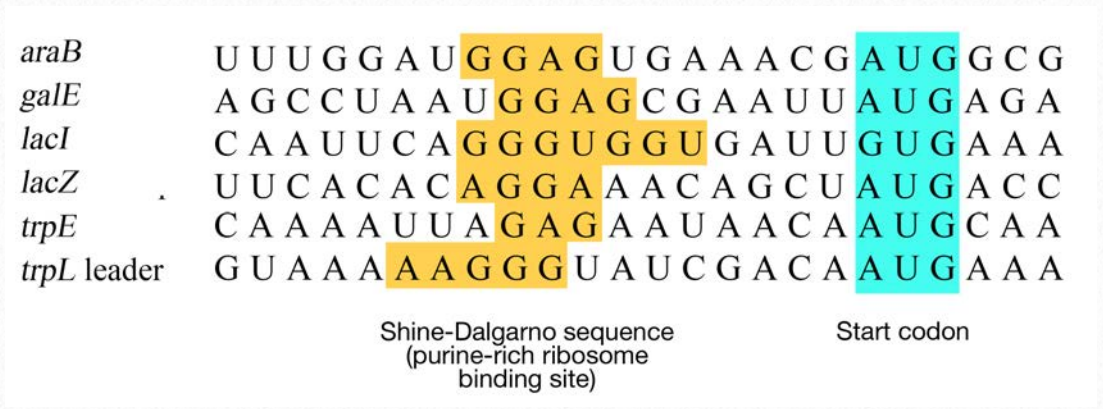

Figure 7.89 - Conserved sequences adjacent to start codons for various bacterial genes

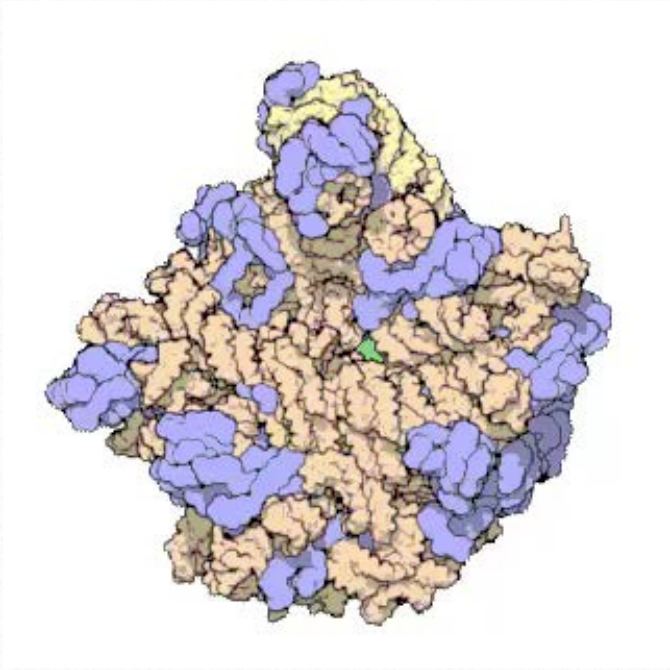
Image by Martha Baker



Movie 7.2 - Large ribosomal subunit
Wikipedia

intended for other positions in proteins. As such, the initiator tRNA is sometimes referred to as $tRNA^{imet}$.

Prokaryotic initiation

In prokaryotes, the 5' end of the mRNA is the only free end available, as transcription is tightly coupled to translation and the entire mRNA is not transcribed before translation begins. Nevertheless, the ribosome must be correctly positioned at the 5' end of the messenger RNA in order to initiate translation. How does the ribosome "know" exactly where to bind in the 5'UTR of the mRNA?

Shine-Dalgarno sequence

Examination of the sequences upstream of the start codon in prokaryotic mRNAs reveals that there is a short purine-rich sequence ahead of the start codon that is crucial to recognition and binding by the small ribosomal subunit (Figure 7.89). This sequence, called the Shine-Dalgarno sequence, is complementary to a stretch of pyrimidines at the 3' end of the 16S rRNA component of the small ribosomal subunit (Figure 7.90). Base-pairing between these complementary sequences positions the small ribosomal subunit at the right spot on the mRNA, with the AUG start codon at the P-site.

Initiation factors

The binding of the small ribosomal subunit to the mRNA requires the assistance of three protein factors called Initiation Factors 1, 2 and 3 (IF1, IF2, IF3). These proteins, which are associated with the small ribosomal subunit, are necessary for its bind-

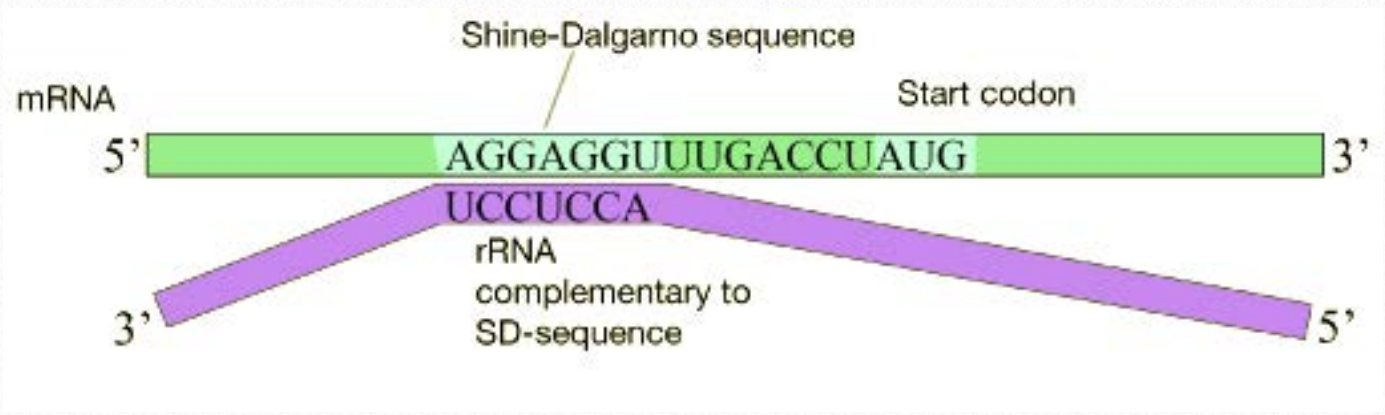


Figure 7.90 - Base pairing between the Shine-Dalgarno sequence in the mRNA and the 16S rRNA

Image by Martha Baker

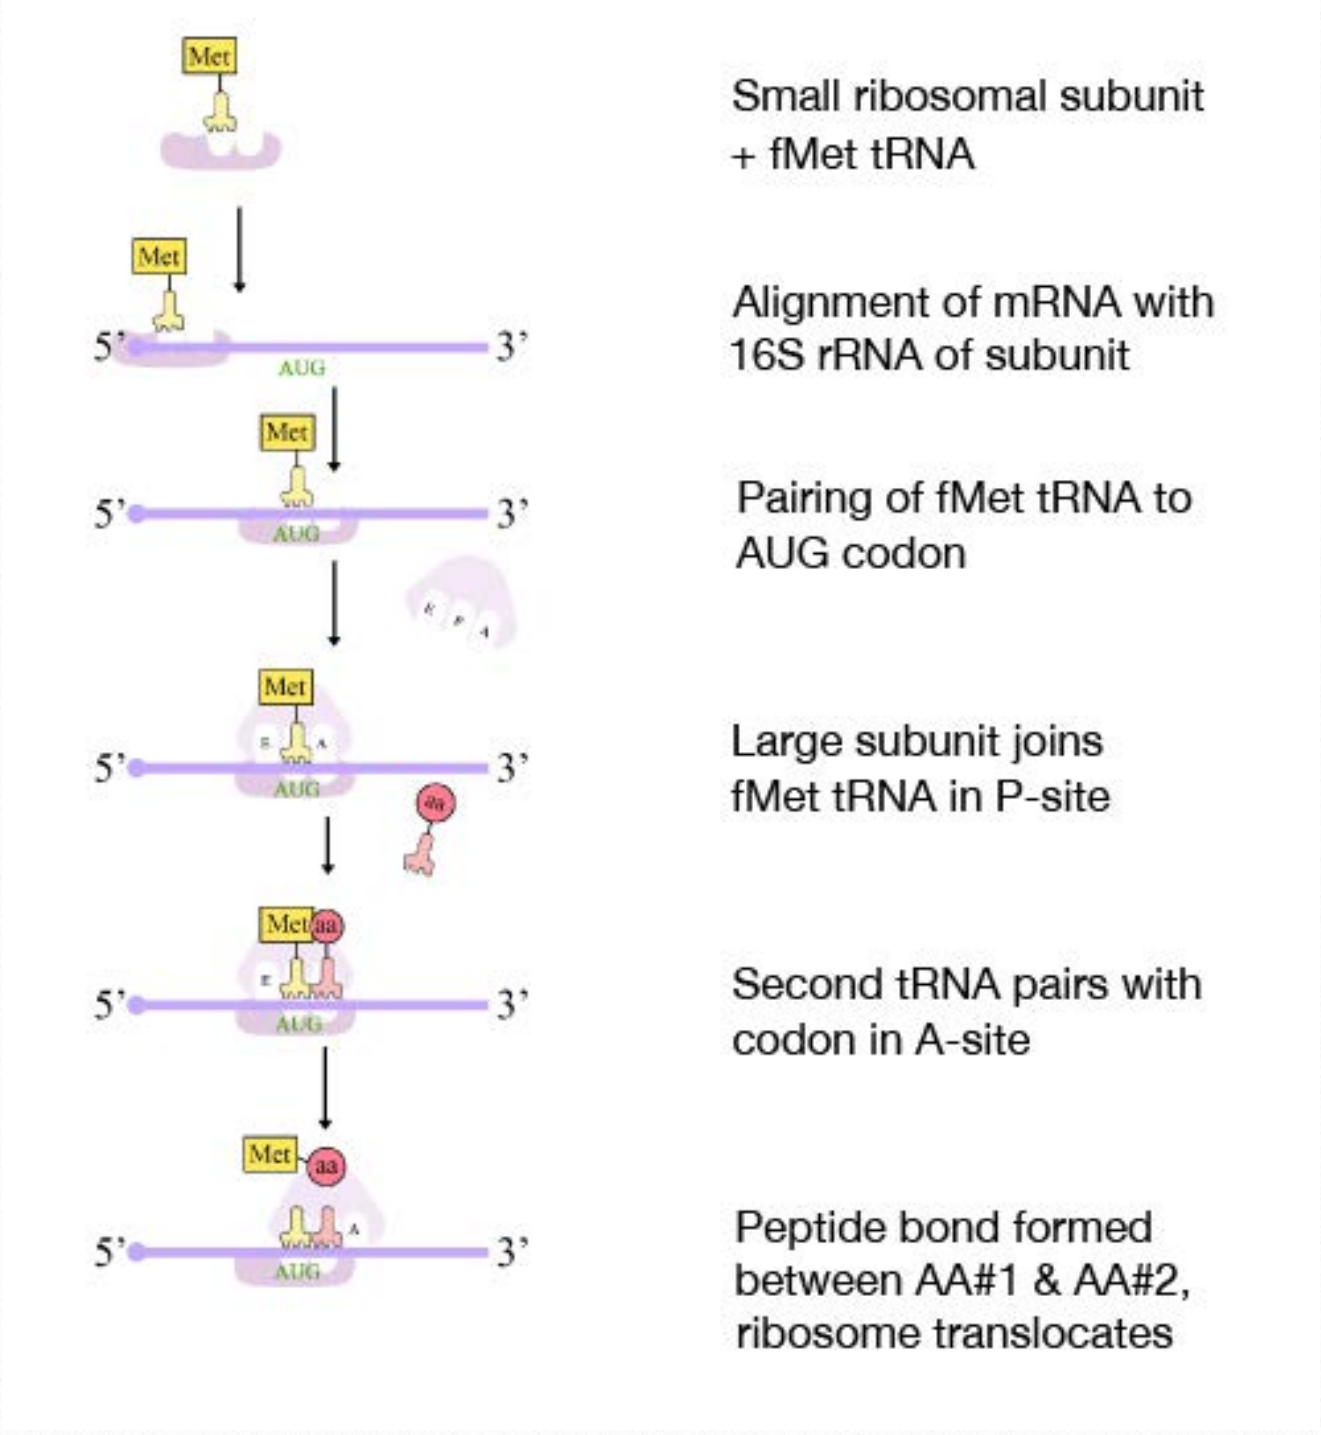

Figure 7.91 - Initiation - assembly of the ribosomal translation complex

Image by Martha Baker

ing to mRNA, but dissociate from it when the 50S ribosomal subunit binds. Of these proteins, IF3 is important for the binding of the small subunit to the mRNA, while IF2 is involved in bringing the initiator tRNA to the partial P-site of the small ribosomal subunit. IF1 occupies the A-site, preventing the binding of the initiator tRNA at that site.

Once the small ribosomal subunit is bound to the mRNA and the initiator tRNA is positioned at the P-site, the large ribosomal subunit is recruited and the initiation complex is formed. Binding of the 50S ribosomal subunit is accompanied by the dissociation of all three initiation factors. The removal of IF1 from the A-site on the ribosome frees up the site for the binding of the charged tRNA corresponding to the second codon (Figure 7.91).

YouTube Lectures by Kevin HERE & HERE

Eukaryotic initiation

In eukaryotes, initiation follows a similar pattern, although the order of events and the specific initiation factors are different.

Eukaryotes have a large number of

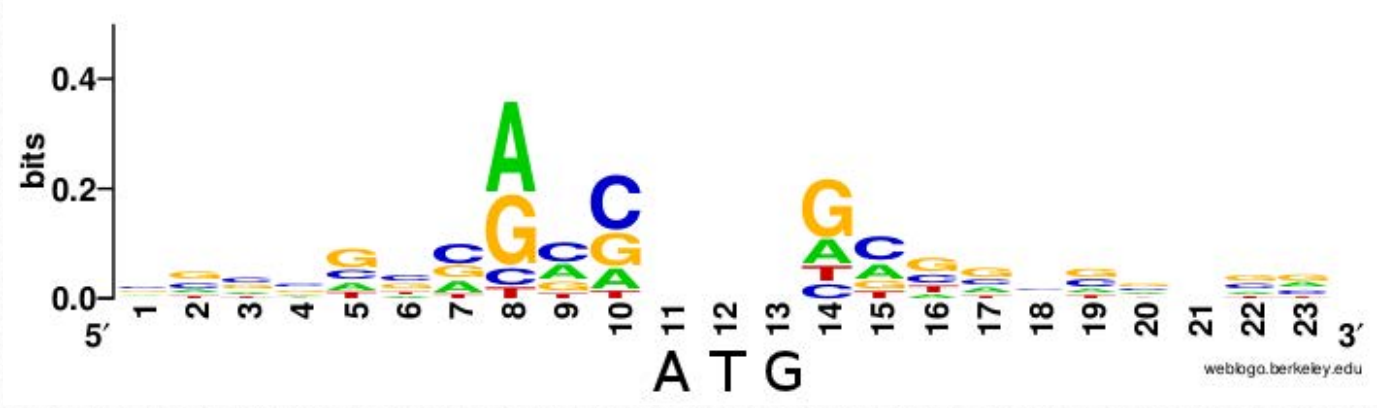

Figure 7.92 - Kozak sequence plot showing relative abundance of bases surrounding the AUG (ATG) start codon of human genes

Kozak sequences

Specific sequences surrounding the AUG, called Kozak sequences for the scientist who defined them, have been shown to be necessary for the binding of the 40S subunit, with the bases at -4 and +1 relative to the AUG being especially important.

IFs that are known as eIFs (eukaryotic initiation factors). These initiation factors are involved in the binding of the initiator tRNA to the small subunit, as well as in association of the small subunit with mRNA and subsequent attachment of the large subunit.

Ribosome assembly

The assembly of the translation machinery in eukaryotes begins with the binding of the initiator tRNA to the 40S (small) subunit. This step requires the assistance of eIF2 and eIF3. Next the small subunit with the initiator tRNA binds to the 7-methyl G cap on the 5'end of the mRNA. The 40S subunit then moves along the mRNA, scanning for a a start codon. Binding of the ribosomal subunit to the mRNA is dependent not just on finding an AUG, but on the sequences surrounding the codon.

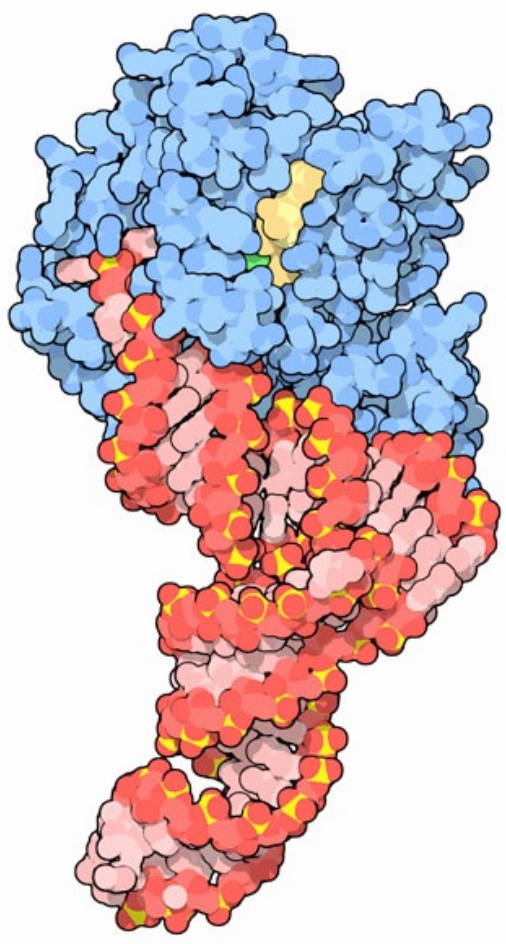

Figure 7.93 - EF-Tu (blue) bound to tRNA (red) and GTP (yellow)

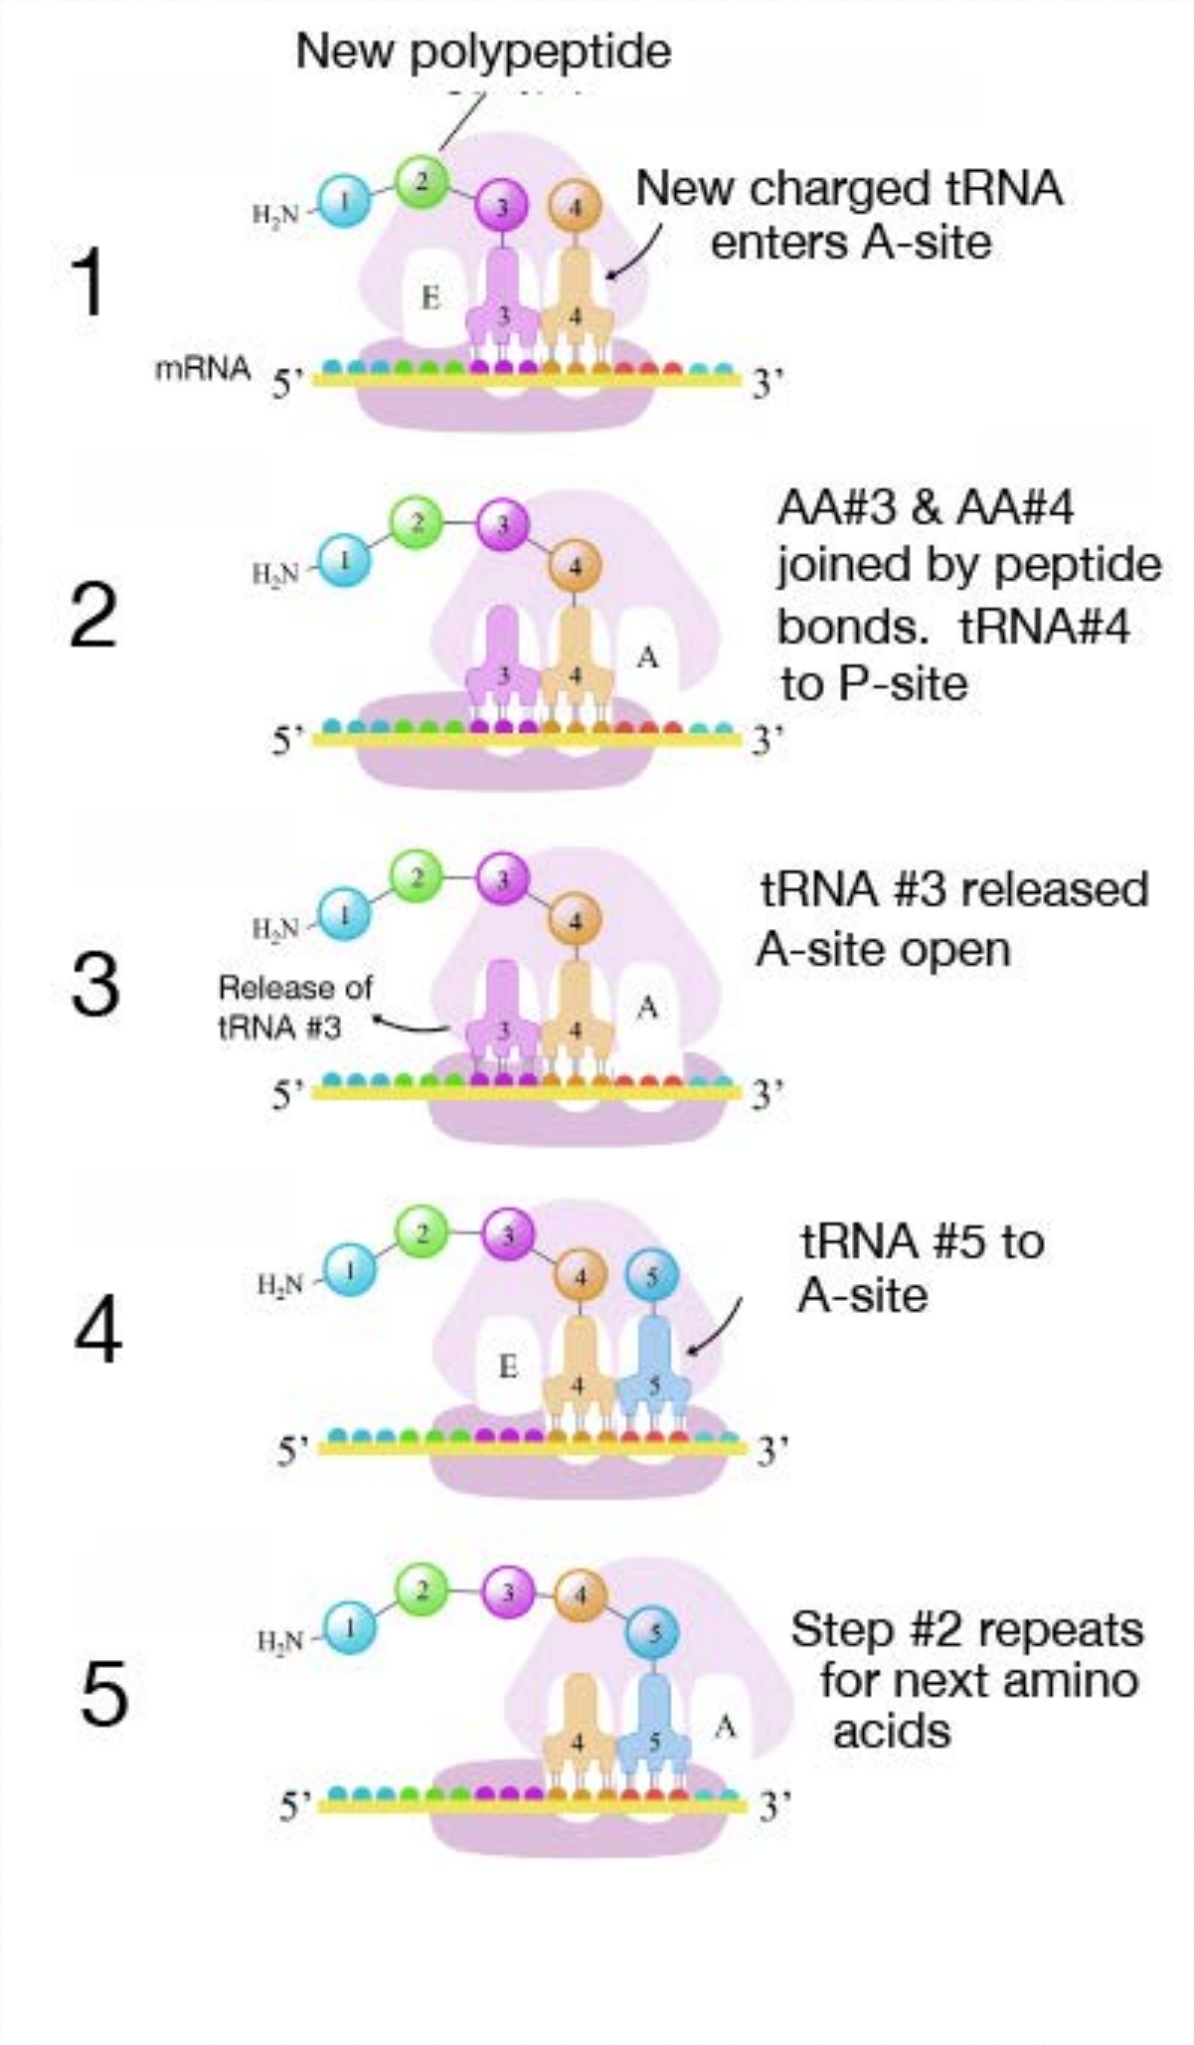

Figure 7.94 - The process of elongation

Image by Martha Baker

tant (Figure 7.92). Once the small subunit is properly positioned, the large ribosomal subunit (60S) binds, forming the initiation complex.

Elongation

After the ribosome is assembled with the initiator tRNA positioned at the AUG in the P-site, the addition of further amino acids can begin. In both prokaryotes and eukaryotes, the elongation of the polypeptide chain requires the assistance of elongation factors. In bacteria, the binding of the second charged tRNA at the A-site requires the elongation factor EF-Tu complexed with GTP (Figure 7.93). When the charged tRNA has been loaded at the A-site, EF-Tu hydrolyzes the GTP to GDP and dissociates from the ribosome. The free EF-Tu can then work with another charged tRNA to help position it at the A-site (Figure 7.94), after exchanging its GDP for a new GTP.

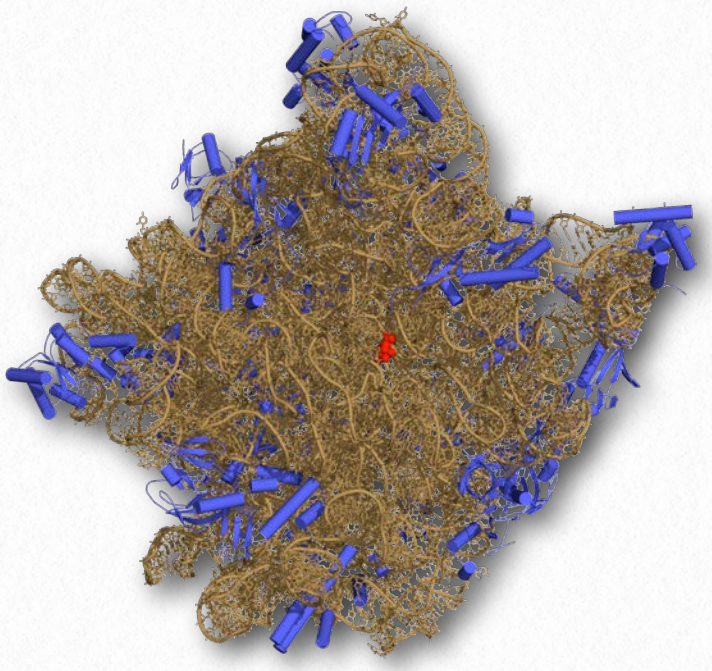

Figure 7.95 - 50S ribosomal subunit. RNA in brown. Protein in blue. Peptidyl transferase site in red.
Wikipedia

The corresponding step in eukaryotic cells is dependent on the elongation factor eEF1α.GTP. Once both P-site and A-site are occupied, the methionine carried by the tRNA in the P-site is joined to the amino acid carried by tRNA in the A-site, forming a peptide bond.

The reaction that joins the amino acids occurs in the ribosomal peptidyl transferase center, which is part of the large ribosomal subunit (Figure 7.95).

Ribozyme

Interestingly, there is strong evidence that this reaction is catalyzed by rRNA components of the large subunit, making the formation of peptide bonds an example of the activity of RNA enzymes, or ribozymes. The result of the peptidyl transferase activity is that the tRNA in the A-site now has two amino acids attached to it, while the tRNA at the P-site has none. This "empty" or deacylated tRNA is moved to the E-site on the ribosome, from which it can exit. The tRNA in the A-site, then moves to occupy the vacated P-site, leaving the A-site open for the next incoming charged tRNA. Yet another elongation factor, EF-G complexed with GTP, is required for the translocation of the ribosome along the mRNA in bacteria, while in eukaryotes, this role is played by eEF2.GTP. Repeated cycles of these steps result in the elongation of the polypeptide by one amino acid per cycle, until a termination, or stop codon is in the A-site.

Interactive Learning Module HERE

Termination

When a stop codon is in the A-site, proteins called release factors (RFs) are needed to recognize the stop codon and cleave and release the newly made polypeptide. In bacteria, RF1 is a release factor that can recognize the stop codon UAG, while RF2 recognizes UGA. Both RF1 and RF2 can recognize UAA. A third release factor, RF3, works with RF1 and RF2 to hydrolyze the linkage between the polypeptide and the final tRNA, to release the newly synthesized protein. This is followed by the dissociation of the ribosomal subunits from the mRNA, ending the process of translation.

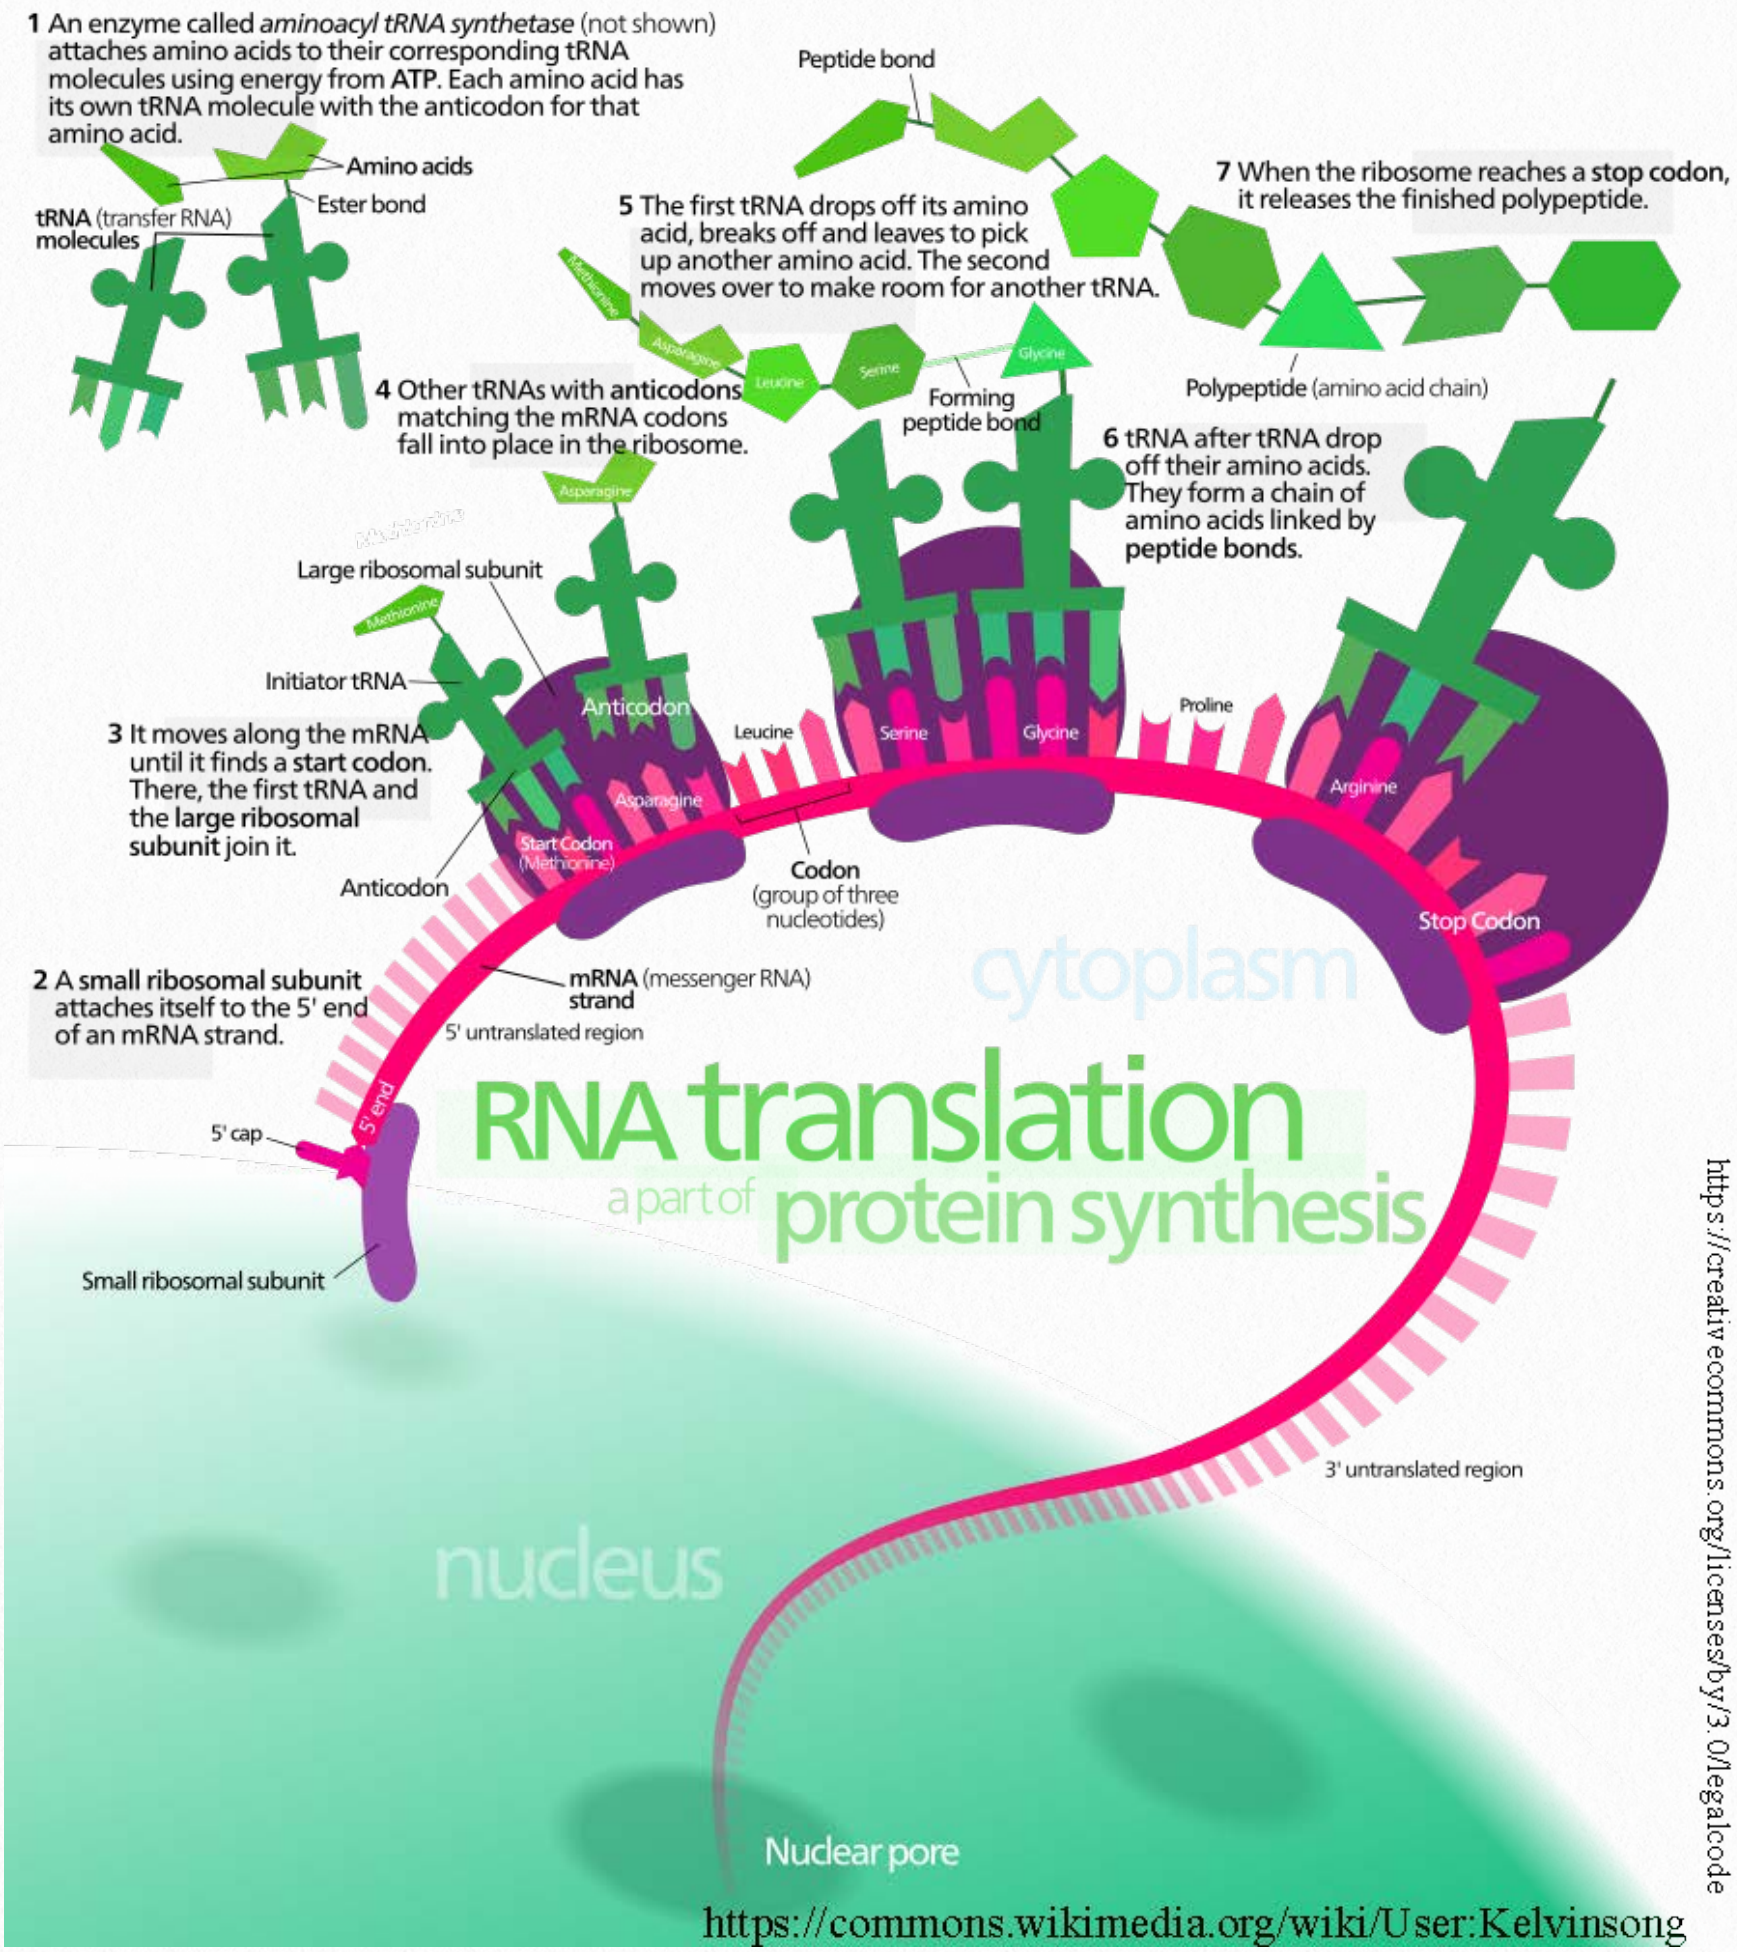

Figure 7.96 - The process of translation

Wikipedia

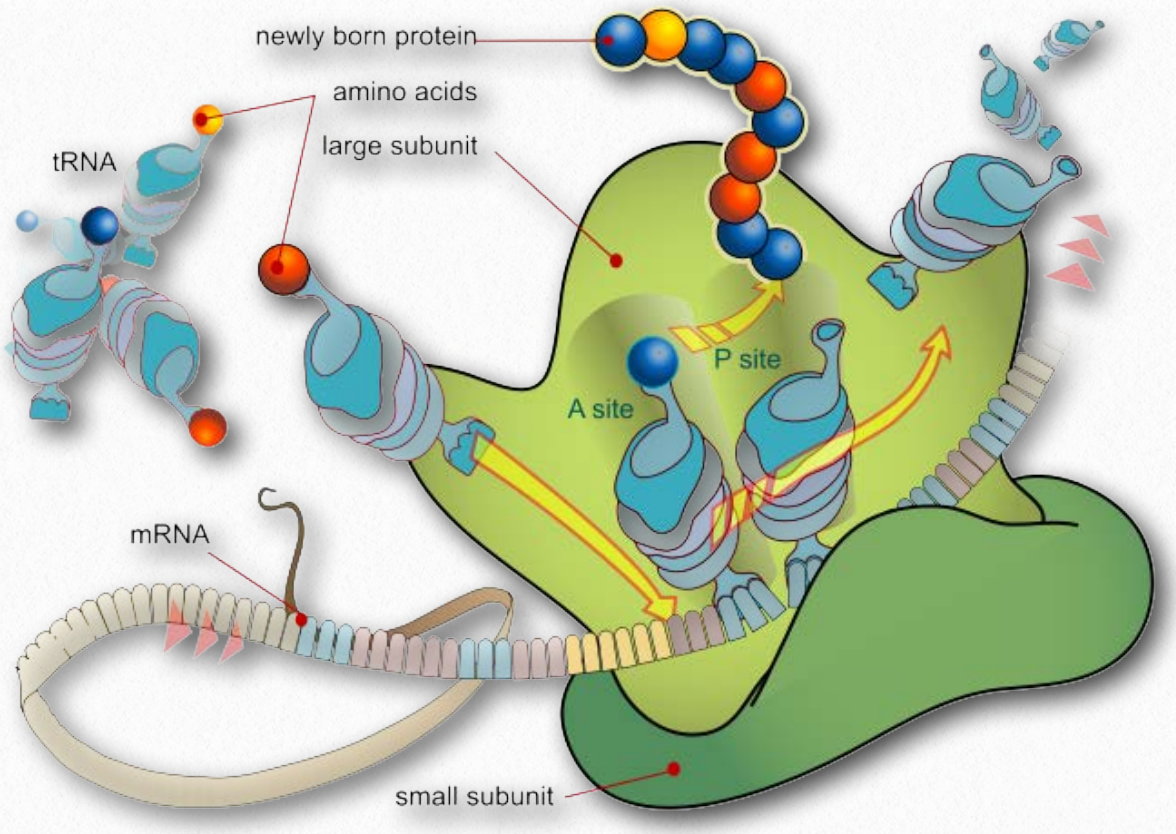

Figure 7.97 - Another perspective of translation. The 3' end of the mRNA is on the left and the ribosome is moving from right to left

But the vast majority of proteins in eukaryotic cells are made by ribosomes, free or membrane-bound, in the cytoplasm of the cell (the exceptions are a handful of proteins made within mitochondria and chloroplasts).

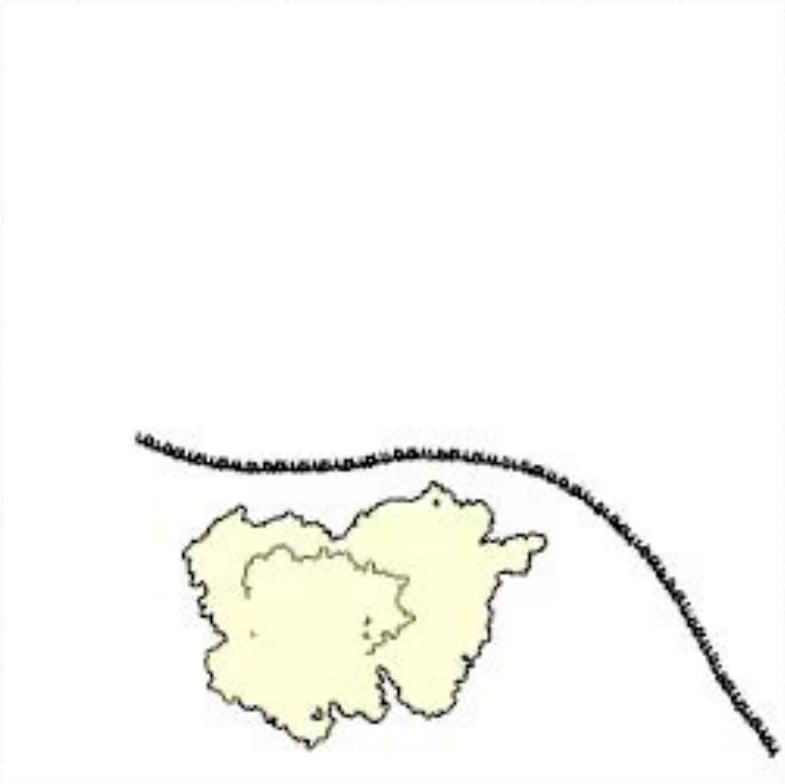
Delivery

Each of the thousands of proteins made in the cytoplasm must, therefore, be delivered to the appropriate cellular compartment in which it functions.

Polypeptide processing

What happens to the newly synthesized polypeptide after it is released from the ribosome? As you know, functional proteins are not simply strings of amino acids. The polypeptide must fold properly in order to perform its function in the cell. It may also undergo a variety of modifications such as the addition of phosphate groups, sugars, lipids, etc. Some proteins are produced as inactive precursors that must be cleaved by proteases to be functional.

An additional challenge in eukaryotic cells is the presence of internal, membrane-bounded compartments. Each compartment contains different proteins with different functions.



Movie 7.3 Translation of a protein secreted into the endoplasmic reticulum. Small subunit in yellow. Large subunit in green. tRNAs in blue.

Wikipedia

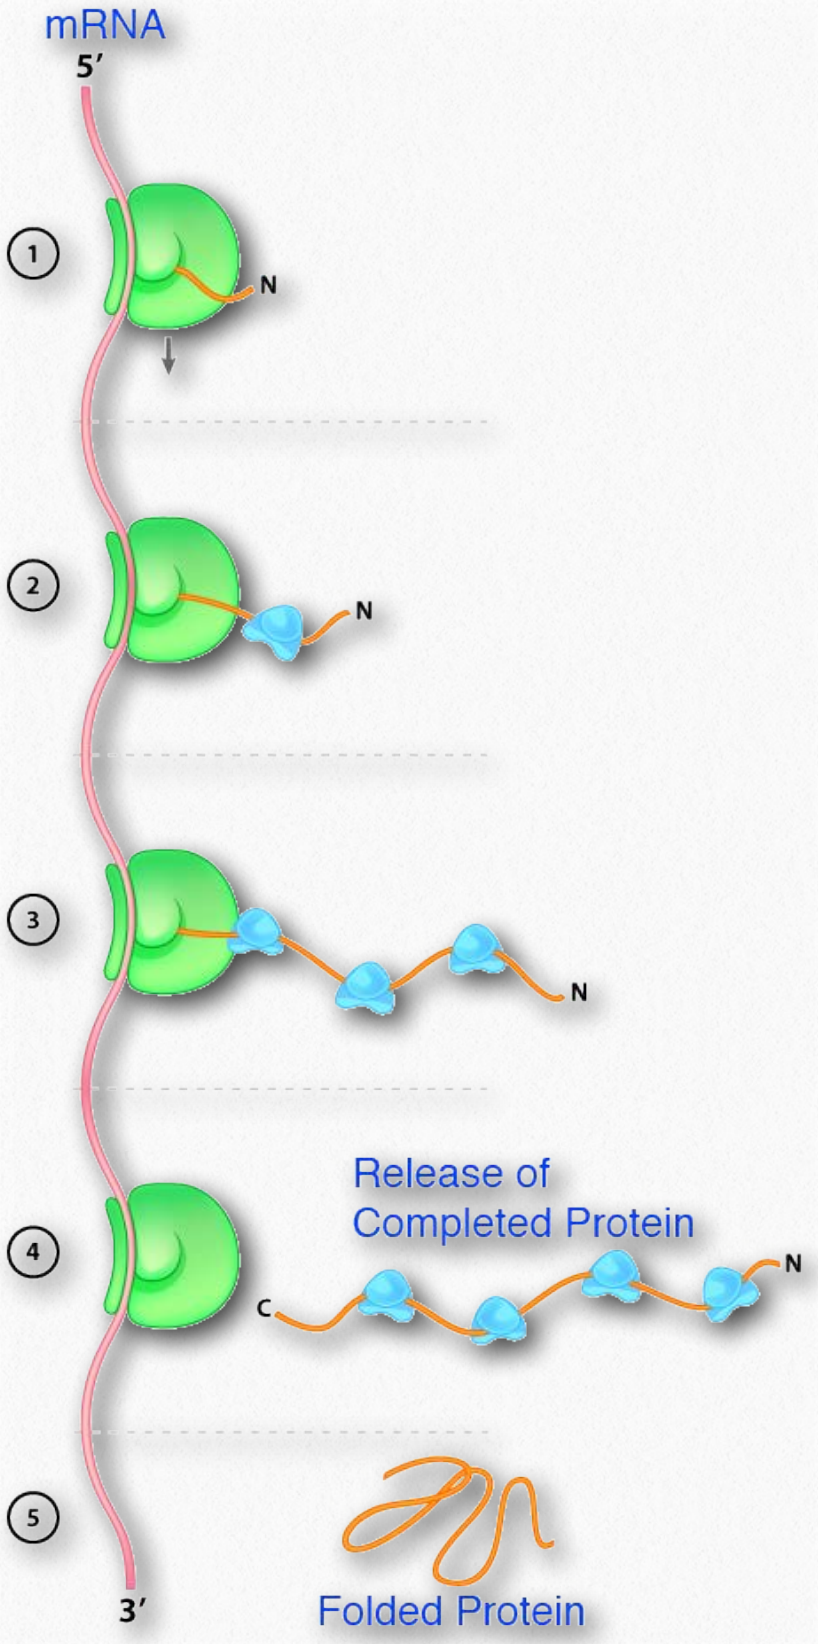


Figure 7.98 - Action of chaperone to facilitate proper folding of a protein (orange)

Image by Aleia Kim

Some proteins are delivered to their destinations in an unfolded state, and are folded within the compartment in which they function. Others are fully folded and may be post-translationally modified before they are sent to their cellular (or extracellular) destinations.

Some proteins are delivered as they are being synthesized (co-translationally - see Movie 7.3) while others are sorted to their compartments post-translationally. But, with the exception of cytosolic proteins, all proteins must cross membrane barriers, through membrane channels or other "gates", or by transport within membrane vesicles that fuse with the membrane of the target organelle to deliver their contents.

YouTube Lectures by Kevin HERE & HERE

Folding and post-translational modifications

Proper folding of a protein into its 3-dimensional conformation is necessary for it to function effectively. As described in an earlier chapter (HERE), the folding of a protein is largely influenced by hydrophobic interactions that result in folding of the protein in such a way as to position hydrophobic residues in the interior, or core, of the protein, away from the aqueous environment of the cell.

Proper folding may also involve the interaction of regions of the polypeptide that are distant from each other, so that portions of the N-terminal region of the polypeptide may be in close proximity to parts of the C-terminus of the final folded mole-

cule.

As a polypeptide emerges from the ribosome, however, the N-terminal region of the polypeptide may begin to fold on itself, with adjacent parts of the chain interacting in inappropriate ways, before the entire protein has been made. This can result in misfolding of the protein and consequent malfunction. To prevent misfolding, cells have protein chaperones, whose function is to bind to and shield regions of polypeptides as they emerge from the ribosome, and keep them from improperly interacting with one another or with other proteins in the vicinity, until they can fold into their correct final shape (Figure 7.98). In addition, there are classes of chaperones that are able sequester proteins in such a way as to permit unfolding and refolding of misfolded polypeptides. These proteins ensure that the vast majority of proteins in cells are folded into their correct, functional 3-dimensional shapes.

Protein sorting

The process by which proteins are identified as belonging to a particular compartment and then correctly delivered to that destination is known as protein sorting. How does a cell know where a particular protein should be sent?

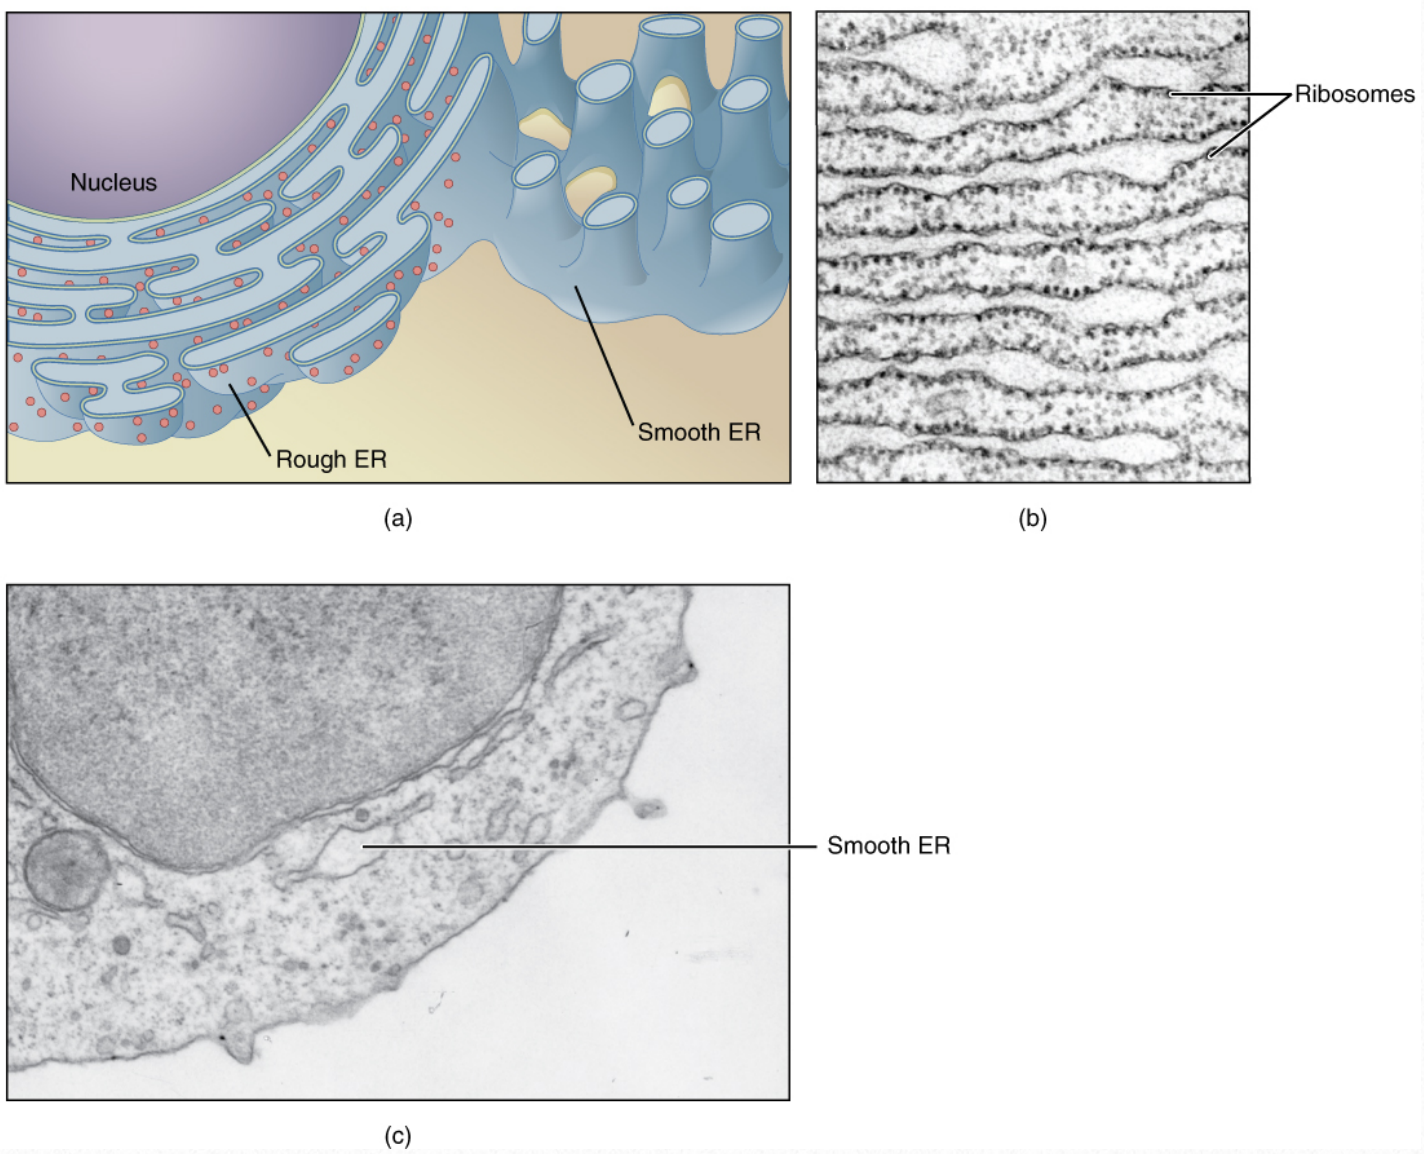

Figure 7.99 - Rough (ribosome bound) and smooth endoplasmic reticulum

Wikipedia

Proteins have "address labels" or sorting signals that indicate which cellular compartment they are destined for. Characteristic sorting signals are found on proteins that are sent to the nucleus, the ER (Figure 7.99), the mitochondria, etc.

Signal sequences

What do these sorting signals look like? Most sorting signals (also called signal sequences) are short stretches of amino acid sequence (that is, they are part of the amino acid sequence of the protein). Different cellular compartments have different "address labels".

Signal sequences may be found at the N-terminal or C-terminal region of proteins, or they may be within the amino acid sequence of the proteins. The location of the signal sequence for any given protein is fixed, however. Signal sequences for proteins to be delivered to the endoplasmic reticulum (ER) are found at the N-terminus of the protein. Mitochondrial and chloroplast proteins encoded by nuclear genes also have N-terminal signal sequences. Signal sequences for nuclear proteins, by contrast, are internal to the polypeptide, and may consist of one or more stretches of amino acids that will be displayed on the surface of these proteins once they are folded.

Figure 7.100 - N-terminal signal sequence (green) emerging from the ribosome.

Free and membrane-bound ribosomes

Proteins are synthesized by ribosomes in the cytoplasm or by those that associate with membranes temporarily (membrane-bound ribosomes). The free ribosomes make proteins that are destined for the nucleus, as well as those going to chloroplasts, mitochondria and peroxisomes. Nuclear proteins are delivered in their folded state, while chloroplast and mitochondrial proteins are threaded through translocation channels in the membranes of these organelles, to be folded at their destination.

Proteins that are destined for the ER, the Golgi apparatus, lysosomes as well as those that are to be secreted from the cell are first delivered to the ER by ribosomes that associate with the membrane of the rough ER and synthesize the protein directly into the ER. Proteins delivered by this manner into the lumen of the ER undergo folding and modification in the ER. All proteins delivered to the ER, regardless of their final destination, have an N-

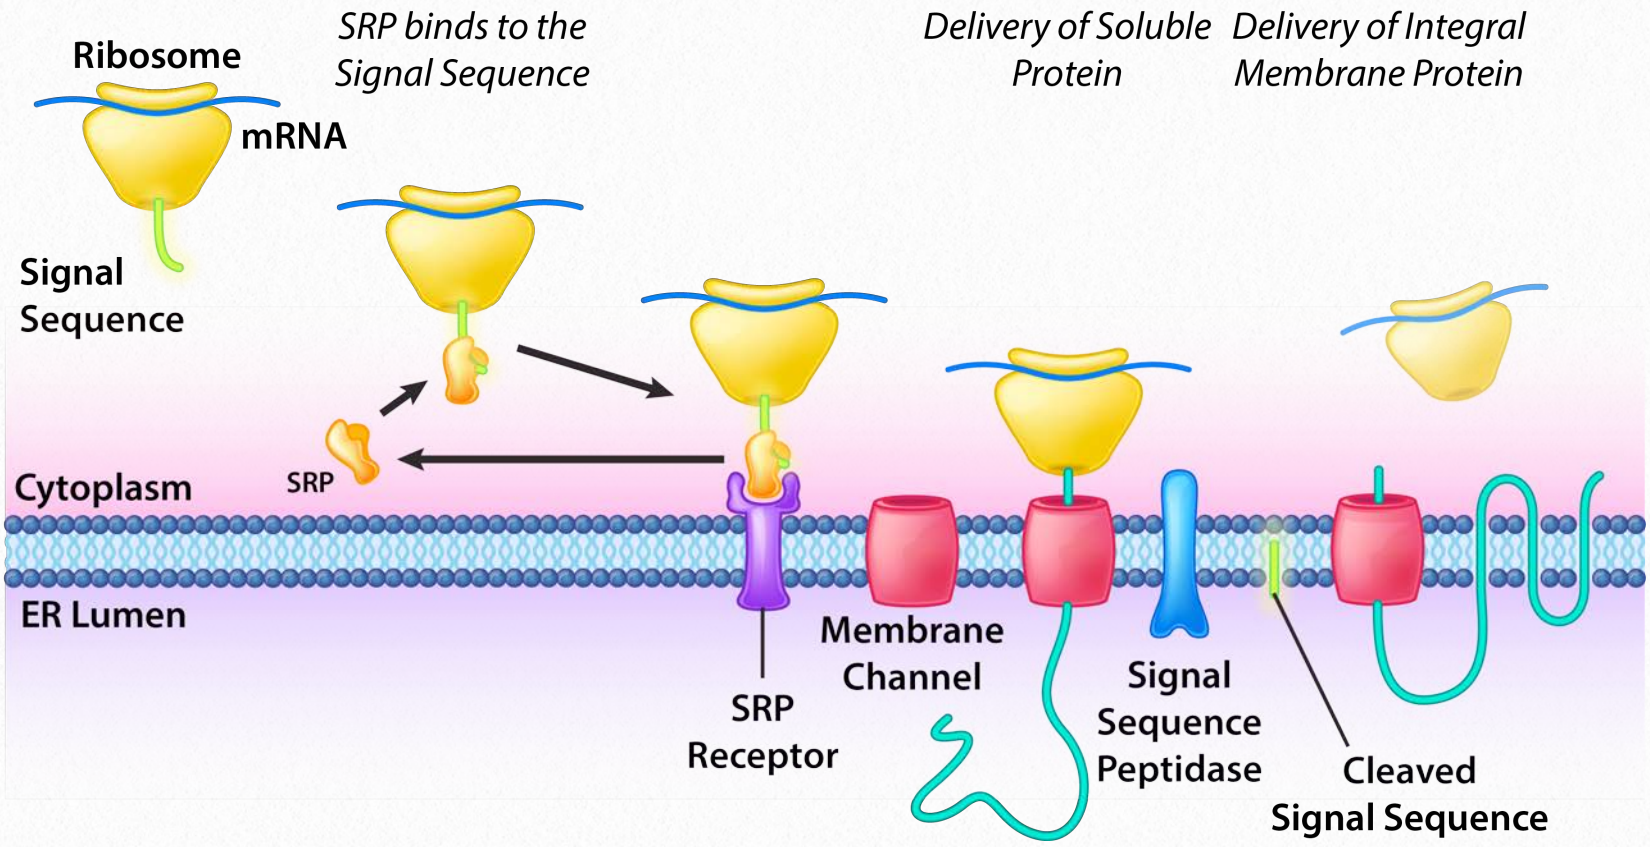

Figure 7.101 - Translation of a protein into the endoplasmic reticulum

Image by Aleia Kim

terminal ER signal sequence of 15-30 amino acids.

Protein delivery into the endoplasmic reticulum

The N-terminal part of a protein is the first part of a nascent polypeptide that emerges from the ribosome (Figure 7.100). The sequence of amino acids in this region, if it is an ER signal, will be recognized and bound by a ribonucleoprotein complex called the Signal Recognition Particle (SRP). Binding of the SRP to the N-terminal signal sequence causes translation to pause. The SRP, in turn, is bound by an SRP receptor in the ER membrane (Movie 7.3 & Figure 7.101), effectively anchoring the ribosome to the membrane.

The location of SRP receptors near membrane channels in the ER positions the ribosome over a translocation channel. Once the ribosome is docked over the channel, the SRP releases the signal sequence, which is threaded through the channel, with its hydrophobic residues interacting with the hydrophobic interior of the membrane. Translation resumes at this point and the rest of the protein is delivered into the lumen of the ER as it is made. The ribosome remains associated with the ER membrane till translation is completed, at which point it dissociates. The signal sequence, which is no longer needed once the protein has been delivered, is cleaved off by a membrane associated signal peptidase, releasing the completed protein into the ER lumen.

While soluble proteins are delivered into the ER, integral membrane proteins do not pass all the way through, but, instead, are anchored in the membrane of the ER by hydrophobic stop transfer sequences.

Folding and modification

Proteins in the lumen of the ER are folded with the help of numerous chaperones resident in the endoplasmic reticulum. The environment within the ER lumen is also more oxidizing than the cytosol, and permits the formation of disulfide bonds to stabilize the folded proteins. Protein disulfide isomerase, an enzyme active in the ER lumen both helps to make disulfide bonds and removes bonds that were incorrectly made during the folding process. In addition, proteins in the ER undergo modifications such as glycosylation and addition of glycolipids. Multimeric proteins are also assembled from their subunits in the ER.

Proteins that have been correctly folded and modified are transported from the ER, in membrane vesicles, to their final destinations. Improperly folded proteins are recognized by a surveillance mechanism in the ER and are sent back to the cytoplasm to be degraded in proteasomes.

Good Protein Synthesis

To the tune of "*Good King Wenceslaus*"

Metabolic Melodies Website HERE

Amino acids cannot join
By themselves together
They require ribosomes
To create the tether

All the protein chains get made
'Cording to instruction
Carried by m-R-N-A
In peptide bond construction

Small subunit starts it all
With initiation
Pairing up two RNAs
At the docking station

Shine Dalgarno's complement
In the 16 esses
Lines the A-U-G up so
Synthesis commences

Elongation happens in
Ribosomic insides
Where rRNA creates
Bonds for polypeptides

These depart the ribosome
Passing right straight through it
In the tiny channels there
Of the large subunit

Finally when the sequence of
One of the stop codons
Parks itself in the A site
Synthesis can't go on

P-site RNA lets go
Of what it was holding
So the polypeptide can
Get on with its folding

Lyrics by Kevin Ahern

Information Processing: Gene Expression

Regulating gene expression

The processes of transcription and translation described so far tell us what steps are involved in the copying of information from a gene (DNA) into RNA and the synthesis of a protein directed by the sequence of the transcript (Figure 7.102). These steps are required for gene expression, the process by which information in DNA directs the production of the proteins needed by the cell.

But what determines whether a gene is expressed at a given time? Cells do not, as we know, express all of their genes all of the time. Some genes are expressed in particular cell types but not others, while others may be expressed at specific stages of development. Cells must also be able alter their patterns of gene expression in response to internal and external cues, controlling the production of proteins as needed, to meet their changing needs. Regulating gene expression is, therefore, crucial. Given that there are multiple steps involved in gene ex-

YouTube Lectures by Kevin HERE & HERE

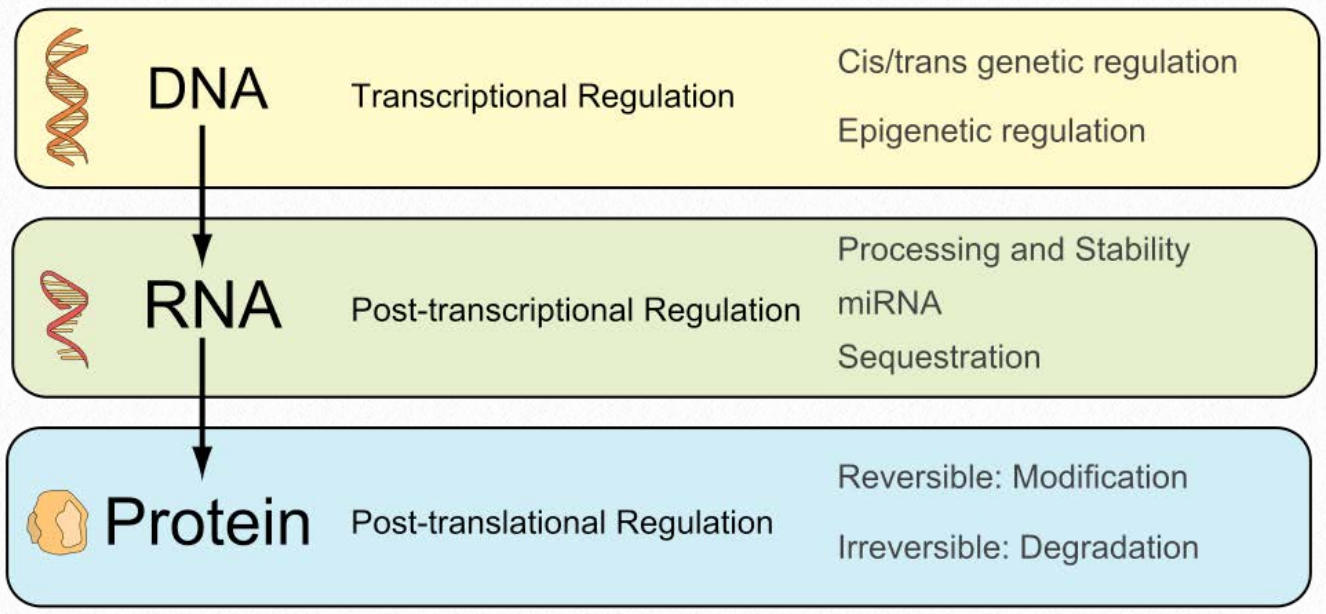

Figure 7.102 - Multiple levels of control of gene expression

Wikipedia

pression, there are several different points at which the process could be regulated. Not surprisingly, many regulatory mechanisms are known, each acting at a different stage in the path from DNA to protein.

Regulation of transcription

The first step in gene expression is transcription, so regulation of transcription is an obvious way to affect whether a gene is expressed and to what extent.

What are the molecular switches that turn transcription on or off? Although there are additional factors that affect transcription, such as the accessibility of a gene to the transcriptional machinery, the basic mechanism by which transcription is regulated depends on highly specific interactions between transcription regulating proteins and regulatory sequences on DNA.

What are these regulatory sequences and what proteins bind them? In addition to the promoter sequences required for transcription initiation, genes have additional *cis* regulatory sequences (sequences of DNA on the same DNA molecule as the gene) that control when a gene is transcribed. Regulatory sequences are bound tightly and specifically by transcriptional regulators, proteins that can recognize DNA sequences and bind to them. The binding of such proteins to the DNA can regulate transcription by preventing or increasing transcription from a particular promoter.

Transcriptional regulation in prokaryotes

Let us first consider some examples from prokaryotes. In bacteria, genes are often clustered in groups, such that genes that need to be expressed at the same time are next to each other and all of them are controlled as a single unit by the same promoter. Groups of genes that are coordinately regulated by a single promoter are referred to as operons. The entire set of genes in an operon can be controlled through the action of DNA binding proteins

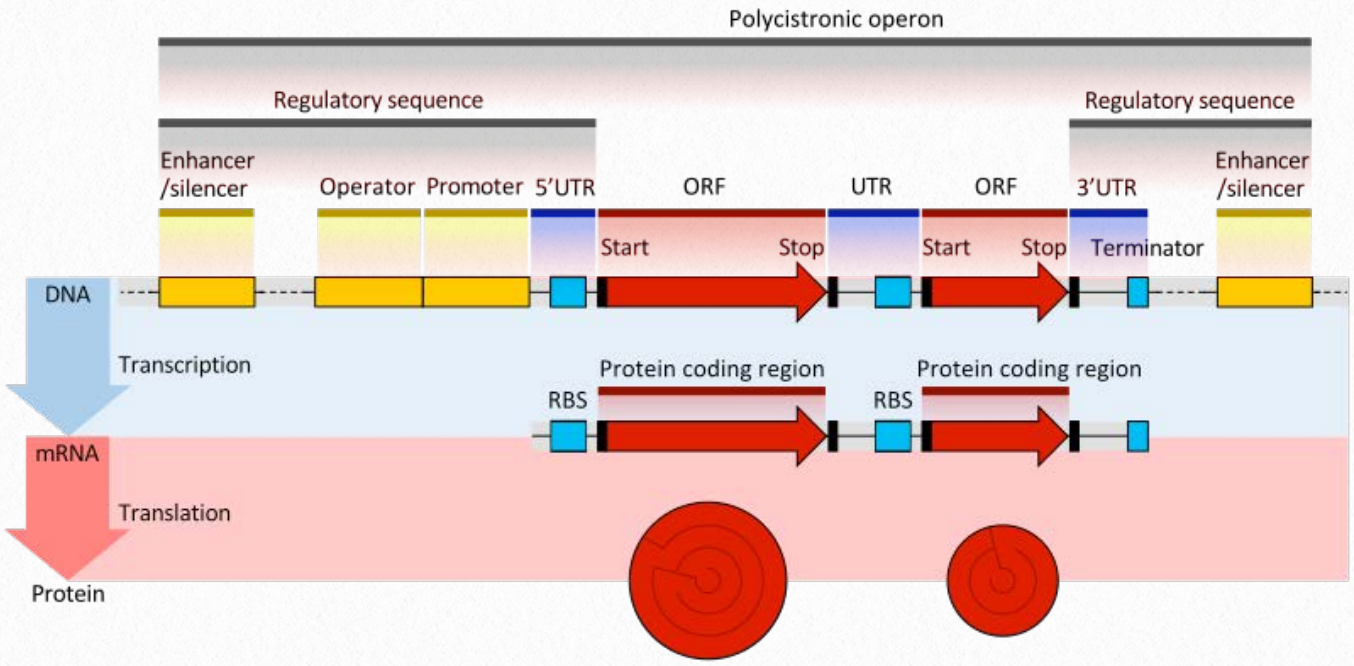

Figure 7.103 - Prokaryotic genes organized in an operon

Wikipedia

that act as either repressors (preventing transcription of the genes) or activators (increasing transcription of the genes). The binding of these proteins to their DNA targets is allosterically controlled by the binding of specific small molecules that signal the state of the cell.

Interactive Learning Module HERE

Induction of the *lac* operon

The *lac* operon is one such group of coordinately regulated genes that encode proteins needed for the uptake and breakdown of the sugar lactose. *E.coli* cells preferentially use glucose for their energy needs, but if glucose is unavailable, and lactose is present, the bacteria will take up lactose and break it down for energy. Since the proteins for taking up and breaking down lactose are only needed when glucose is absent and lactose is available, the bacterial cells need a way to express the genes of the *lac* operon only under those conditions. The default state of the *lac* operon is OFF.

Removing a repressor

Transcription of the *lac* cluster of genes is primarily controlled by a repressor protein that binds to a region of the

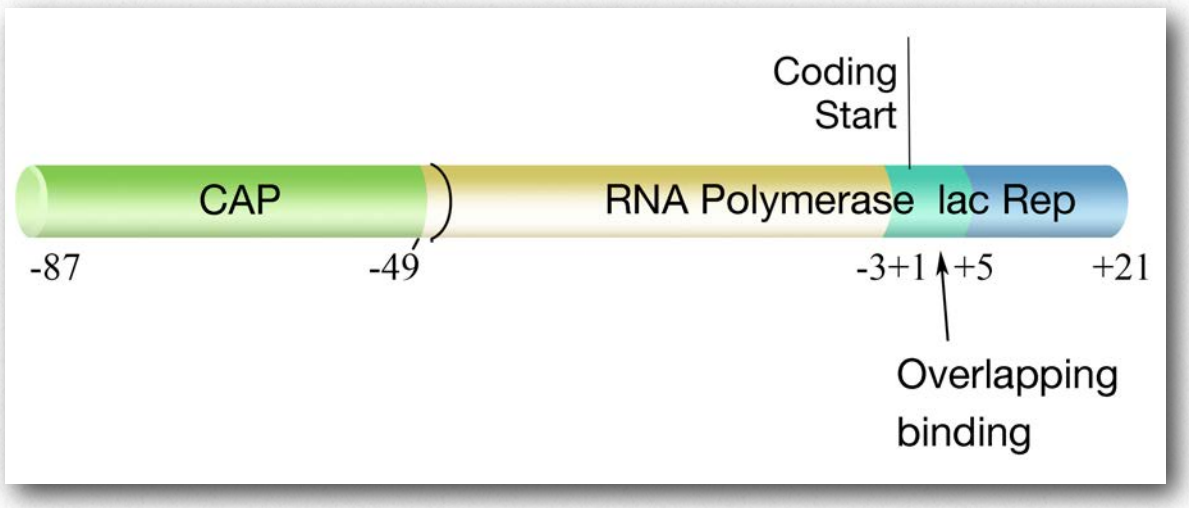

Figure 7.104 - Protein binding sites in the lac regulatory region

Image by Martha Baker

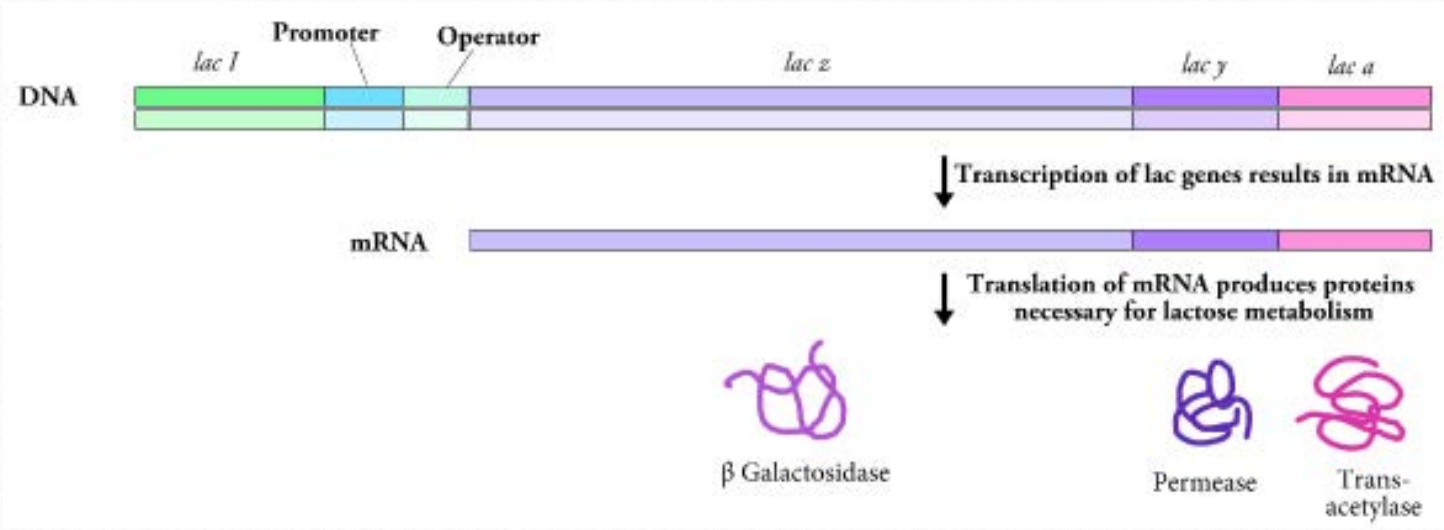

Figure 7.105 - Lac operon structure and products

Image by Martha Baker

DNA just downstream of the -10 sequence of the *lac* promoter (Figure 7.104). Recall that the promoter is where the RNA polymerase must bind to begin transcription. The location on the DNA where the lac repressor is bound is called the operator (Figure 7.105). When the repressor is bound at this position, it physically blocks the RNA polymerase from transcribing the genes, just as a vehicle blocking your driveway would prevent you from pulling out. Obviously, if you want to leave, the vehicle that is blocking your path must be removed. Likewise, in order for transcription to occur, the repressor must be removed from the operator to clear the path for RNA polymerase (Figure 7.106).

How is the repressor removed? When the sugar lactose is present, a small amount of it is taken up by the cells and converted to an isomeric form, allolactose (Figure 7.107). Allolactose binds to the repressor, changing its conformation so that it no longer binds to the operator. When the repressor is no longer bound to the operator, the "roadblock" in front of the RNA polymerase is re-

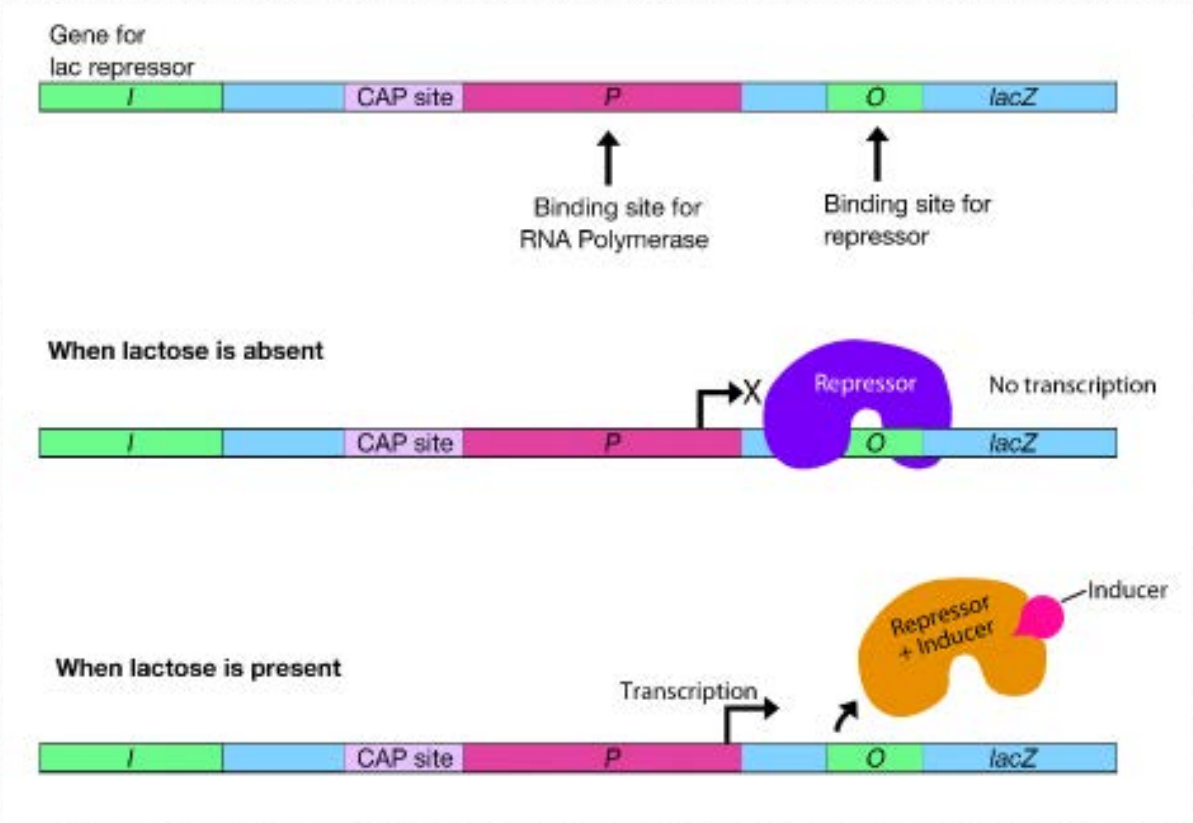

Figure 7.106 - Lac operon in the absence (middle) and presence (bottom) of inducer

Image by Martha Baker

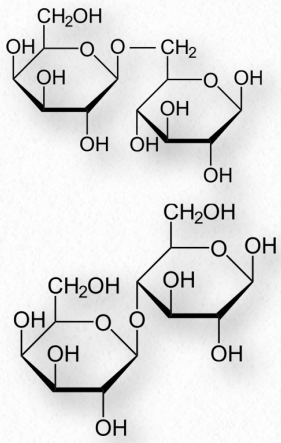

Figure 7.107 - Allolactose (top) and lactose (bottom)

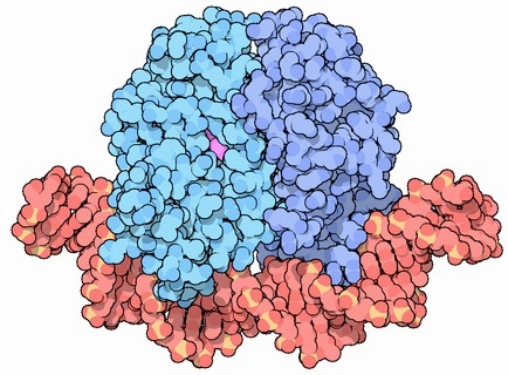

Figure 7.108 - CAP (blue) bound to the DNA adjacent to the lac promoter (orange). cAMP shown in pink.

Wikipedia

moved, permitting the transcription of the genes of the *lac* operon

What makes this an especially effective control system is that the genes of the *lac* operon encode proteins that enable the break down of lactose. Turning on these genes requires lactose to be present. Once the lactose has been broken down, the lac repressor binds to the operator once more and the *lac* genes are no longer expressed. This allows the genes to be expressed only when they are needed.

Recruiting RNA polymerase

But how do glucose levels affect the expression of the *lac* genes? We noted earlier that if glucose was present, lactose would not be used. A second level of control is exerted by a protein called Catabolite Activator Protein (CAP - Figure 7.108)). CAP (also sometimes called CBP or cAMP binding protein) binds to a site adjacent to the promoter and is necessary to recruit RNA polymerase to bind the *lac* promoter.

cAMP binding

CAP binds to its site only when glucose levels are low. Low glucose levels are linked to the activation of an enzyme, adenylate cyclase, that makes the molecule cyclic AMP

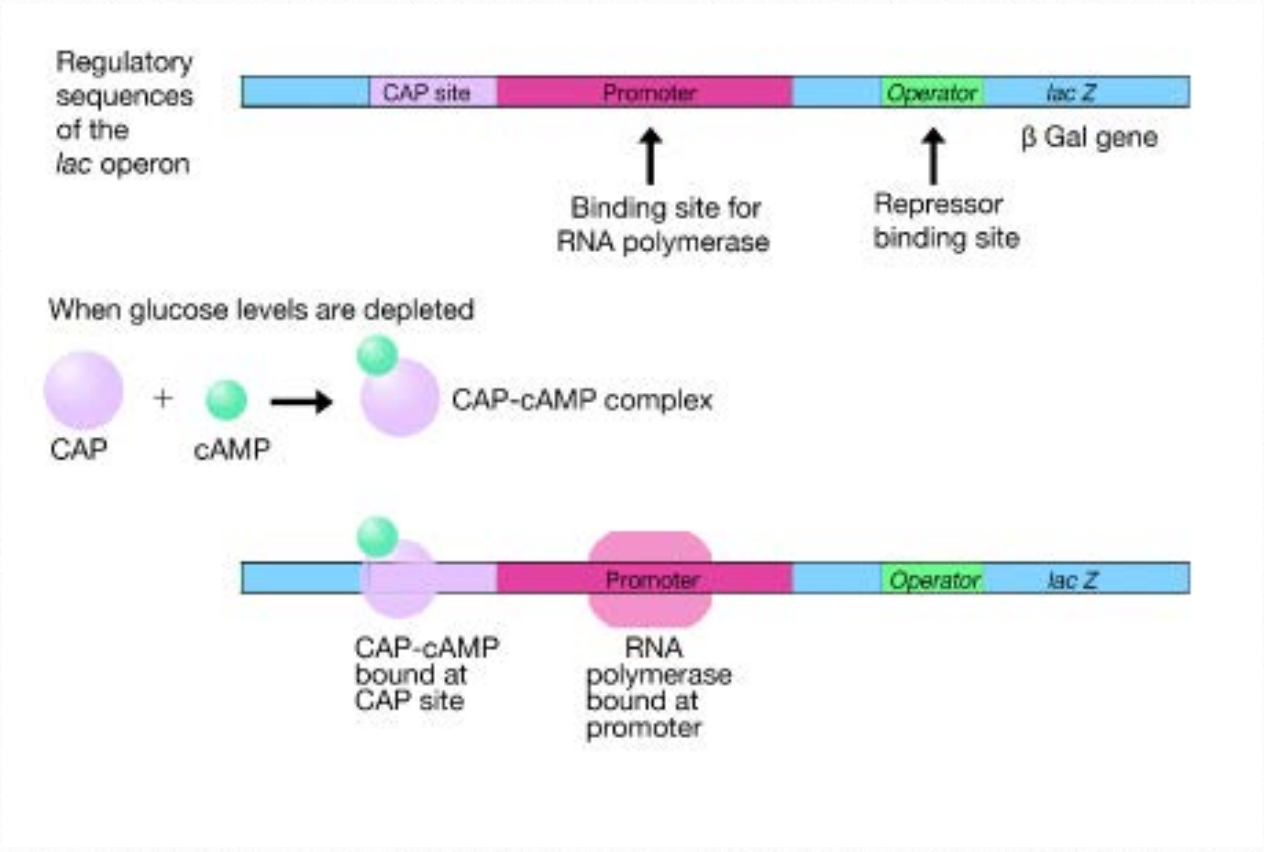

Figure 7.109 - Lac operon in the presence (top) and absence (bottom) of glucose

Image by Martha Baker

(cAMP). The binding of cAMP to the CAP causes a conformational change in CAP that allows it to bind to the CAP-binding site. When CAP is bound at this site, it is able to recruit RNA polymerase to bind at the promoter, and begin transcription.

YouTube Lectures by Kevin HERE & HERE

The combination of CAP binding and the lac repressor dissociating from the operator when lactose levels are high ensures transcription of the lac operon just when it is most needed. The binding of CAP may be thought of as a green light for the RNA polymerase, while the removal of lac repressor is like the lifting of a barricade in front of it. When both conditions are met, the RNA polymerase transcribes the downstream genes.

Control of the *trp* operon by repression

The *lac* operon we have just described is a set of genes that are expressed only under the specific conditions of glucose depletion and lactose availability. Other genes may be expressed *unless* a particular condition is met. For these genes, the default state is ON.

An example of this is the *trp* operon, which encodes enzymes necessary for the synthesis of the amino acid tryptophan. These genes are constitutively expressed (always on), except when tryptophan is available from the cell's surroundings, making its synthesis unnecessary. Under conditions where tryptophan is abundant in the environment, the trp genes can be turned off. This is achieved by a repressor protein that will bind to the operator only in the presence of tryptophan (Figure 7.110). Binding of tryptophan to the repressor causes binding of the repressor to the operator. Be-

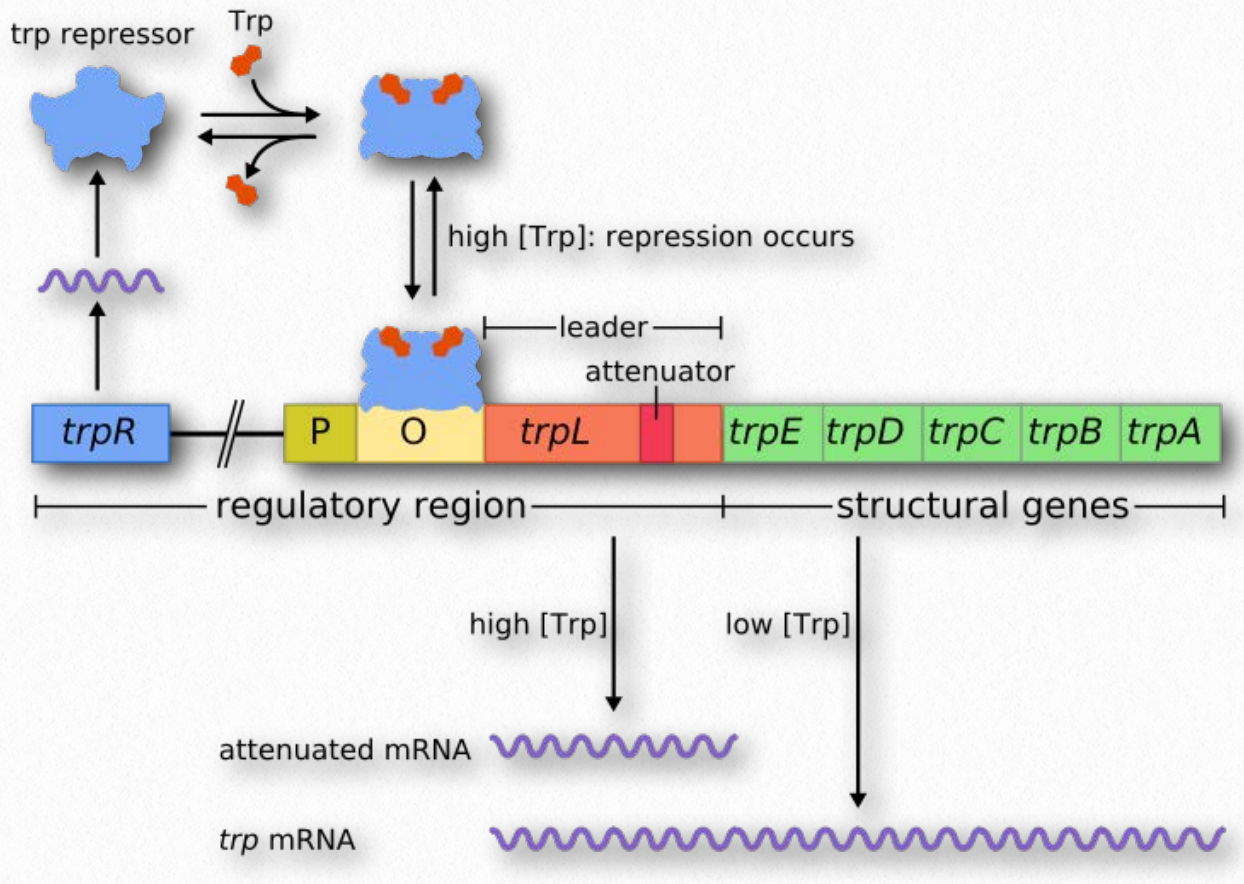

Figure 7.110 - Structure and regulation of the trp operon
Wikipedia

Attenuation

Another mechanism that regulates the expression of the trp operon is attenuation. Attenuation is a process by which the expression of an operon is controlled by termination of transcription before the first gene of the operon (Figure 7.111).

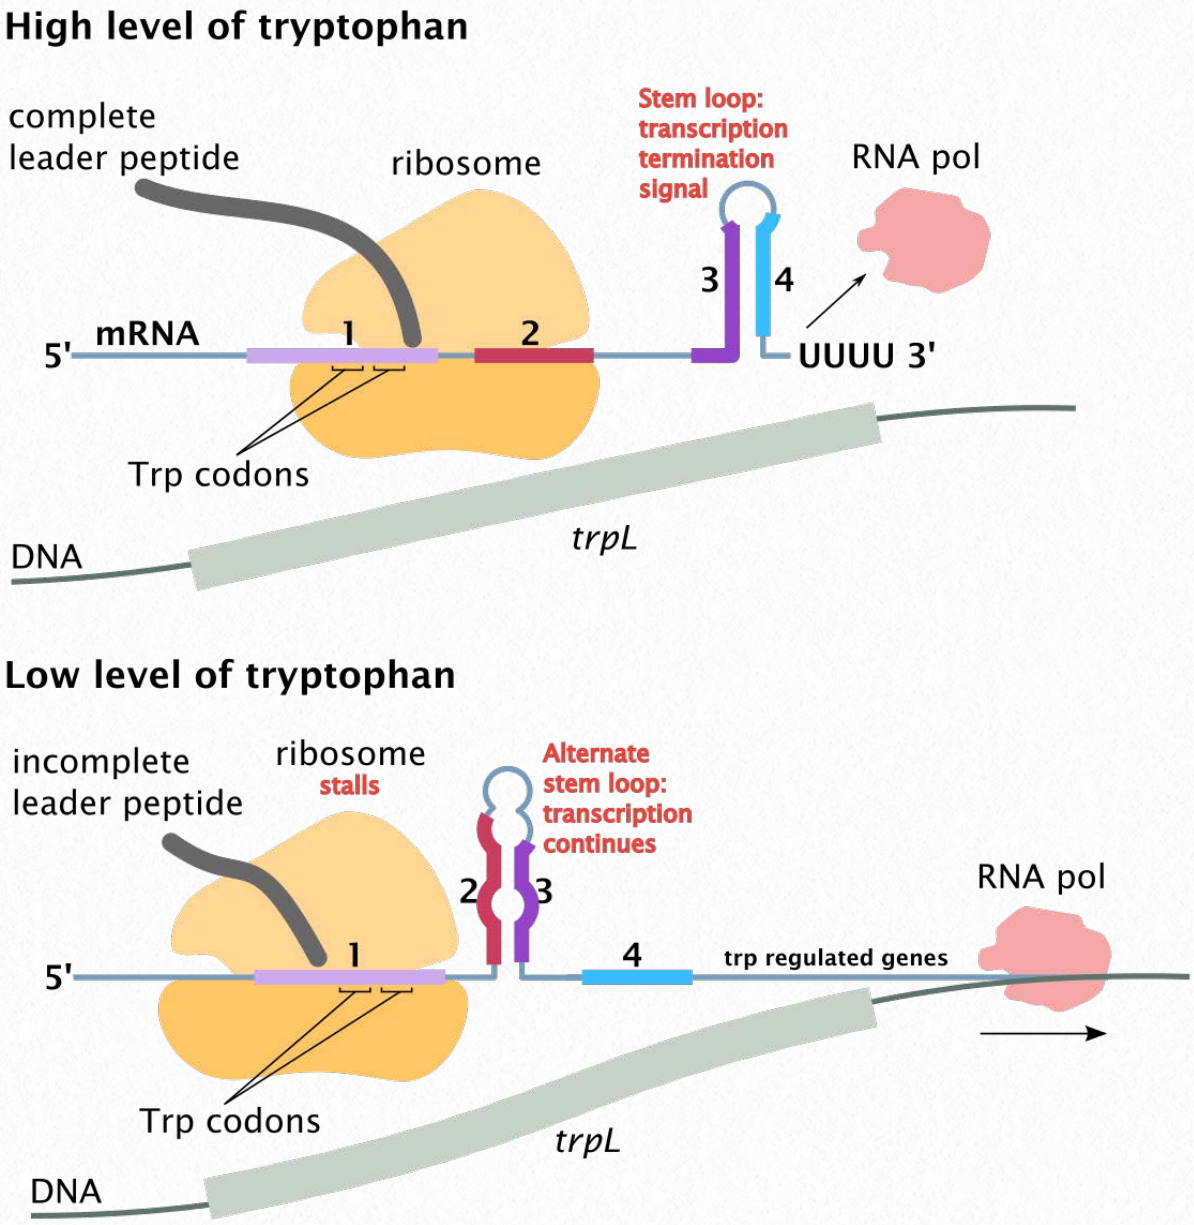

Figure 7.111 - Attenuation in regulation of the trp operon

Wikipedia

In the *trp* operon, this functions as follows: Transcription begins some distance upstream of the first gene in the operon, producing what is termed a 5' leader sequence. This leader sequence contains an intrinsic terminator that can form a hairpin structure that stops transcription when high levels of tryptophan are available to the cells. It can also form a different structure that permits continued tran-

cause it acts together with the repressor to turn off the trp genes, tryptophan is called a co-repressor.

XX AUG AAA GCA AUU UUC GUA CUG AAA GGU UGG UGG CGC ACU UCC UGA -XX
MET LYS ALA ILE PHE VAL LEU LYS GLY TRP TRP ARG THR SER STOP

Figure 7.112 - Sequence of the leader region of the *trp* operon

scription of the genes in the operon when tryptophan levels are low. How does the level of tryptophan influence which of these two structures are formed?

Recall that the 5' end of the RNA is the first part of the transcript to be made and that in bacteria translation is linked to transcription, so the 5' end of the RNA begins to be translated before the entire transcript is made. It turns out that the 5' leader sequence of the *trp* operon mRNA encodes a short peptide that contains two tryptophan codons. If there is plenty of tryptophan available, the leader sequence will be easily translated. Under these conditions, the leader sequence is able to form the termination hairpin, preventing the transcription of the downstream *trp* genes.

If, however, levels of tryptophan are low, then the ribosome stalls as it attempts to translate the leader sequence. Under these conditions, the leader sequence adopts a different conformation that permits continued transcription of the genes of the *trp* operon.

Riboswitches

Similar in concept to the attenuation of the *trp* operon described above, but not dependent on translation, is a control mechanism called a riboswitch (Figure 7.113). Riboswitches are typically found in the 5'UTR of messenger RNAs (i.e., they are part of the sequence of the RNA). These sequences can control transcription of the downstream genes based on the conformation they adopt. One conformation allows continued transcription, while the other terminates it. So, what determines which conformation they adopt?

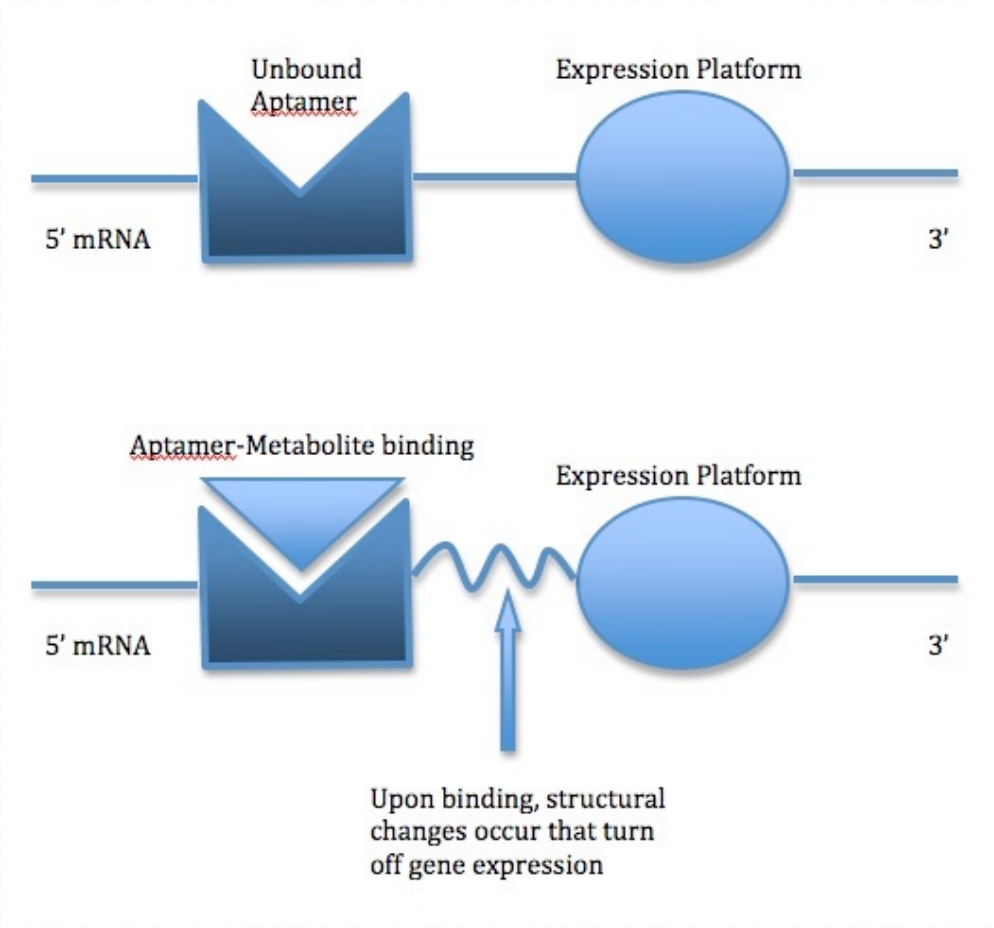

Figure 7.113 - Riboswitch features

Features

Riboswitches have two characteristic features that are important for their function. One is a region of the sequence called an aptamer, which folds into a three-dimensional shape that can bind a small effector molecule. The other is an adjacent region of the

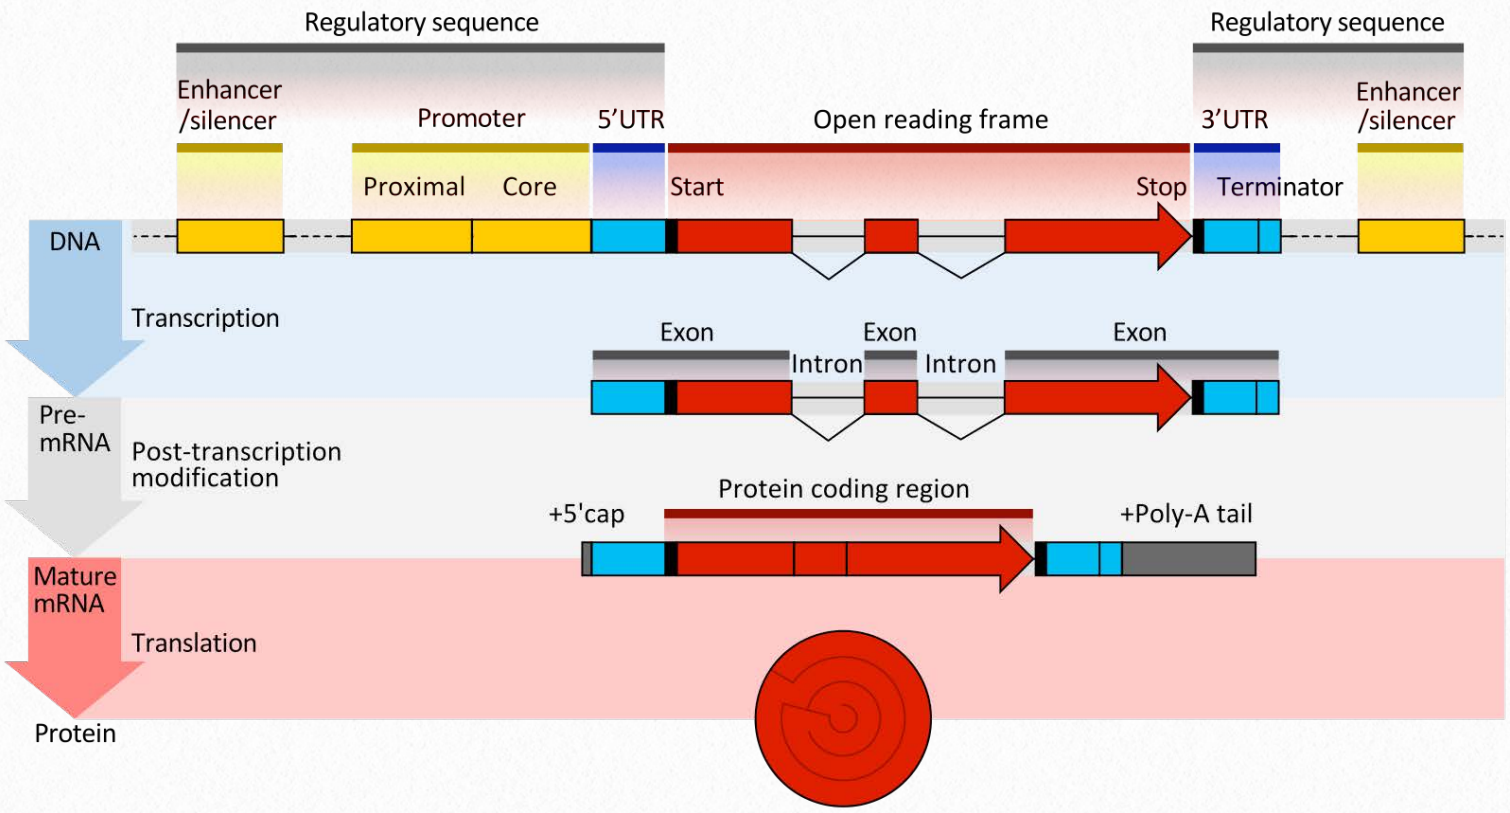

Figure 7.114 - Regulatory sequences for a eukaryotic gene

Wikipedia

RNA, called the expression platform, that can fold into different conformations depending on whether or not the aptamer is bound to the effector.

An example of a riboswitch found in bacteria is the guanine riboswitch, which controls the expression of genes required for purine biosynthesis. The aptamer region of this riboswitch binds to the effector, guanine, when levels of the base are high. The binding of the guanine triggers a change in the folding of the downstream expression platform, causing it to adopt a conformation that terminates transcription of the genes needed for the synthesis of guanine. In the absence of guanine, the expression platform assumes a different conformation that allows transcription of the purine biosynthesis genes. Thus, levels of guanine can be sensed and the genes needed for its synthesis can be expressed as needed.

Regulation of transcription in eukaryotes

Transcription in eukaryotes is also regulated by the binding of proteins to specific DNA sequences, but with some differences from the simple schemes outlined above.

For most eukaryotic genes, general transcription factors and RNA polymerase (i.e., the transcription initiation complex) are necessary but not sufficient for high levels of transcription. Promoter-proximal DNA sequences like the CAAT box and GC

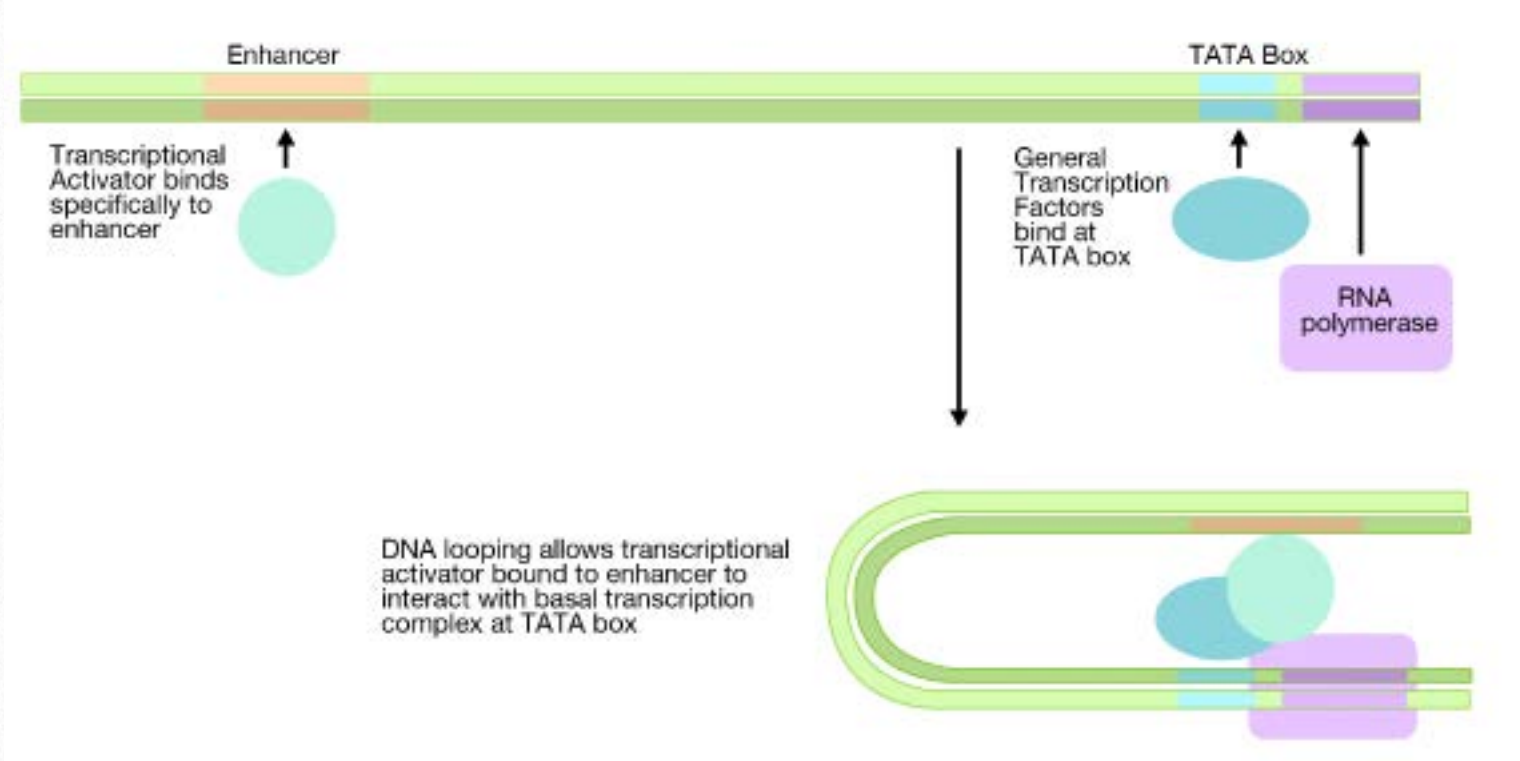

Figure 7.115 - DNA looping allows contact between activator bound at a distant enhancer and the basal transcription complex

Image by Martha Baker

box bind proteins that interact with the transcription initiation complex, influencing its formation (Figure 7.114).

Distant regulatory sequences

Additional regulatory sequences called enhancers and the proteins that bind to them are needed to achieve high levels of transcription. Enhancers are short DNA sequences that regulate the transcription of genes, but may be located at a distance from the gene they control (although they are on the same DNA molecule as the gene). Often enhancers are many kilobases away on the DNA, either upstream or downstream of the gene. As the name suggests, enhancers can enhance (increase) transcription of a particular gene. How can a DNA sequence far from the gene being transcribed affect the level of transcription?

Transcriptional activators

Enhancers work by binding proteins (transcriptional activators) that can, in turn, interact with the proteins bound at the promoter. The enhancer region of the DNA, with its associated transcriptional activator(s) can come in contact with the transcription initiation complex that is bound at a distant site by looping of the DNA (Figure 7.115). This allows the protein bound at the enhancer to make contact with the proteins in the basal transcription complex. The interaction of the activator with the transcription initiation complex may be direct, or it may be through a “middle-man”, a protein complex called mediator.

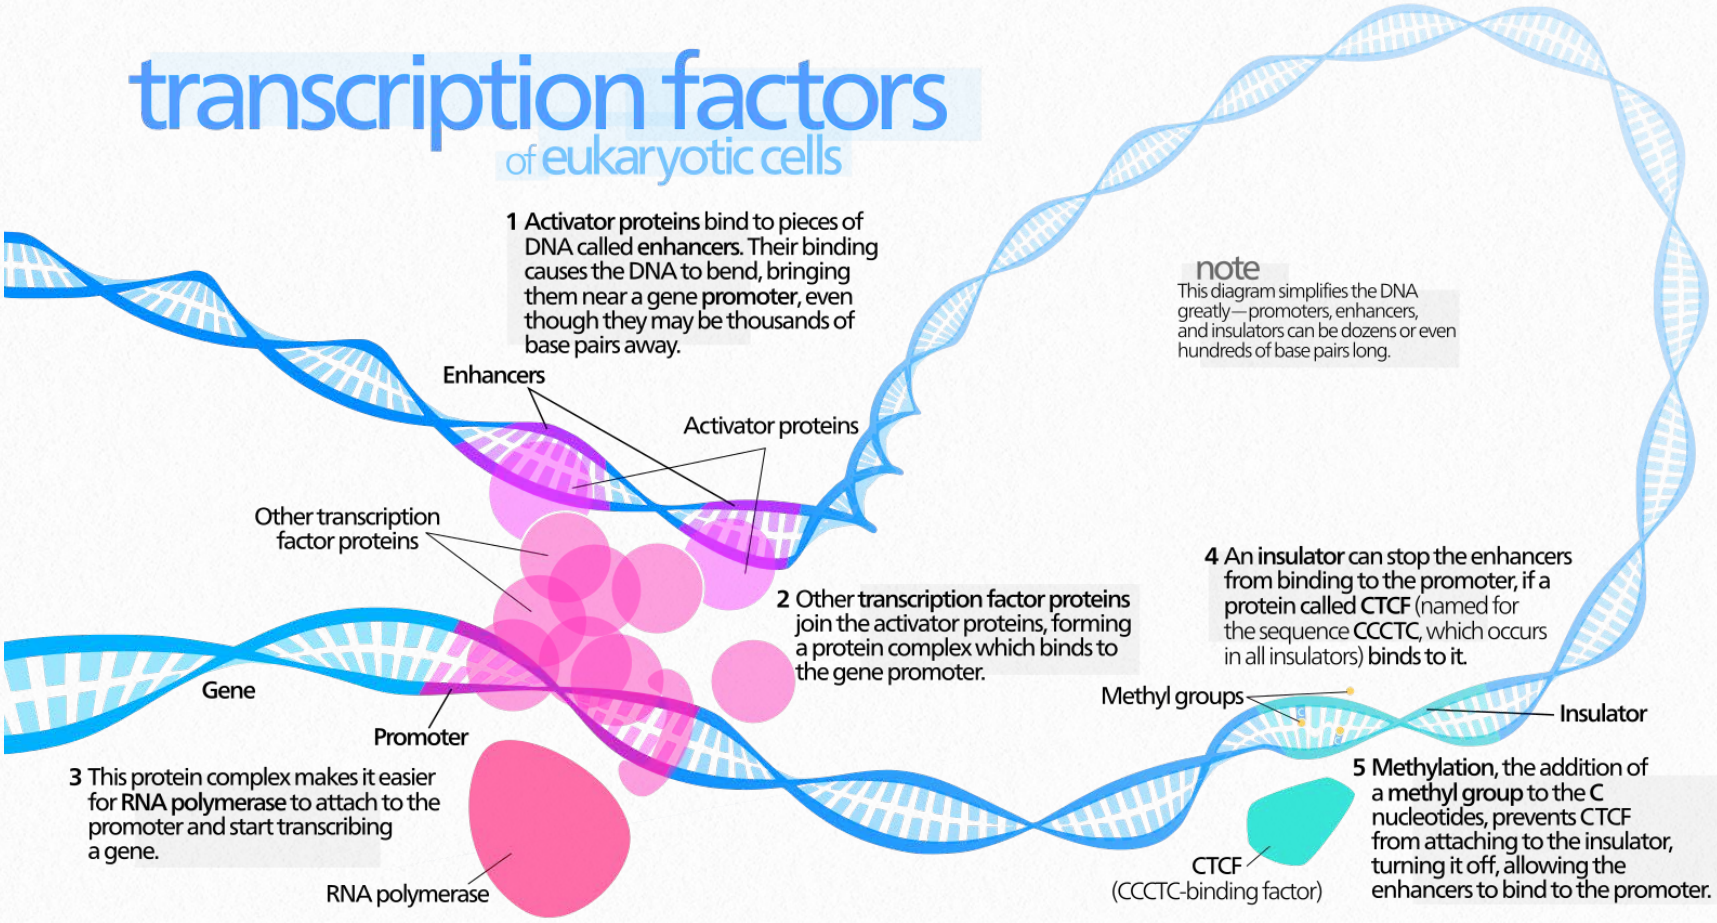

Figure 7.116 - Transcription factors in regulation of eukaryotic transcription

Wikipedia

One effect of this interaction is to assist in recruiting proteins necessary for transcription, like the general transcription factors and RNA polymerase to the promoter, increasing the frequency and efficiency of formation of the transcription initiation complex. There is also evidence that at some promoters, following assembly of the transcription initiation complex, the RNA polymerase remains stalled at the promoter. In such cases, the interaction with the transcription initiation complex of an activator bound to an enhancer could play a role in facilitating the transition of the RNA polymerase to the elongation phase of transcription.

YouTube Lectures by Kevin HERE & HERE

Chromatin remodeling proteins

Another mechanism by which activators bound at the enhancer can affect transcription is by recruiting to the promoter proteins that can modify the structure of that region of the chromosome. In eukaryotes, DNA is packaged with proteins to form chromatin. When the DNA is tightly associated with these proteins, it is difficult to access for transcription. So proteins that can make the DNA more accessible to the transcription machinery can also play a role in the extent to which transcription occurs.

Silencers

In addition to enhancers, there are also negative regulatory se-

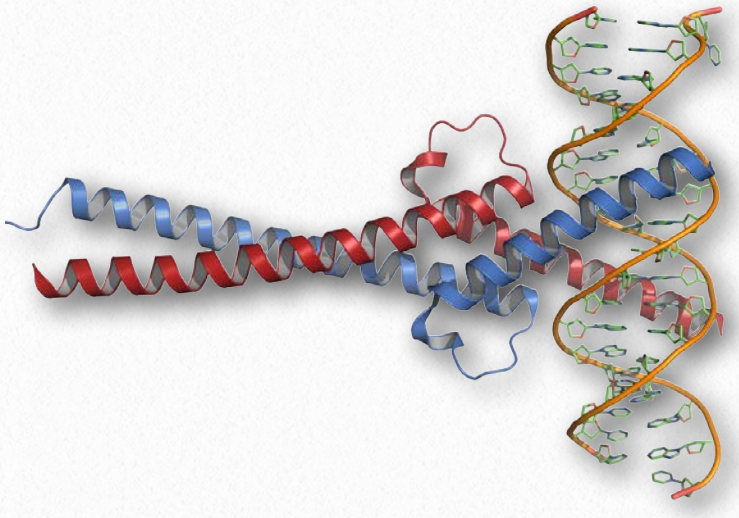

Figure 7.117 - Binding of c-myc protein to its target DNA sequence

Wikipedia

quences called silencers. Such regulatory sequences bind to transcriptional repressor proteins. Like the transcriptional activators, these repressors work by interacting with the transcription initiation complex. In the case of repressors, the effect they have on the transcription initiation complex is to reduce transcription.

DNA binding proteins

Transcriptional activators and repressors are modular proteins- they have a part that binds DNA and a part that activates or represses transcription by interacting with the transcription initiation complex (Figure 7.118). The DNA binding domain is the part of the protein that confers specificity for determining which gene(s) will be activated or repressed. The activation domain is the part of the protein that stimulates or represses transcription. The DNA binding domains of transcriptional activators form characteristic structures that recognize their target DNA sequences by making contacts with bases, usually in the major groove of the DNA helix. It is possible to engineer hybrid transcription factors that combine the DNA binding domain of one activator with the activation domain of another. Such proteins retain the specificity dictated by the DNA binding domain. Truncated transcription factors can also be generated that have their DNA binding domain but lack the activation domain. Such transcription factors can be useful tools in studying transcriptional regulation because their DNA binding domains can compete with the endogenous

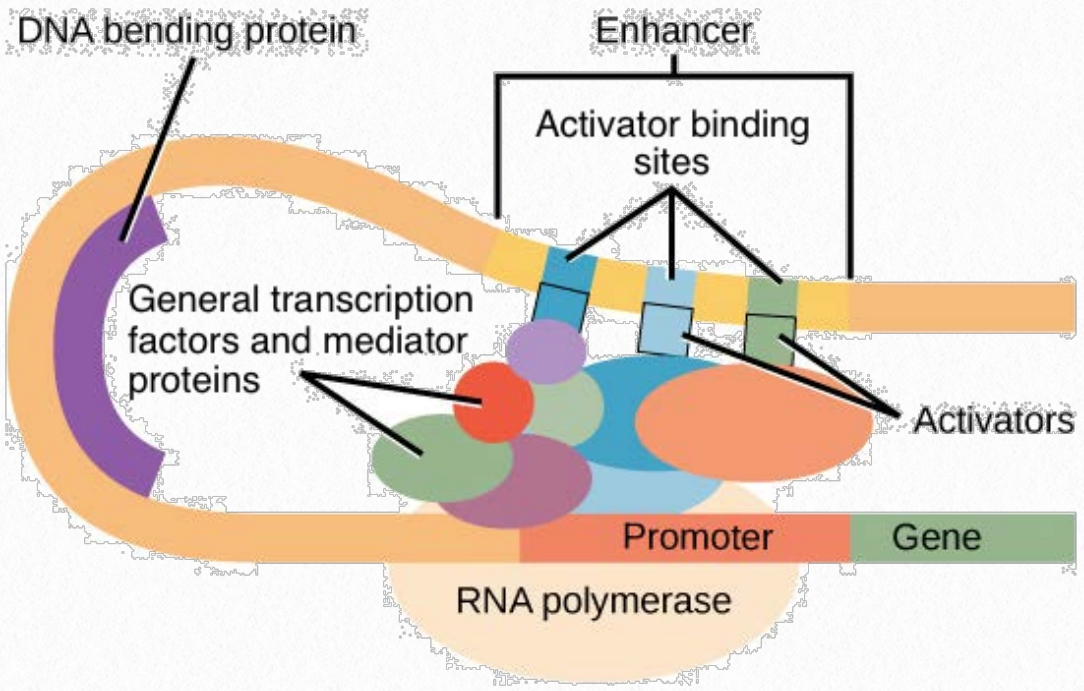

Figure 7.118 Activators bound at multiple sites can regulate transcription from a given promoter

OpenStax

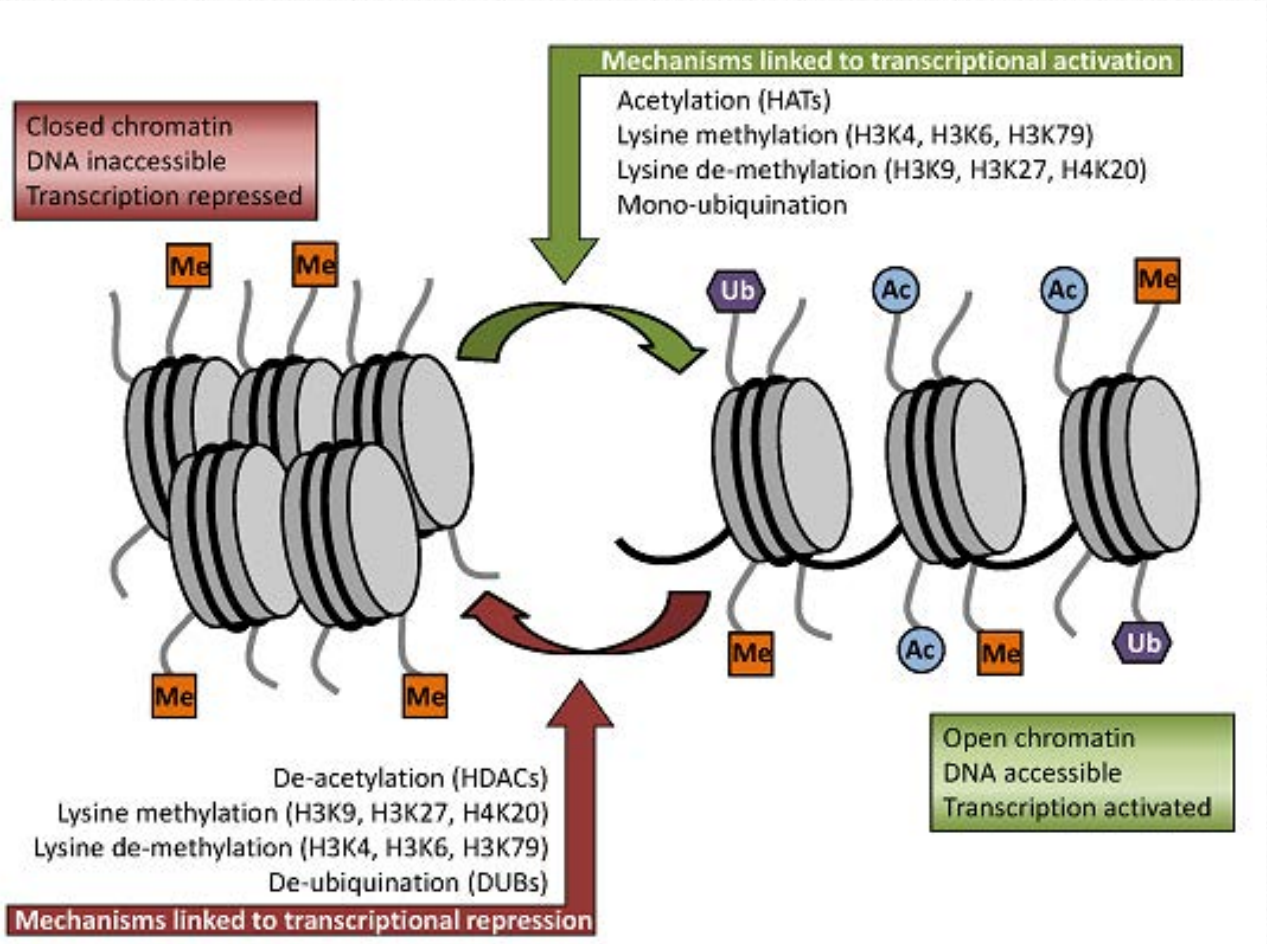

Figure 7.119 - Transcriptional activation (right) and deactivation (left) by histone modification

Wikipedia

transcription factors for regulatory binding sites without increasing transcription from the target promoters.

Multiple factors

The description above may suggest that each gene in eukaryotes is controlled by the binding of a single transcriptional activator or repressor to a particular enhancer or silencer site. However, it turns out that the transcription of any given gene may be simultaneously regulated by a combination of proteins, both activators and repressors, bound at multiple regulatory sites on the DNA, all of which interact with the transcription initiation complex. The combinatorial nature of such regulation provides great versatility, with different combinations of regulatory elements and proteins working together in response to a wide variety of conditions and signals.

The mechanisms described so far have focused on the sequence elements in DNA that regulate transcription through the activator and repressor proteins bound to them. Following transcription, alternative splicing (see HERE) and editing of the transcripts can also modify the proteins that are produced by the cell. We will now examine some of the other ways in which gene expression is modulated in cells.

First, we will consider some so-called epigenetic mechanisms that affect gene expression. The term epigenetics derives from epi (above, or on top of) and genetic (of genes) and refers to the fact that these mechanisms act in addition to, or overlaid on, the information in the gene sequences. Two such epigenetic mechanisms are the covalent modifications of his-

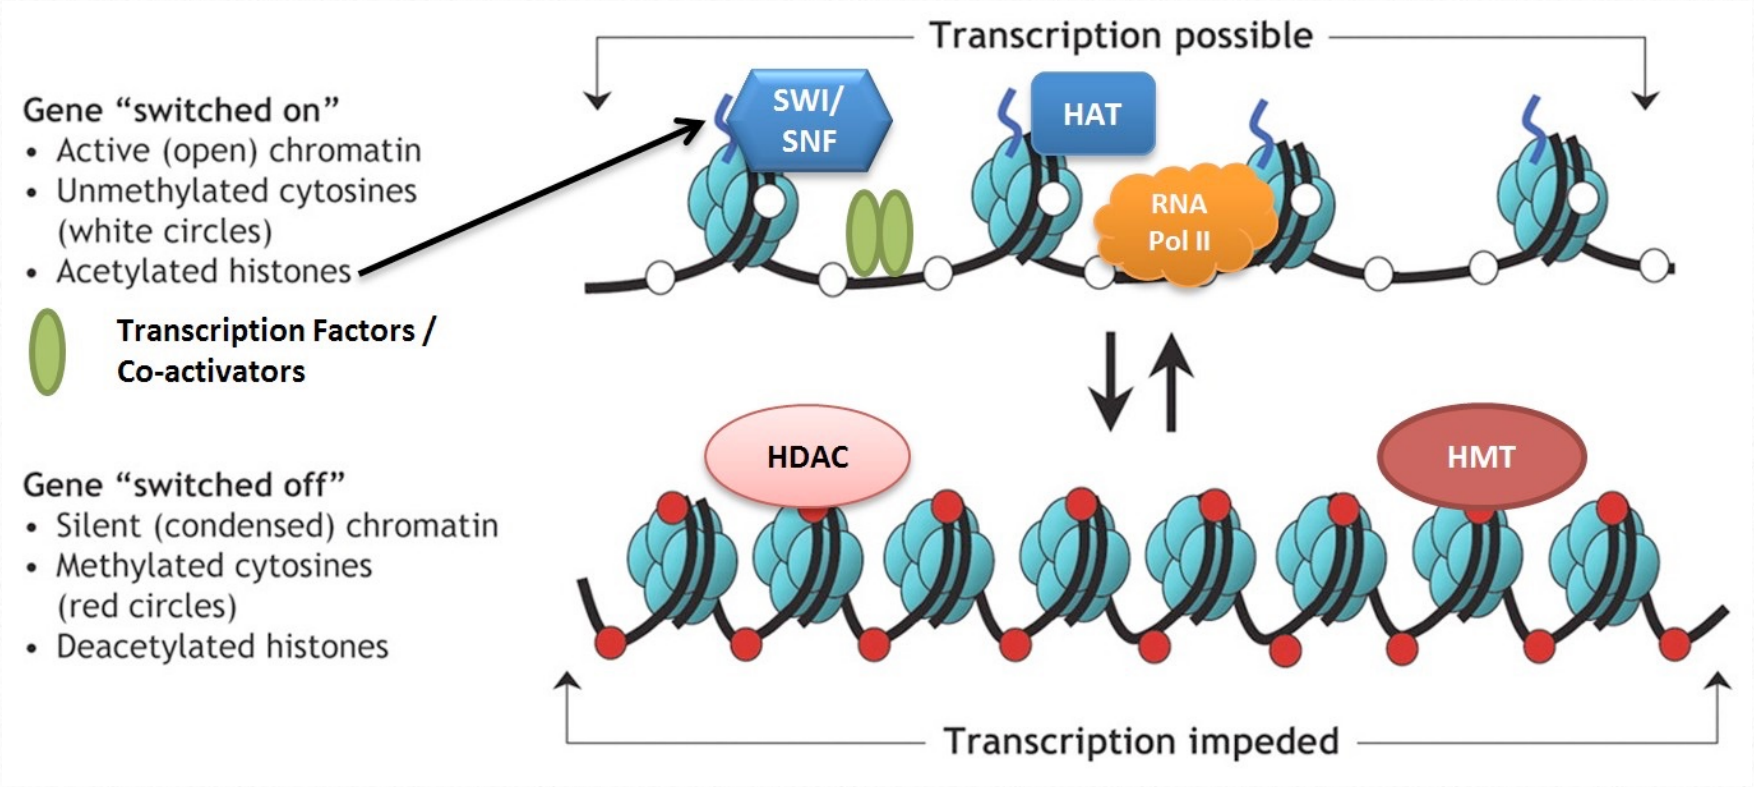

Figure 7.120 - Chromatin configuration affects transcription

Wikipedia

tones in chromatin and the methylation of DNA sequences.

Histone modification

As noted earlier, transcription in eukaryotes is complicated by the fact that the DNA is packaged with histones to make chromatin. This means that for a gene to be transcribed, the relevant regions of the chromatin must be opened up to allow access to the RNA polymerase and transcription factors. This provides another potential point of control of gene expression. Chromatin remodeling factors, mentioned earlier, assist in reorganizing the nucleosome structure at regions that need to be made accessible.

Interactive Learning Module HERE

But what determines that a given region of the chromatin will be acted upon by the remodeling complexes? Transcriptional activator proteins bound at enhancers, sometimes work by recruiting histone modifying enzymes to the promoter region. An example of such a modifying enzyme is histone acetyl transferase (HAT) that works to acetylate specific amino acid residues in the tails of the histones forming the nucleosome core (Figures 7.119 & 7.120). Acetylation of histones is thought to be responsible for loosening the interaction between histones and the DNA in nucleosomes and helps to make the DNA more readily accessible for transcription. The opposite effect may be achieved if the enzymes recruited are histone deacetylases

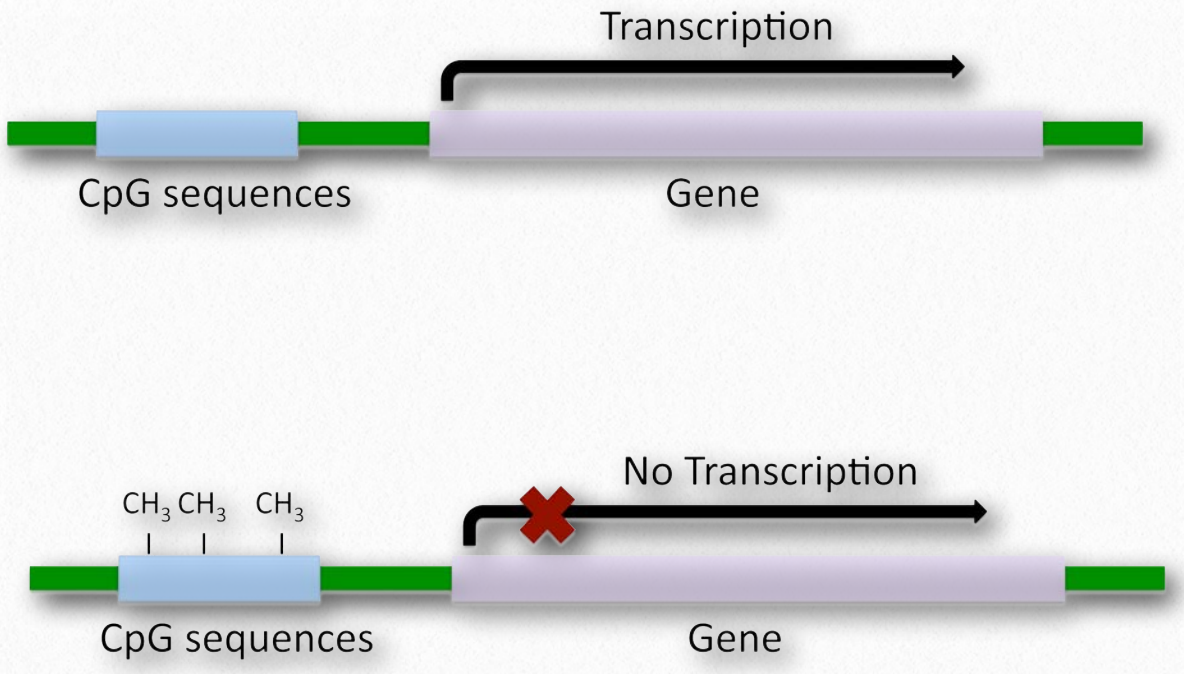

Figure 7.121 - Inactivation of transcription by CpG methylation

Image by Indira Rajagopal

(HDAC) which remove acetyl groups from the tails of the histones in the nucleosome, and lead to tighter packing of the chromatin.

Writers, readers and erasers

In addition to the histone acetyl transferases and the deacetylases, other enzymes may add or remove methyl groups, phosphate groups, and other chemical moieties to specific amino acid side chains on the histone tails. The patterns of these covalent modifications, sometimes called the histone code, are established by the so-called "writers", or enzymes, such as histone methyltransferases, that add the chemical groups on to the histone tails. Yet other enzymes, like the histone demethylases, may act as "erasers," removing the chemical groups added by the "writers." The histone code is interpreted by "readers," proteins that bind to specific combinations of the modifications and assist in either silencing the expression of genes in the vicinity or making the region more transcriptionally active.

YouTube Lectures by Kevin HERE & HERE

DNA methylation

Gene expression can also be regulated by methylation of the other component of chromatin - DNA. Enzymes called DNA methyltransferases (DNMTs) catalyze the covalent addition of a methyl group to C_5 of cytosines in DNA. Patterns of cytosine methylation vary in different organisms, with methylation concentrated in some parts of the genome in some groups and scattered throughout the genome in others. In vertebrates, the cytosines that are methylated are generally next to a guanine (the CG dinucleotide is commonly abbreviated as CpG). Methylation of DNA seems to correlate with gene silencing while demethylation is associated with increased transcription (Figure 7.121).

How does methylation of the DNA at CpG sites regulate gene expression? Although the extent of DNA methylation near promoters

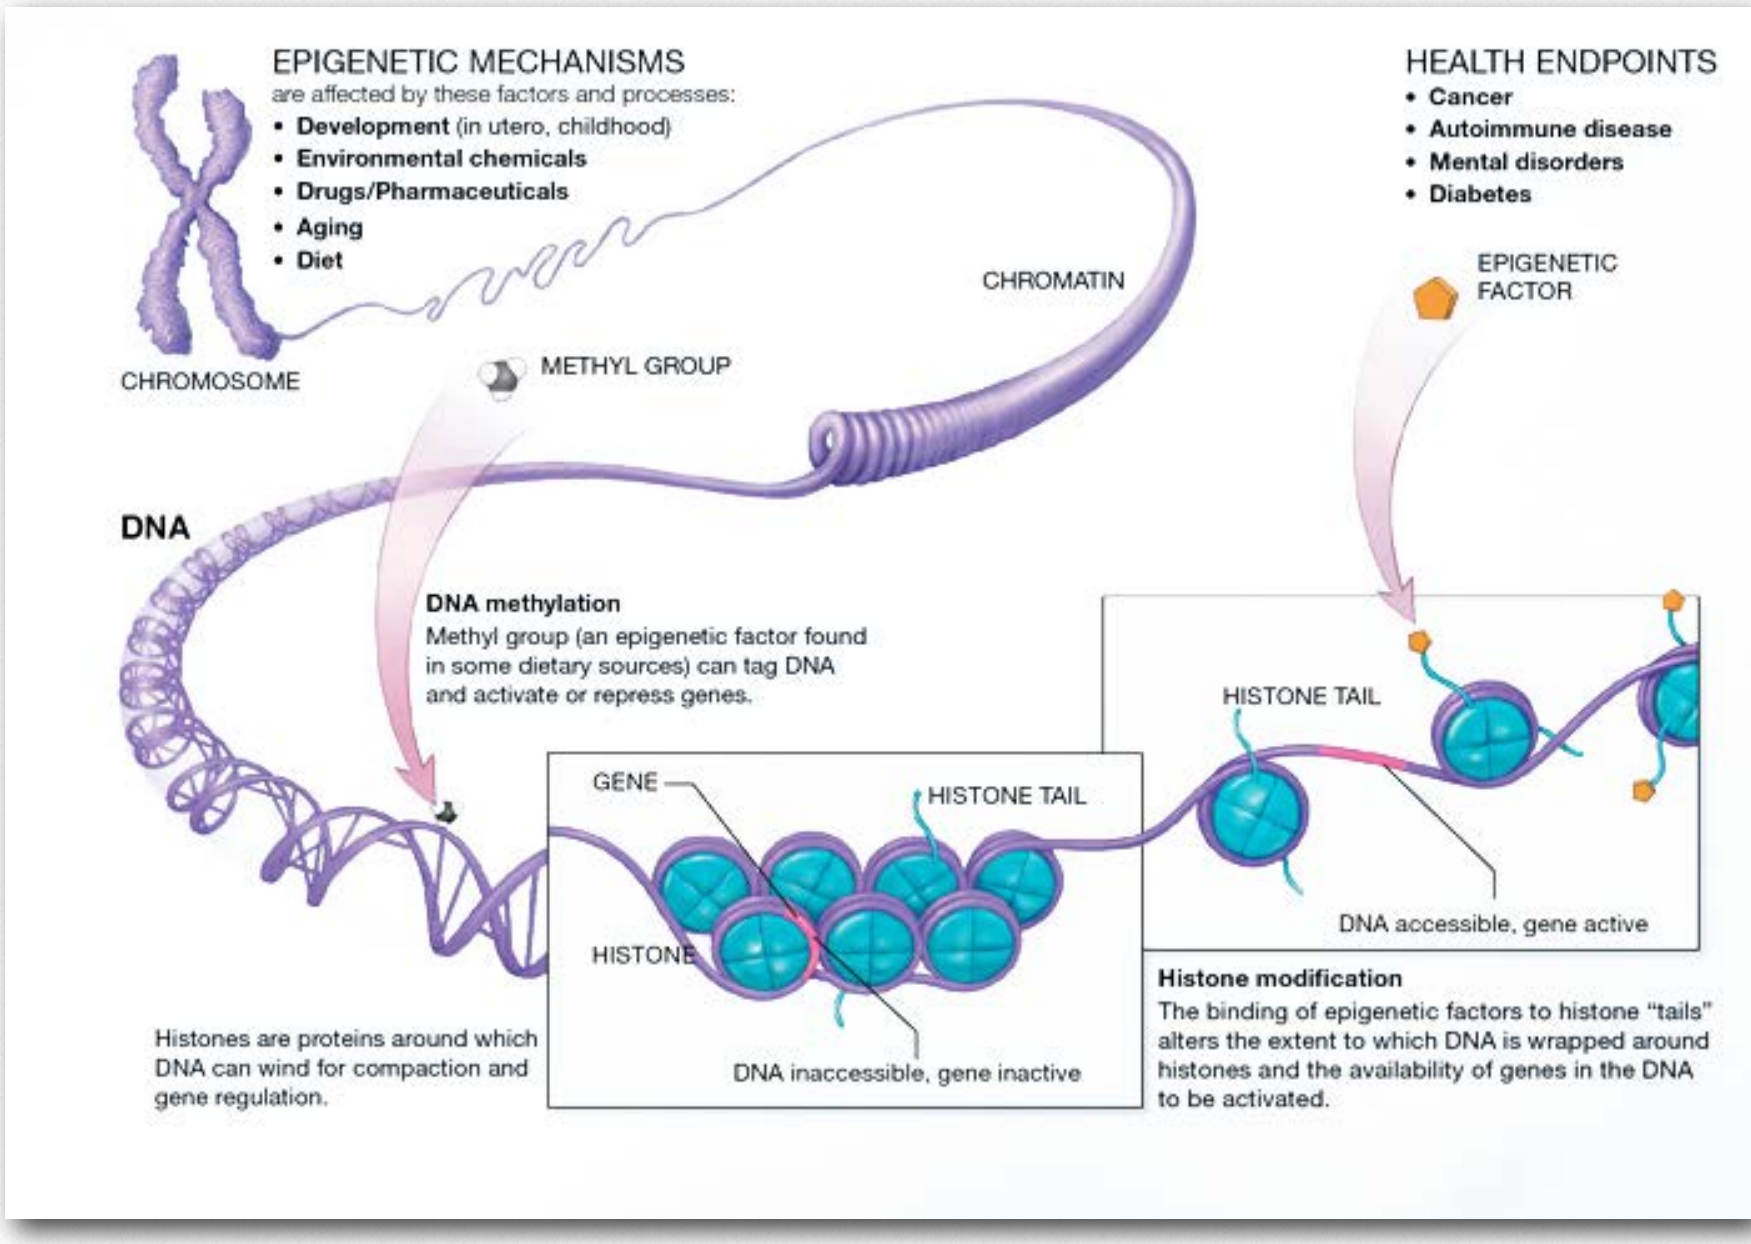

Figure 7.122 - Epigenetic changes through histone and DNA modification

has been observed to correlate with gene silencing, it is not clear how exactly methylation brings about this effect. It has been suggested that methylation could block the binding of proteins necessary for transcription. Methylation at enhancer sites might also prevent the binding of transcriptional activators to them.

Another interesting observation is that certain proteins that bind to methylated CpG sites also seem to interact with histone deacetylases. As noted above, histones deacetylases remove acetyl groups from histones, and promote tighter packing of chromatin and transcriptional silencing. Thus, methylation on DNA likely works in combination with histone modification to affect gene expression.

Regulatory RNAs

One of the most unexpected discoveries in the past few decades has been the role that RNAs play in regulating gene expression. The classic view that RNA either encoded proteins (mRNA) or assisted in their synthesis (rRNA

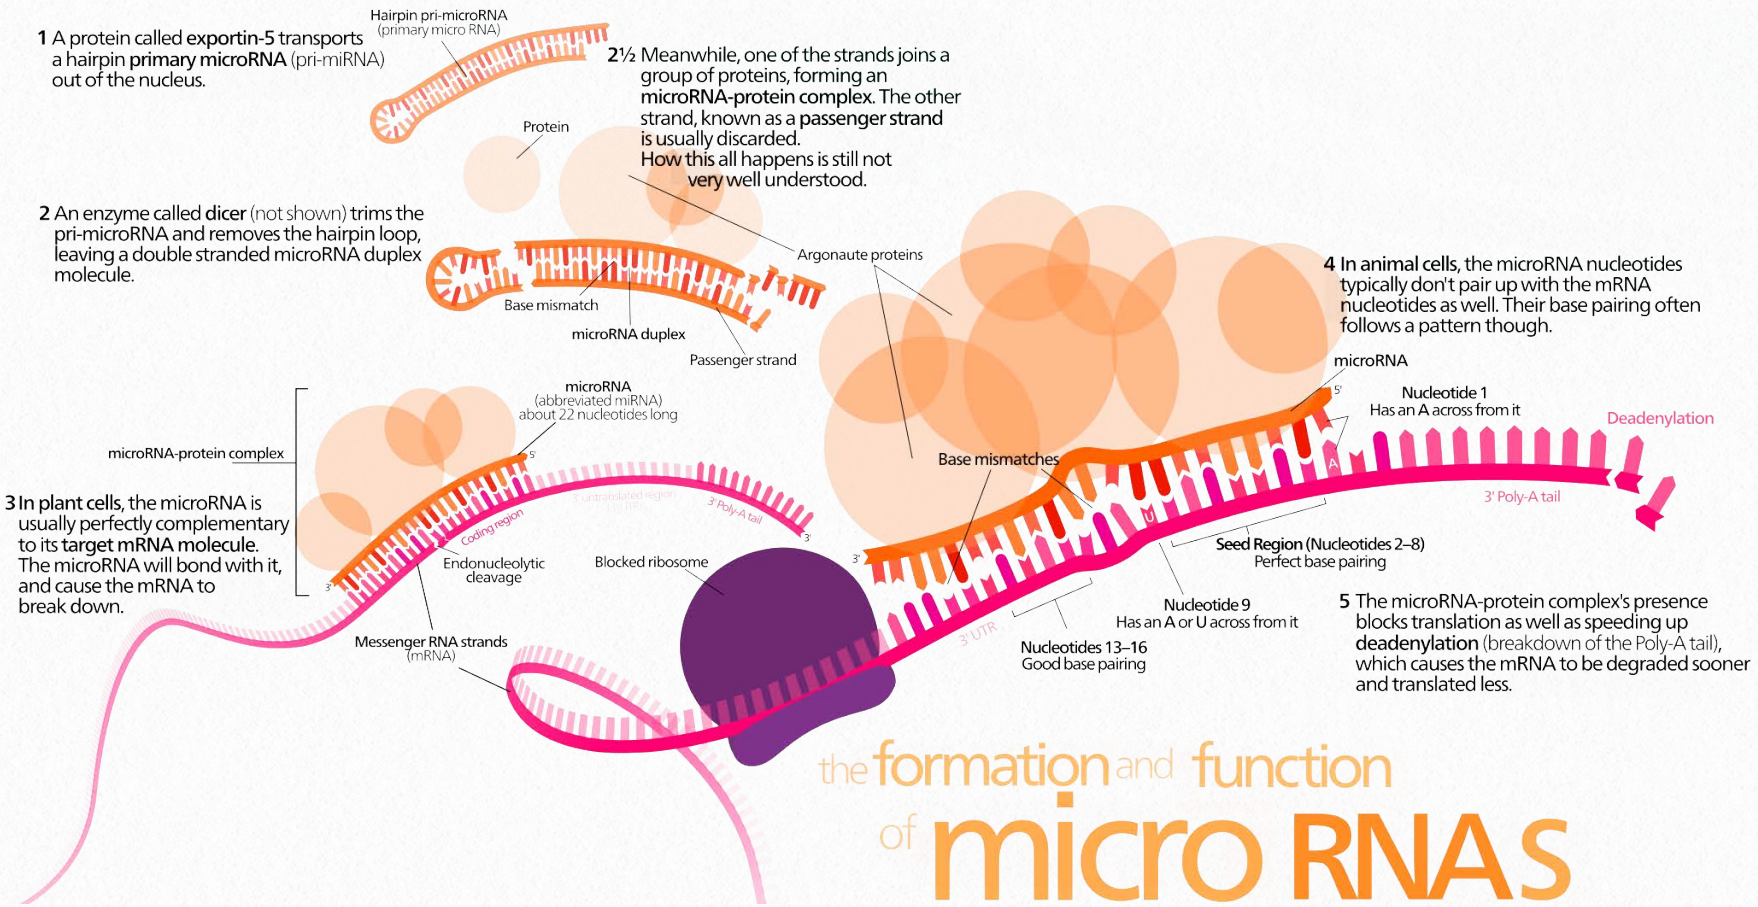

Figure 7.123 - miRNAs function in the regulation of gene expression

Wikipedia

and tRNA) is now known to be a vast underestimate of the various ways in which RNAs function in gene expression. It is now clear that regulatory RNAs have widespread and significant effects on gene expression, a realization that has revolutionized our understanding of gene regulation.

RNAs (siRNAs) are small, non-coding RNAs that act at the post-transcriptional level to regulate gene expression (Figure 7.123 & 7.124). These RNAs appear to silence genes by base-pairing with target mRNAs and marking them for degradation, or by

What are some of the ways in which regulatory RNAs function to modulate the expression of genes?

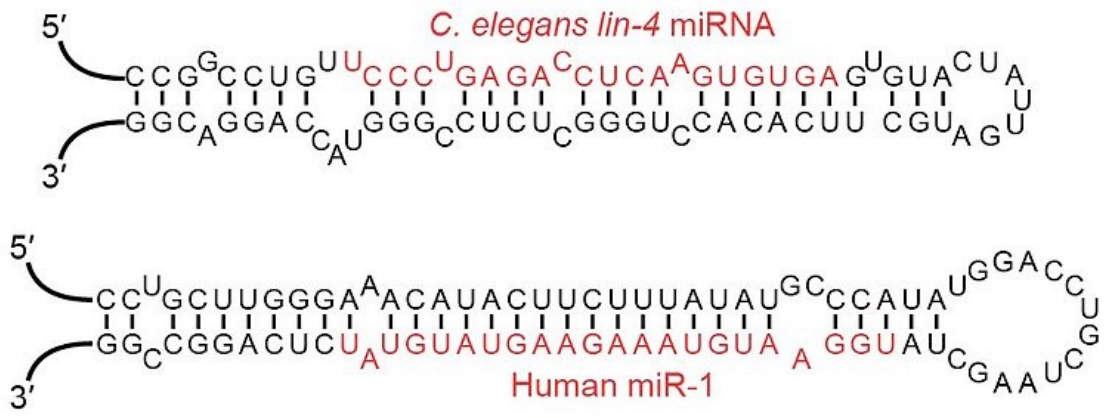

Figure 7.124 Pre-miRNA hairpin structures with the mature guide miRNAs shown in red

Wikipedia

Small regulatory RNAs

MicroRNAs (miRNAs) and Short Interfering

blocking their translation. The functional forms of both miRNAs and siRNAs are from 20-30 nucleotides long and are derived by processing from longer primary transcripts. Mature miRNAs and siRNAs work in association with a class of proteins called Argonaute proteins to form a gene silencing complex.

MicroRNAs are transcribed from specific genes by RNA polymerase II. The primary transcript, known as a pri-miRNA folds on itself to form double-stranded hairpin structures that are cleaved by an RNase in the nucleus called Drosha. The products of Drosha cleavage, double-stranded RNAs of roughly 60-70 nucleotides known as pre-miRNAs, are exported to the cytoplasm, where they are further processed into the small 20-30 nucleotide lengths of mature double-stranded miRNAs by an enzyme known as Dicer. The RNA duplexes of miRNAs are not perfectly matched, and have loops and mismatches (Figure 7.124).

siRNAs also derive from double-stranded RNAs, but these may arise from either endogenous or exogenous sources (such as viruses). These double-stranded RNAs are processed in the cytoplasm by the same enzyme, Dicer, that generates the mature miRNAs, to produce the small, 20-30 nucleotide double-stranded RNAs.

In contrast to miRNAs, the mature siRNAs are perfectly base-paired along their lengths.

RISC assembly

Both miRNAs and siRNAs then are assembled with Argonaute proteins to form a silencing complex called RISC (RNA-induced silencing complex). Recall that both miRNAs

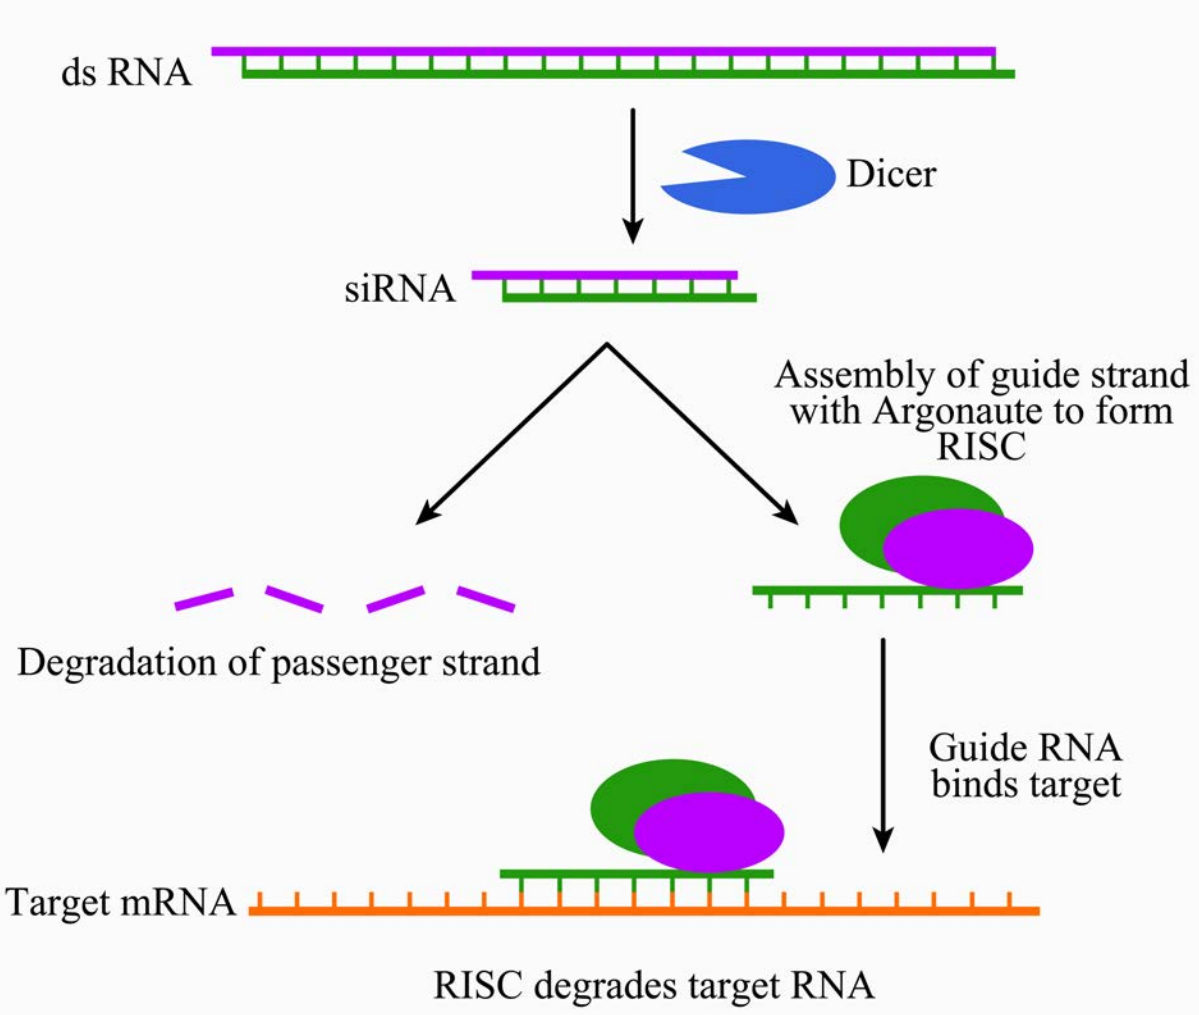

Figure 7.125 - Gene silencing by siRNA

Image by Pehr Jacobson

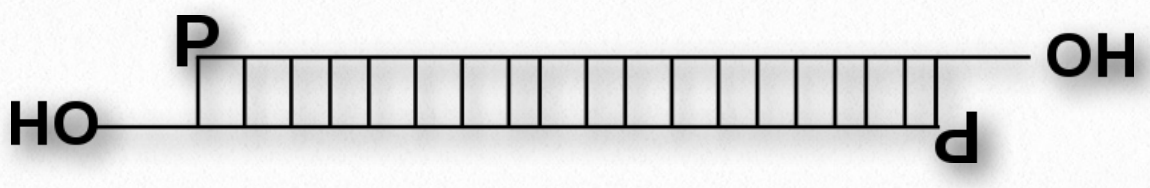

Figure 7.126 - Processed siRNA duplex with perfect base-pairing, 5' phosphates and two bases overhanging at each 3' end

and siRNAs are, at this point double-stranded. One strand of the RNA is referred to as the guide RNA, while the other is called the passenger RNA.

During the process of loading the RNA onto the Argonaute protein, the guide strand of the RNA remains associated with the protein, while the passenger strand is removed. The guide RNA associated with the Argonaute protein is the functional gene silencing complex (Figure 7.125).

Sequence specific base-pairing of the guide RNA with an mRNA leads to either the degradation of the mRNA by the Argonaute protein (in the case of the siRNAs) or in suppression of translation of the mRNA (for miRNAs). The extent to which these processes play a role in regulating gene expression is impressive. The expression of at least a third of all human genes has already been shown to be modulated by miRNAs, demonstrating clearly that these RNAs play a major role in gene regulation.

Long noncoding RNAs

Long noncoding RNAs (lncRNAs) are RNAs of greater than 200 nucleotides that do not code for proteins. Some of these RNAs are derived from intron sequences, while others, transcribed from intergenic regions form a subset of lncRNAs called lincRNAs (long intergenic noncoding RNAs). Yet other lncRNAs are produced as antisense transcripts of coding genes. An astounding 30,000 transcripts in humans are thought to be lncRNAs, but little is known of their function. From the few lncRNAs that have been intensively studied, it is evident that they do not all function in the same way. However, they appear to affect gene expression in a variety of ways including modification of chromatin structure, regulation of splicing, or serving as structural scaffolds for the assembly of nucleoprotein complexes. Additional mechanisms will doubtless be uncovered as these fascinating RNAs are investigated in years to come.

Regulation of translation

The synthesis of proteins is dependent on the availability of the mRNAs encoding them. If an mRNA is blocked at its 5' end, it cannot be translated. The rate of degradation of an mRNA will influence how long it is around to direct the synthesis of the protein it codes for. Gene expression can also, there-

YouTube Lectures by Kevin HERE & HERE

fore, be regulated by mechanisms that alter the rate of mRNA degradation. Regulation of translation is used to control the production of many proteins. Two examples, ferritin and the transferrin receptor, are important for iron storage and transport in cells. Ferritin is an iron-binding protein that sequesters iron atoms in cells to keep them from reacting. When iron levels are high, there is a need for more ferritin than when iron levels are low. How are ferritin levels regulated? The 5'UTR of the ferritin mRNA contains a 28-nucleotide sequence called the Iron Response Element, or IRE (Figure 7.127). When iron levels are low, the IRE is bound by a protein. The presence of the IRE-binding protein at the 5'UTR blocks translation of the ferritin mRNA. However, if iron levels are high, the iron binds to the IRE-binding protein, which undergoes a conformational change and dissociates from the IRE. This frees up the 5' end of the ferritin mRNA for ribosome assembly and translation, producing more ferritin.

The other protein involved in iron transport, the transferrin receptor, is required for uptake of iron into cells, when intracellular iron levels are low. In the case of the transferrin receptor, it is when iron levels are low that more of it is needed. When iron levels are high, there is no need to make more transferrin receptor. The mRNA encoding the transferrin receptor also has IRE sequences, but in this case, the IRE is situated in the 3'UTR of the transcript (Figure 7.128). The IRE is, as in the case of ferritin, bound by the IRE-binding protein. When iron levels in the cell are high, the iron binds the IRE-binding protein, which dissociates from the IRE. This leaves the 3'UTR susceptible to attack by RNases, leading to degradation of the transferrin receptor

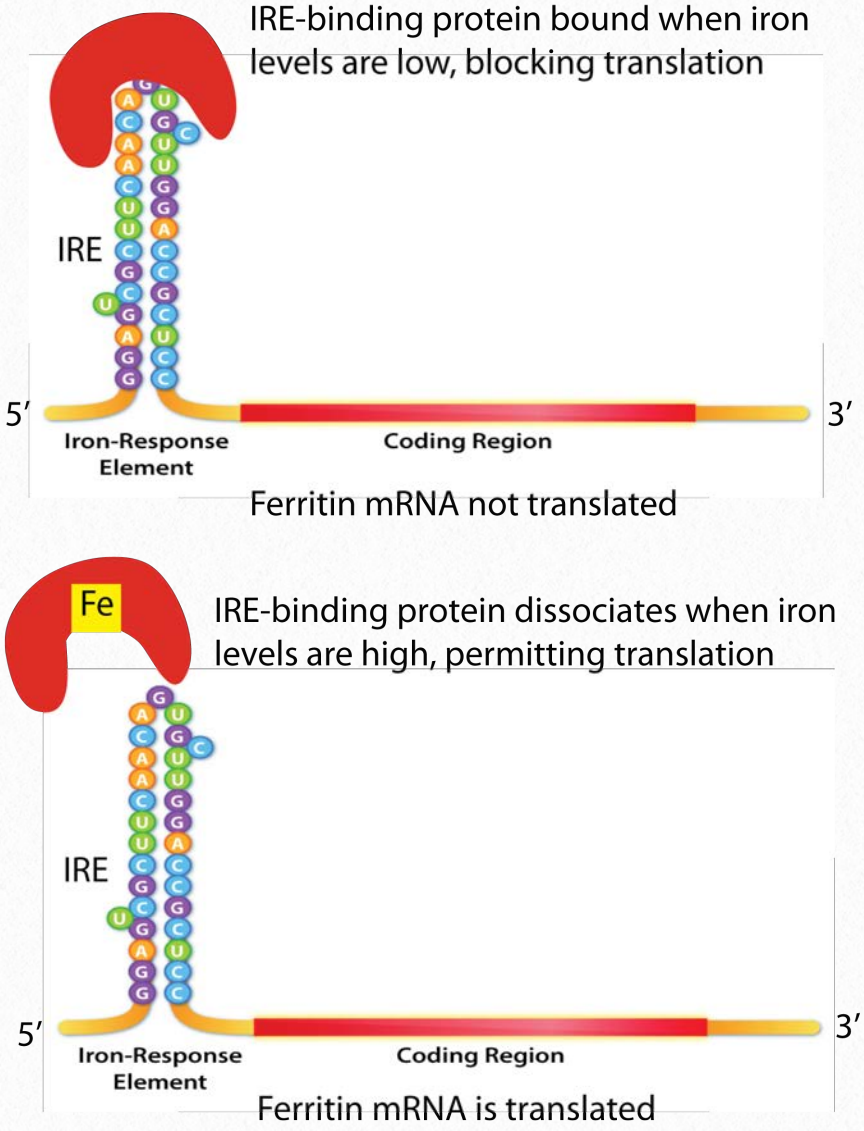

Figure 7.127 -Regulation of ferritin mRNA translation

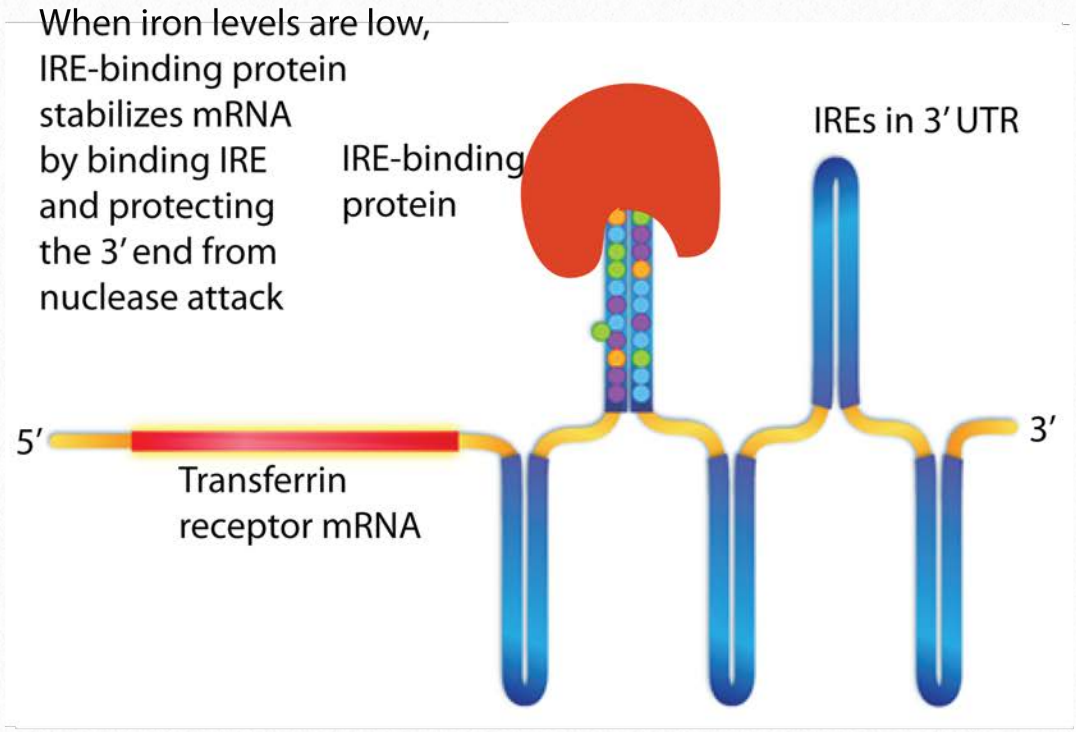
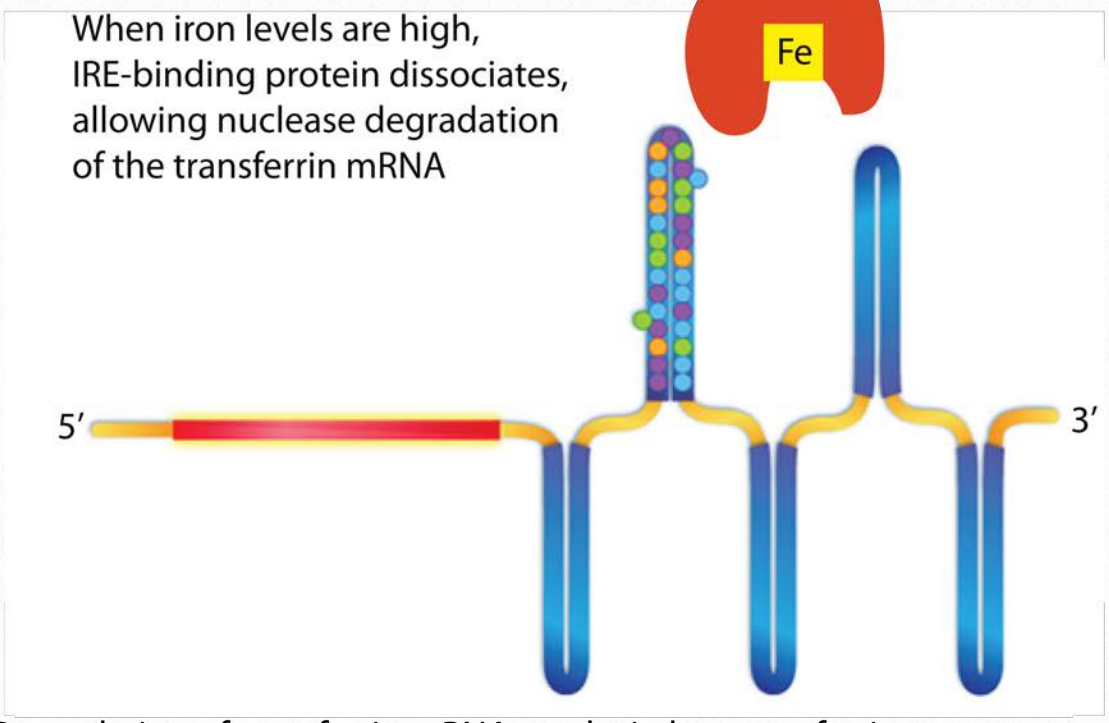
Image by Aleia Kim



Stabilized transferrin mRNA is translated to make more transferrin receptor



Degradation of transferrin mRNA results in less transferrin receptor made

Figure 7.128 -Regulation of transferrin receptor mRNA translation

Image by Aleia Kim

mRNA. At times when iron levels are low, the IRE-binding protein remains bound to the 3' UTR of the mRNA, stabilizing it and permitting more transferrin receptor to be made by translation.

Gene expression is controlled at many steps

As can be seen from the examples in this section, regulation of gene expression in eukaryotic cells is a function of multiple mechanisms that act at different stages in the flow of information from DNA to protein, responding to the internal state of the cell as well as external conditions and signals.

Information Processing: Signaling

Cellular communication

Up to this point we have considered how cells carry out biochemical reactions and how they regulate the expression of the genes in response to their internal and external environments. It is intuitively obvious that even unicellular organisms must be able to sense features of their environment, such as the presence of nutrients, if they are to survive. In addition to being able to receive and respond to information from the environment, multicellular organisms must also find ways by which their cells can communicate among themselves.

YouTube Lectures by Kevin HERE & HERE

Coordination

Since different cells take on specialized functions in a multicellular organism, they must be able to coordinate activities. Cells grow, divide, or differentiate in response to specific signals. They may change shape or migrate to another location. At the physiological level, cells in a multicellular organism, must respond to everything from a meal

Signal Category	Examples
Indoleamine	Serotonin, melatonin
Catecholamine	Epinephrine, norepinephrine
Peptide hormone	Insulin, glucagon, EGF
Steroid hormone	Cortisol, estrogen, testoterone
Eicosanoids	Leukotrienes, prostaglandins, endocannabinoids

Figure 7.129 - Some examples of signal molecules

just eaten to injury, threat, or the availability of a mate. They must know when to divide, when to undergo apoptosis (programmed cell death), when to store food, and when to break it down. A variety of mechanisms have arisen to ensure that cell-cell communication is not only possible, but astonishingly swift, accurate and reliable.

How are signals sent between cells? Like pretty much everything that happens in cells, signaling is dependent on molecular recognition. The basic principle of cell-cell signaling is simple. A particular kind of molecule, sent by a signaling cell, is recognized and bound by a receptor protein in (or on the surface of) the target cell. The signal molecules are chemically varied- they may be proteins, short peptides, lipids, nucleotides or catecholamines, to name a few.

Signal properties

The chemical properties of the signal determine whether its receptors are on the cell surface or intracellular. If the signal is small and hydrophobic it can cross the cell membrane and bind a receptor inside the cell. If, on the other hand, the signal is charged, or very large, it would not be able to diffuse through the plasma membrane. Such signals need receptors on the cell surface, typically transmembrane proteins that have an extracellular portion that binds the signal and an intracellular part that passes on the message within the cell (Figure 7.130).

Receptors are specific for each type of signal, so each cell has many different kinds of receptors that can recognize and bind the many signals it receives. Because different

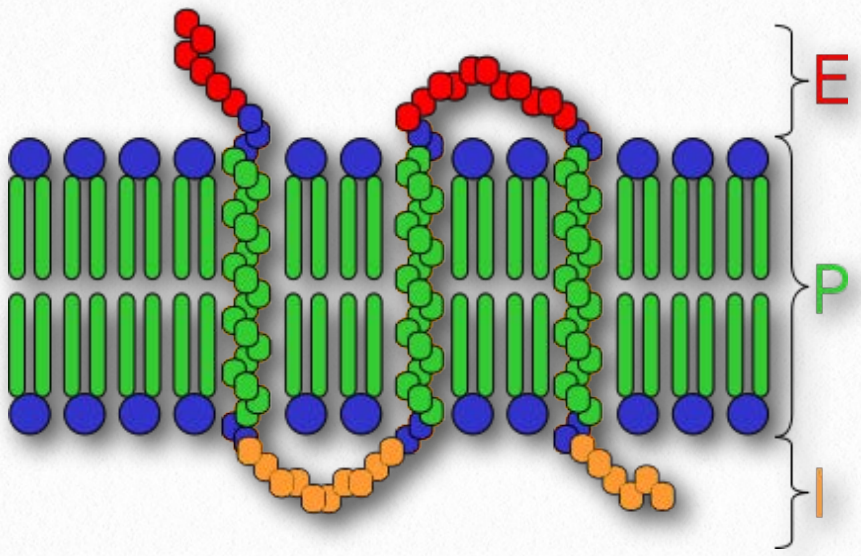

Figure 7.130 - Schematic representation of a transmembrane receptor protein. E = extracellular; P = plasma membrane; I = intracellular

Wikipedia

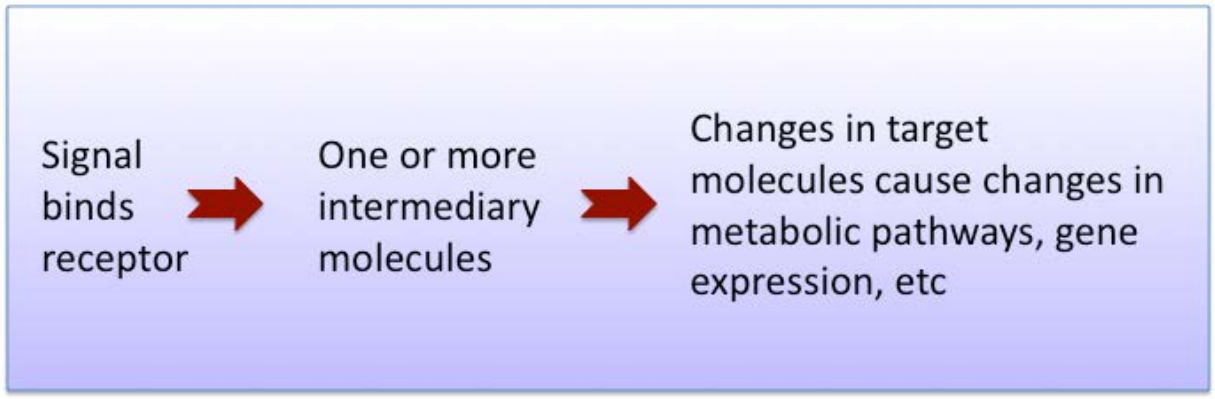

Figure 7.131 -General features of signal transduction pathways

cells have different sets of receptors, they respond to different signals or combinations of signals. The binding of a signal molecule to a receptor sets off a chain of events in the target cell. These events could cause change in various ways, including, but not limited to, alterations in metabolic pathways or gene expression in the target cell.

How the binding of a signal to a receptor brings about change in cells is the topic of this section. We will examine a few of the major receptor types and the consequences of signal binding to these receptors. Although the specific molecular components of the various signal transduction pathways differ, they all have some features in common (Figure 7.131):

• The binding of a signal to its receptor is usually followed by the generation of a new signal(s) within the cell.

The process by which the original signal is converted to a different form and passed on within the cell to bring about change is called signal transduction.

• Most signaling pathways have multiple signal transduction steps by which the signal is relayed through a series of molecular messengers that can amplify and distribute the message to various parts of the cell.

• The last of these messengers usually interacts with a target protein(s) and changes its activity, often by phosphorylation.

• When a signal sets a particular pathway in motion, it is acting like an ON switch. This means that once the desired result has been

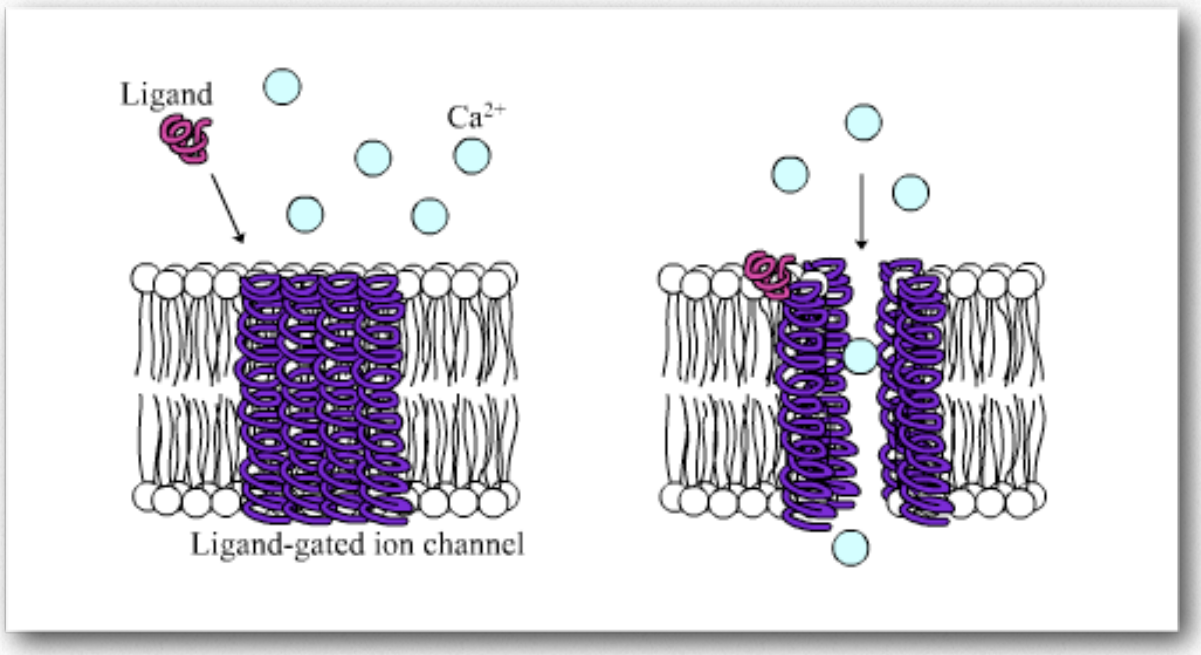

Figure 7.132 - Ligand-gated ion channel receptor opening in response to a signal (ligand)

Wikipedia

obtained, the cell must have a mechanism that acts as an OFF switch.

Understanding this underlying similarity is helpful, because learning the details of the different pathways becomes merely a matter of identifying which molecular component performs a particular function in each individual case. We will consider several different signal transduction pathways, each mediated by a different kind of receptor.

Ligand-gated ion channel receptors

The simplest and fastest of signal pathways is seen in the case of signals whose receptors are gated ion channels (Figure 7.132). Gated ion channels are made up of multiple transmembrane proteins that create a pore, or channel, in the cell membrane. Depending upon its type, each ion channel is specific to the passage of a particular ionic species. The term "gated" refers to the fact that the ion channel is controlled by a "gate" which must be opened to allow the ions through. The gates are opened by the binding of an incoming signal (ligand) to the receptor, allowing the almost instantaneous passage of millions of ions from one side of the membrane to the other. Changes in the interior environment

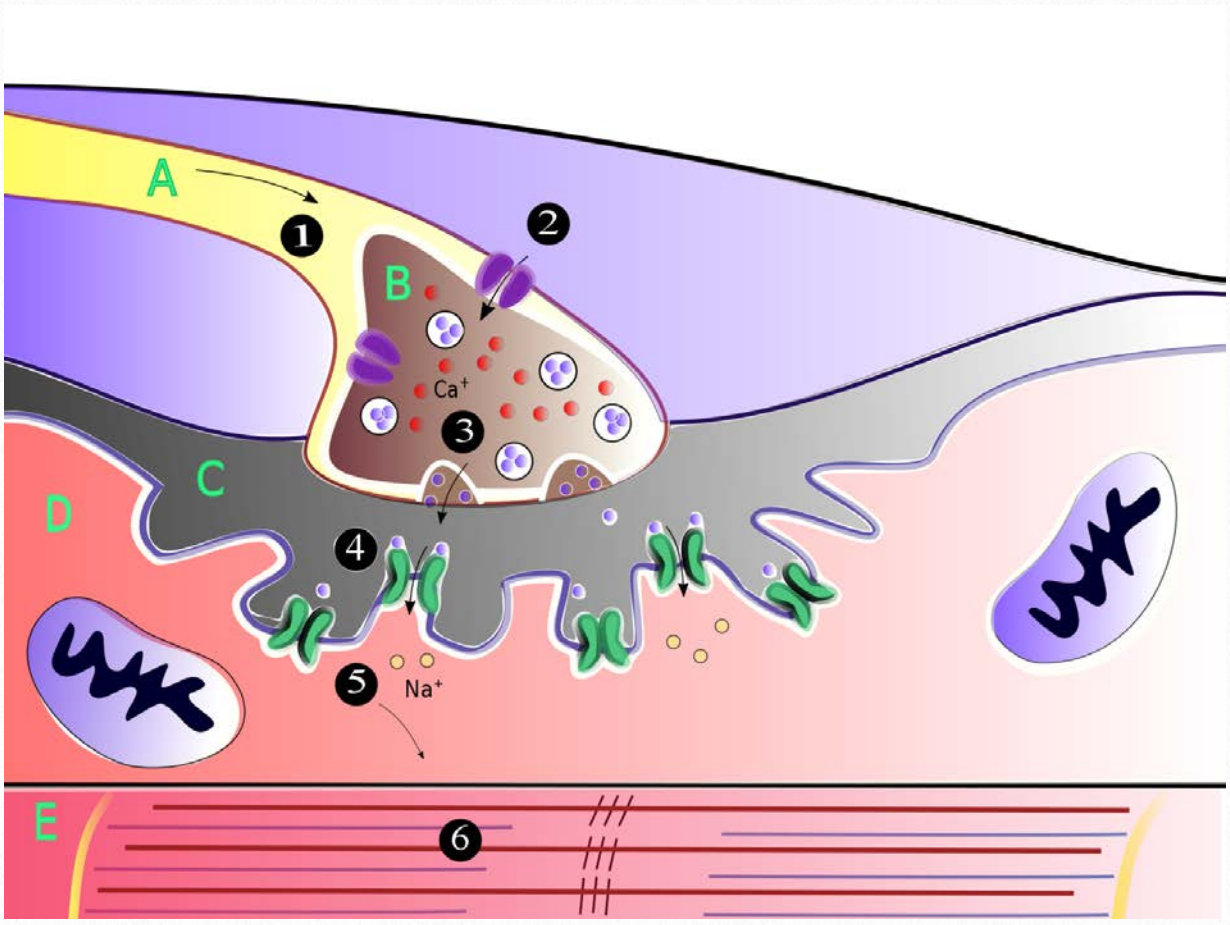

Figure 7.133 - Neuromuscular signaling - A = motor neuron axon; B = axon terminal; C = synaptic cleft; D = muscle cell; E = myofibril . Steps in the process - 1) action potential reaches the axon terminal; 2) voltage-dependent calcium gates open; (3) neurotransmitter vesicles fuse with the presynaptic membrane and acetylcholine (ACh) released into the synaptic cleft; (4) ACh binds to postsynaptic receptors on the sarcolemma; (5) ACh binding causes ion channels to open and allows sodium ions to flow across the membrane into the muscle cell; 6) flow of sodium ions across the membrane into the muscle cell generates action potential which travels to the myofibril and results in muscle contraction.

Wikipedia

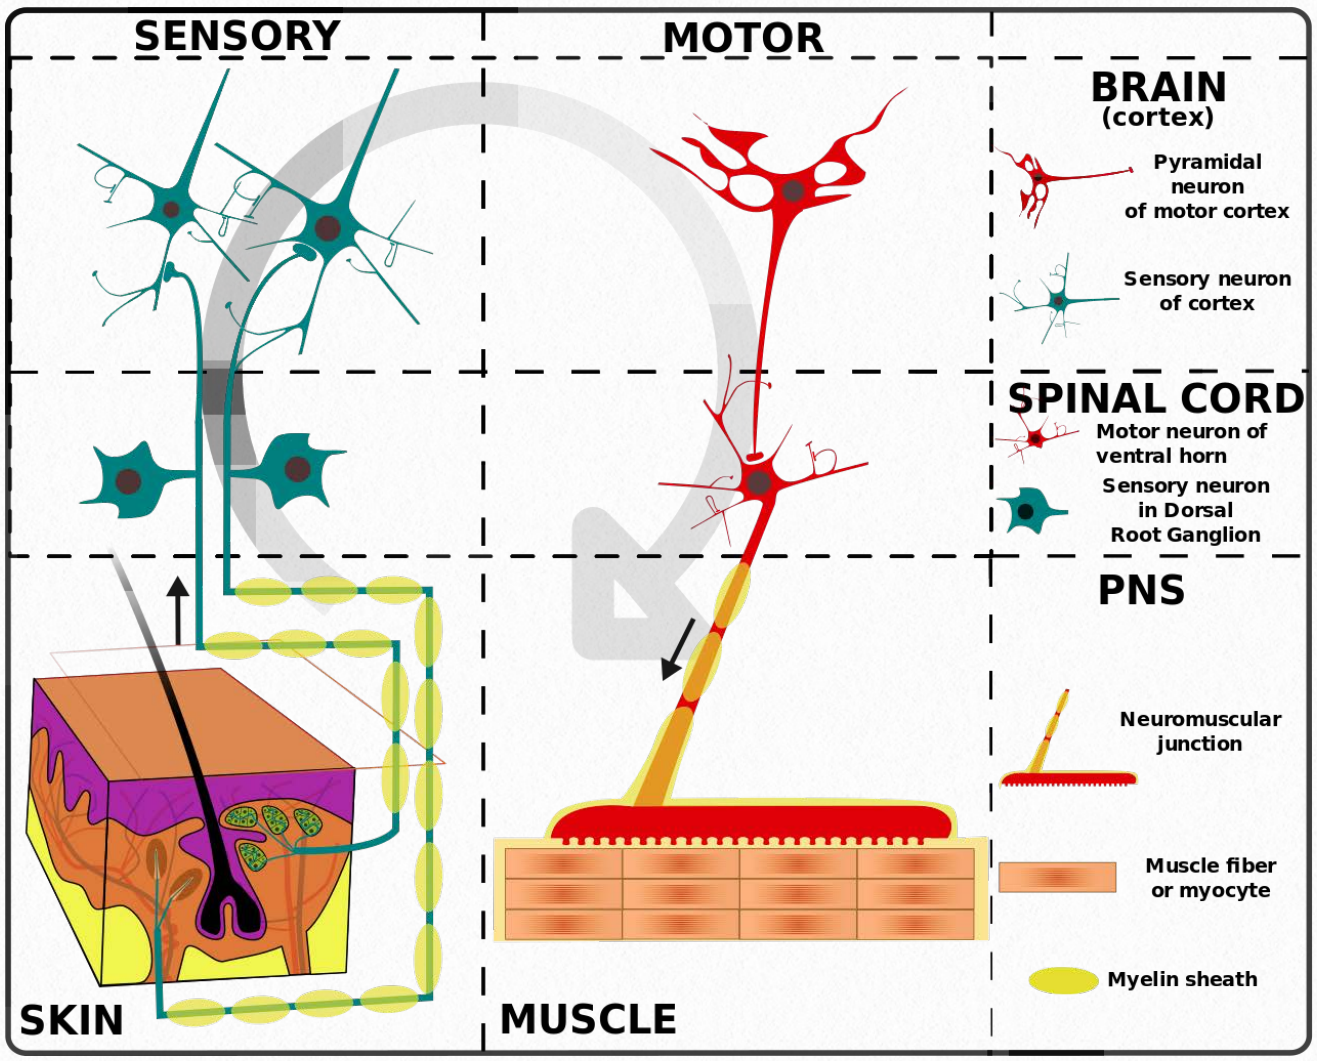

Figure 7.134 - Nerve systems

Wikipedia

of the cell are thus brought about in microseconds and in a single step.

Swift response

This type of swift response is seen, for example, in neuromuscular junctions, where muscle cells respond to a message from the neighboring nerve cell (Figure 7.133). The nerve cell releases a neurotransmitter signal into the synaptic cleft, which is the space between the nerve cell and the muscle cell it is "talking to". An example of such a neurotransmitter signal is acetylcholine. When the acetylcholine molecules are released into the synaptic cleft, they diffuse rapidly till they reach their receptors on the membrane of the muscle cell. The binding of the acetylcholine to its receptor, an ion channel on the membrane of the muscle cell, causes the gate in the ion channel to open. The resulting ion flow through the channel can immediately change the membrane potential of the cell. This, in turn, can trigger other changes in the cell.

The speed with which changes are brought about in neurotransmitter signaling is evident when you think about how quickly you remove your hand from a hot surface. Sensory neurons carry information to the brain from your hand on the hot surface and motor neurons signal to your muscles to move the hand, in less time than it took you to read this sentence!

Nuclear hormone receptors

The receptors for signals like steroid hormones are part of a large group of proteins known as the nuclear hormone receptor superfamily. These receptors recognize and bind not only steroid hormones, but also reti-

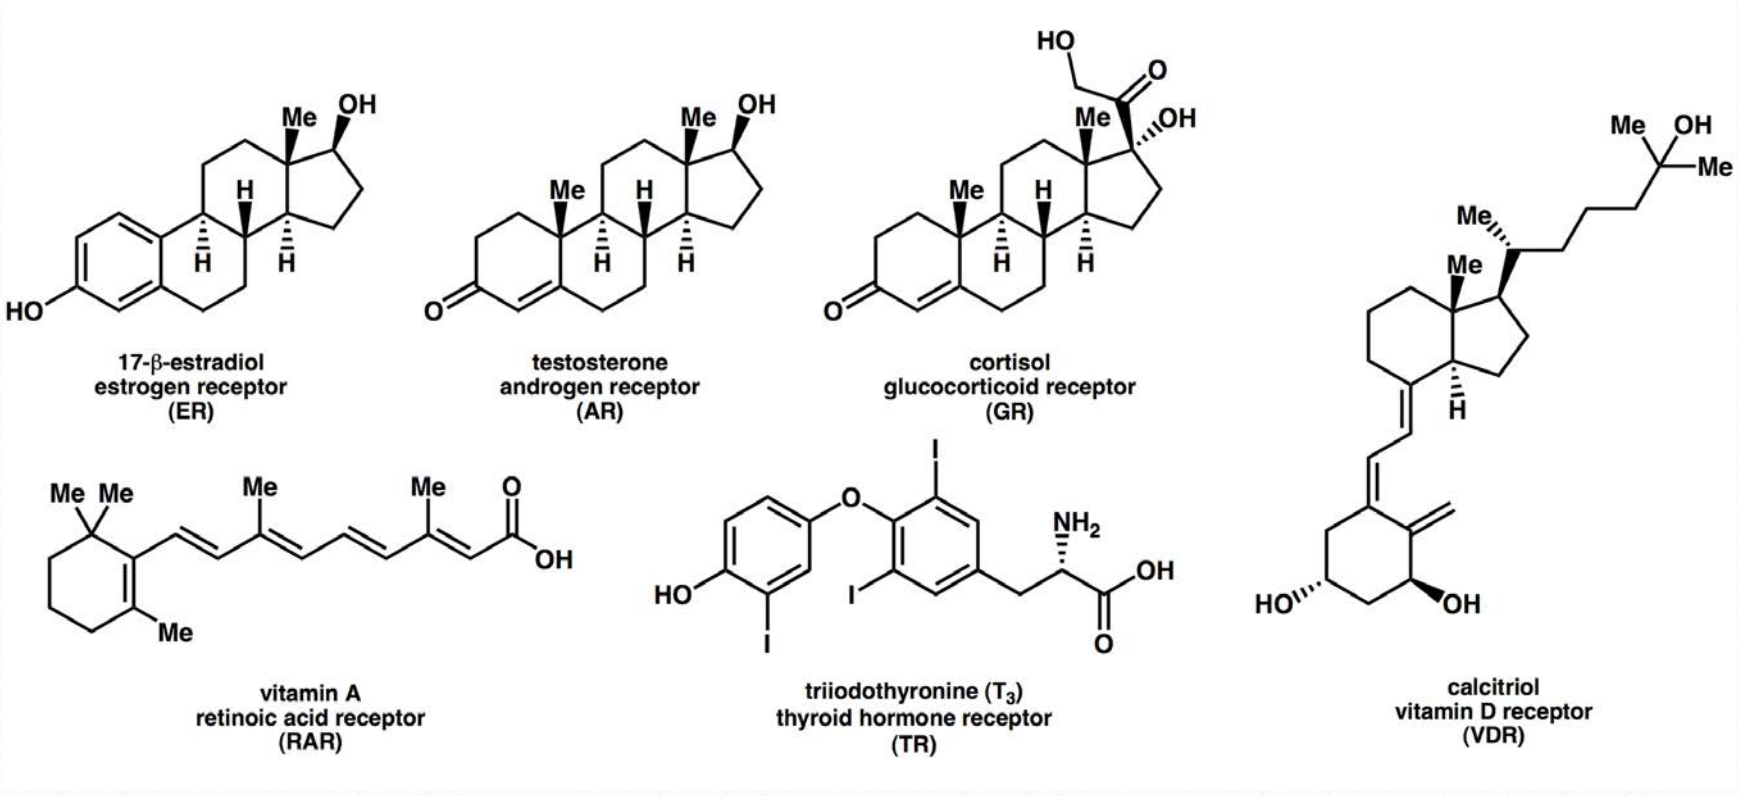

Figure 7.135 - Steroid hormones structures, with the names of their receptors

Wikipedia

noic acid, thyroid hormone, vitamin D and other signals. The subset of the nuclear hormone receptors that bind steroid hormones are intracellular proteins. Steroid hormones (Figure 7.135), as you are aware, are related to cholesterol, and as hydrophobic molecules, they are able to cross the cell membrane by themselves. This is unusual, as most signals coming to cells are incapable of crossing the plasma membrane, and thus, must have cell surface receptors.

Once within the cell, steroid hormones bind to their receptors, which may reside in the cytoplasm or in the nucleus. Steroid hormone receptors are proteins with a double life: they are actually dormant transcription regulators that are inactive till a steroid hormone binds and causes a conformational change in them. When this happens, the receptors, with the hormone bound, bind to regulatory sequences in the DNA and modulate gene expression. Because steroid hormone receptors act by modulating gene expression, the responses to steroid hormones are relatively slow. (There are also some effects of steroid hormones that do not involve transcriptional regulation, but the majority work through changing gene expression.) Like other transcriptional activators, steroid receptors have a DNA-binding domain (DBD) and an activation domain. They also have a ligand-binding domain (LBD) that binds the hormone.

Glucocorticoid receptor

Examples of such signaling path-

Wikipedia

ways are those mediated by the glucocorticoid receptor (Figures 7.136 & 7.137). Glucocorticoids, sometimes described as stress hormones, are made and secreted by the adrenal cortex. Physiologically, they serve to maintain homeostasis in the face of stress and exhibit strong anti-inflammatory and immunosuppressive properties. Because of these effects, synthetic glucocorticoids are used in the treatment of a number of diseases from asthma and rheuma-

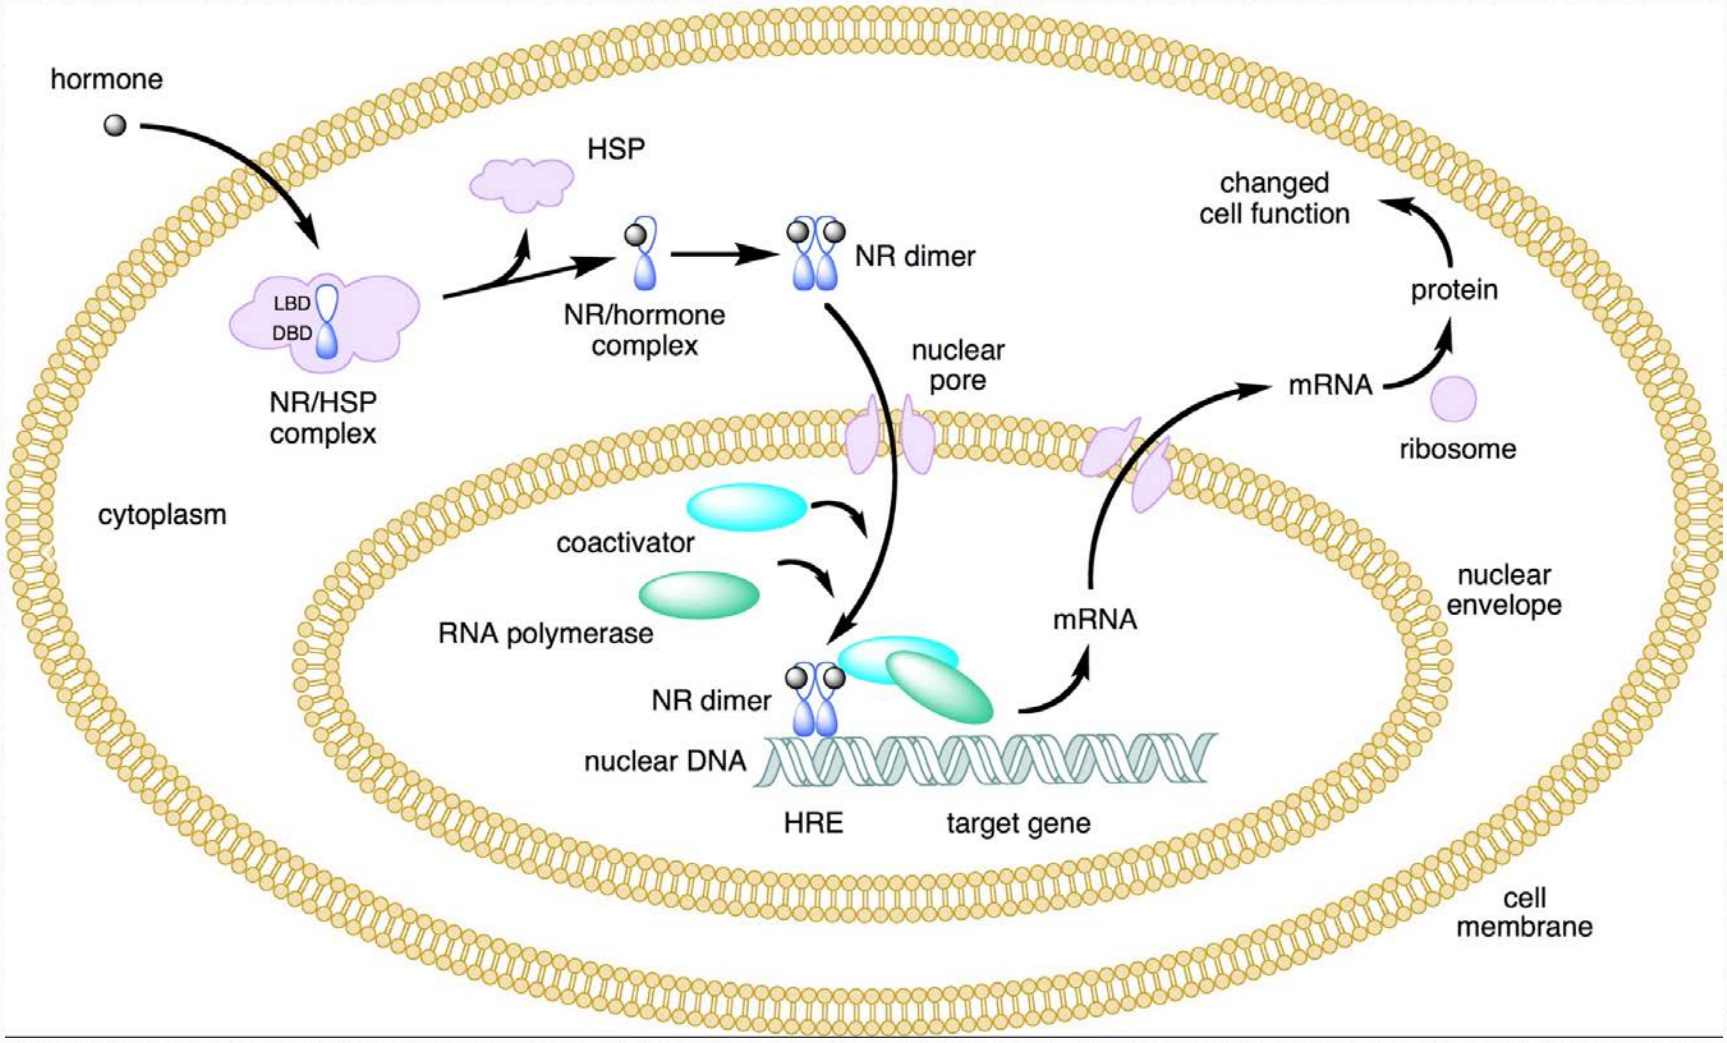

Figure 7.137 - Glucocorticoid signaling pathway

Wikipedia

toid arthritis to multiple sclerosis. All of these effects are mediated through the signaling pathway which starts with the binding of a glucocorticoid hormone to its receptor. Recall that steroids can cross the plasma membrane, so glucocorticoids can diffuse into the cell and bind their receptors which are in the cytoplasm.

In the absence of the signal, glucocorticoid receptors are found bound to a protein chaperone, Hsp90 (Figure 7.137). This keeps the receptors from being transported to the nucleus. When a glucocorticoid molecule binds the receptor, the receptor undergoes a conformational change and dissociates from the Hsp90. The receptor, then, with the hormone bound, translocates into the nucleus. In the nucleus, it can increase the transcription of target genes by binding to specific regulatory sequences (labeled HRE for hormone-response elements). The binding of the hormone-receptor complex to the regulatory elements of hormone-responsive genes modulates their expression. Many of these genes encode anti-inflammatory proteins, and their increased production accounts for the physiological effect of corticosteroid therapies.

The steroid receptor pathways are relatively simple and have only a couple of steps (Figure 7.138). Most other signaling pathways involve multiple steps in which the original signal is passed on and amplified through

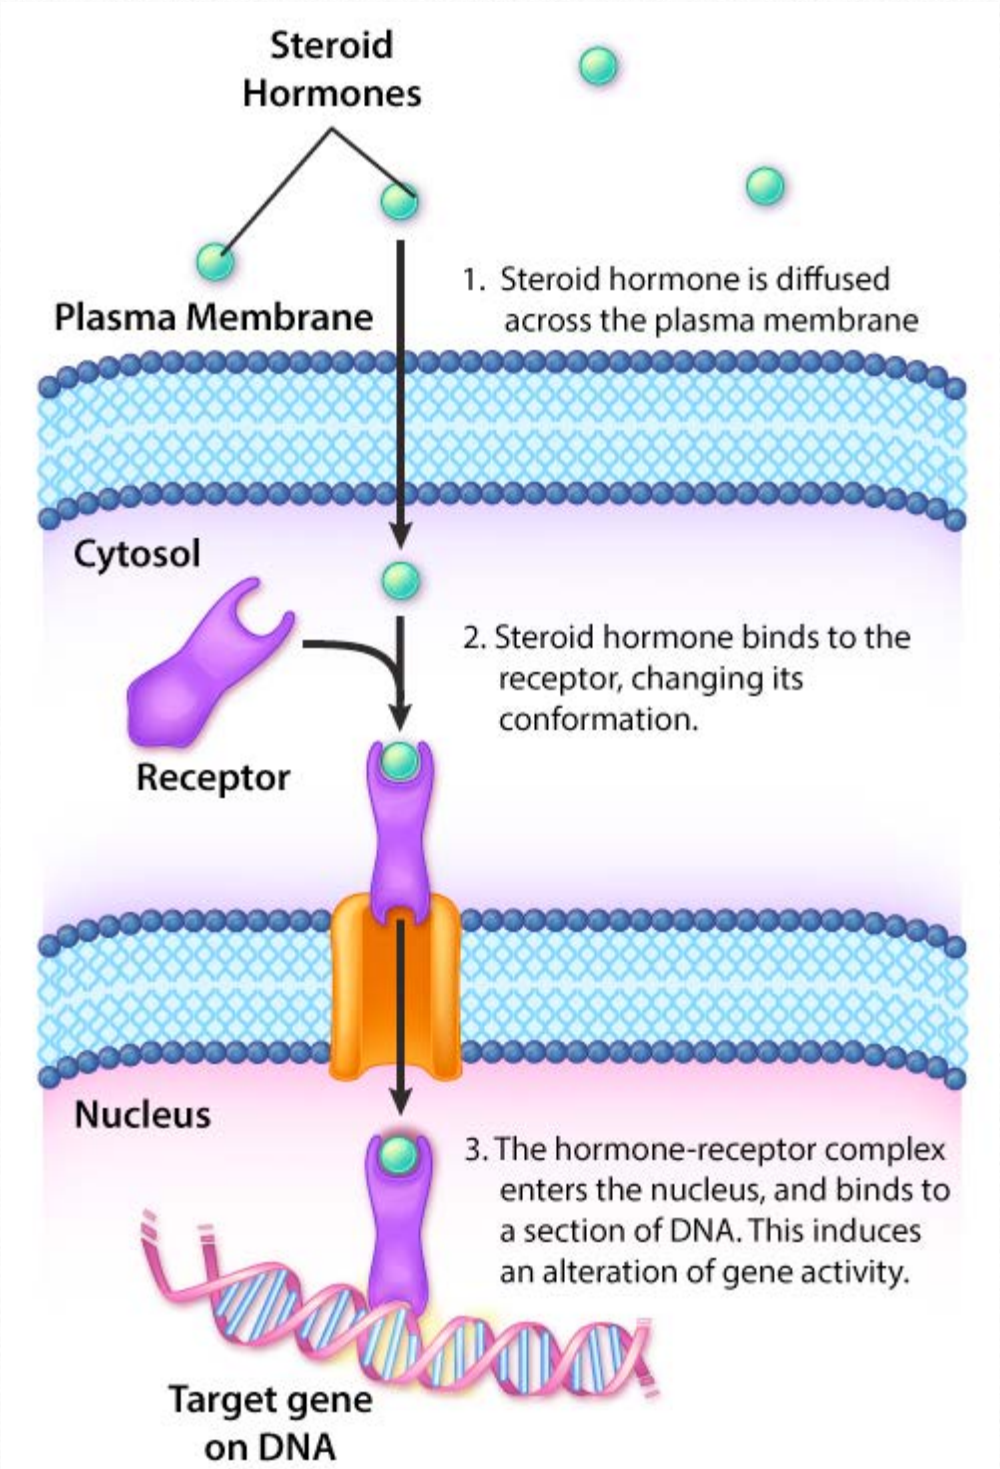

Figure 7.138 - Steroid hormone signaling

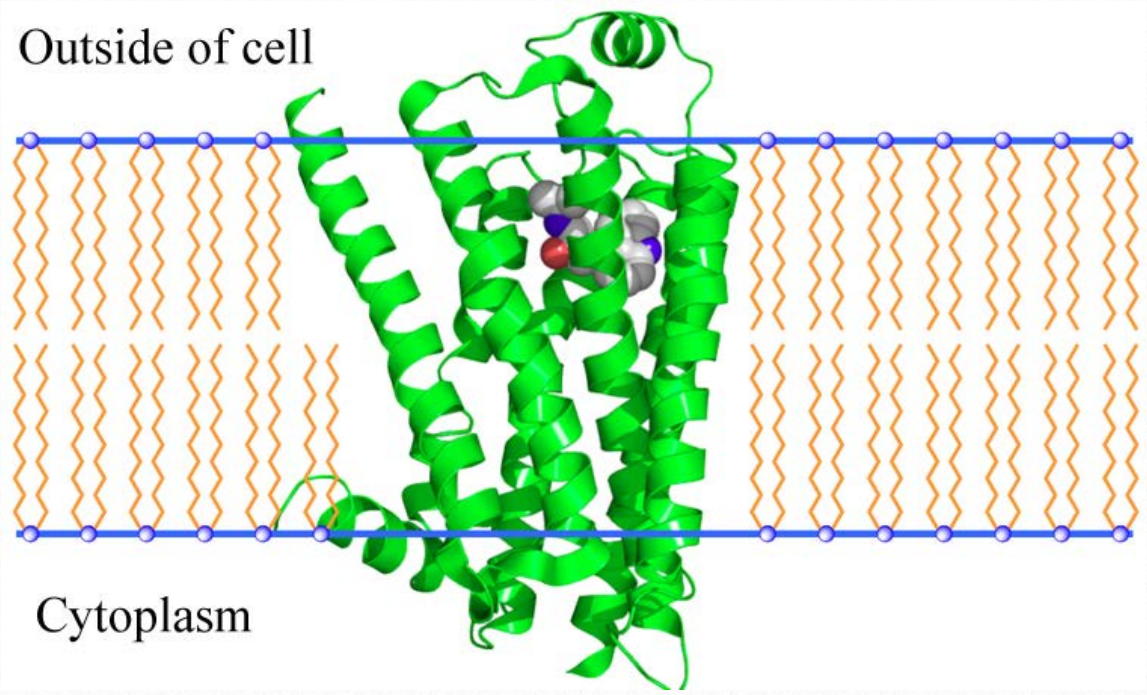

Figure 7.139 - Structure of a G-protein linked receptor
Wikipedia

a number of intermediate steps, before the cell responds to the signal.

Cell surface receptors

We will now take a look at two signaling pathways, each mediated by a major class of cell surface receptor- the G-protein coupled receptors (GPCRs) and the receptor tyrosine kinases (RTKs). While the specific details of the signaling pathways that follow the binding of signals to each of these receptor types are different, it is easier to learn them when you can see what the pathways have in common, namely, interaction of the signal with a receptor, followed by relaying and amplification of the signal through a variable number of intermediate molecules, with the last of these molecules interacting with a target or target proteins and modifying their activity in the cell.

G-protein coupled receptors

G-protein coupled receptors (GPCRs) are involved in responses of cells to many different kinds of signals, from epinephrine, to odors, to light. In fact, a variety of physiological phenomena including vision, taste, smell, and the fight-or-flight response are mediated by GPCRs. What are G-protein coupled receptors?

G-protein coupled receptors are cell surface receptors that pass on the signals that they receive with the help of guanine nucleotide binding proteins (a.k.a. G-proteins). Before thinking any further about the signaling pathways downstream of GPCRs, it is necessary to know a few important facts about these receptors and the G-proteins that assist them.

GPCR structure

Though there are hundreds of different G-protein coupled receptors, they all have the same basic structure (Figure 7.139):

They all consist of a single polypeptide chain that threads back and forth seven times through the lipid bilayer of the plasma membrane. For this reason, they are sometimes called seven-pass transmembrane

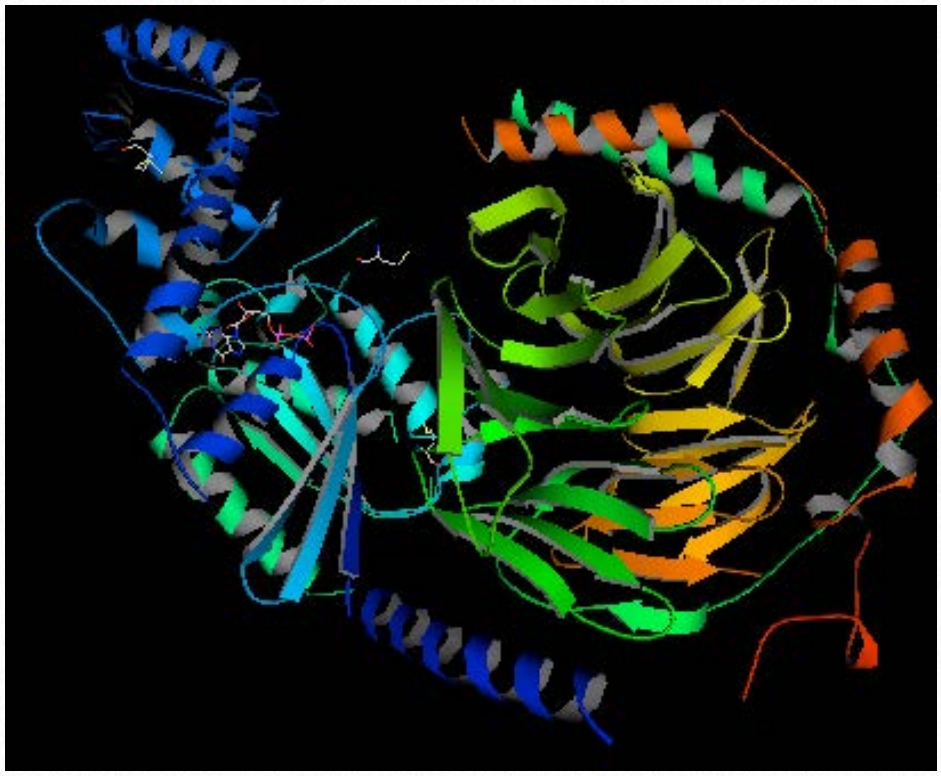

Figure 7.140- A heterotrimeric G-protein: α subunit in blue, βγ subunits red and green

(7TM) receptors. One end of the polypeptide forms the extracellular domain that binds the signal while the other end is in the cytosol of the cell.

When a ligand (signal) binds the extracellular domain of a GPCR, the receptor undergoes a conformational change, on its cytoplasmic side, that allows it to interact with a G-protein that will then pass the signal on to other intermediates in the signaling pathway.

G-proteins

What is a G-protein? As noted above, a G-protein is a guanine nucleotide-binding protein that can interact with a G-protein linked receptor. G-proteins are associated with the cytosolic side of the plasma membrane, where they are ideally situated to interact with the tail of the GPCR, when a signal binds to the GPCR. There are many different G-proteins, all of which share a characteristic structure- they are composed of three subunits called α, β and γ (Figure 7.140). Because of this, they are sometimes called heterotrimeric G proteins (hetero=different, trimeric= having three parts).

Ligand binding

The guanine nucleotide binding site is on the α subunit of the G-protein. This site can bind GDP or GTP. The α subunit also has a GTPase activity, i.e., it is capable of hydrolyzing a GTP molecule bound to it into GDP.

In the unstimulated state of the cell, that is, in the absence of a signal bound to the GPCR, the G-proteins are found in the trimeric form (α-β-γ bound together) and the α subunit has a GDP molecule bound to it. In this form, the α subunit is inactive. With this background on the structure and general properties of the GPCRs and the G-proteins, we can now look at what happens when a signal arrives at the cell surface and binds to a GPCR (Figure 7.141).

Wikipedia

tor causes the cytosolic tail of the receptor to interact with, and alter the conformation of, a G-protein associated with the inner face of the plasma membrane.

This has two consequences. First, the α subunit of the G-protein loses its GDP and binds a GTP, instead. Second, the G-protein breaks up into the GTP-bound α part and the β-γ part.

YouTube Lectures by Kevin HERE & HERE

The binding of GTP to the α subunit and its dissociation from the β-γ subunits activate the α subunit. The activated α subunit can diffuse freely along the cytosolic face

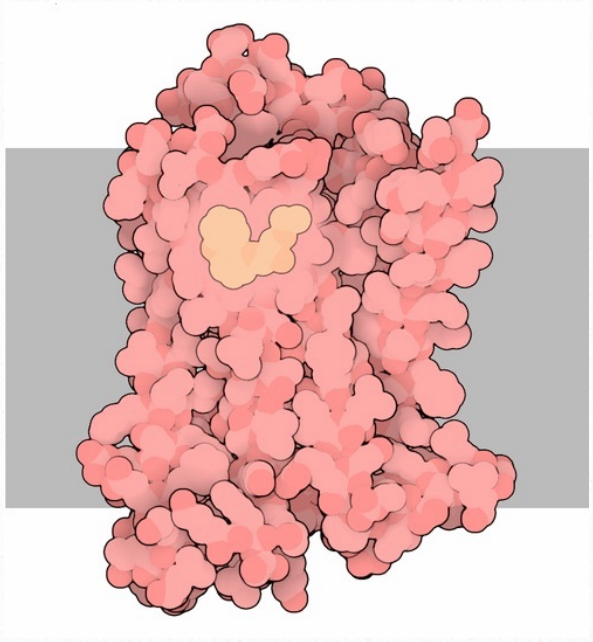

Figure 7.142 - β_2-adrenergic receptor embedded in membrane (gray)

Wikipedia

of the plasma membrane and act upon its targets. (The β-γ unit is also capable of activating its own targets.)

What happens when G-proteins interact with their target proteins? That depends on what the target is. G-proteins interact with different kinds of target proteins, of which we will examine two major categories:

Ion channels

We have earlier seen that some gated ion channels can be opened or closed by the direct binding of neurotransmitters to a receptor that is an ion-channel protein. In other cases, ion channels are regulated by the binding of G-proteins. That is, instead of the signal directly binding to the ion channel, it binds to a GPCR, which activates a G-protein that then may cause opening of the ion channel, either directly, by binding to the channel, or indirectly, through activating other proteins that can bind to the channel. The change in the distribution of ions across the plasma membrane causes a change in the membrane potential.

Enzyme activation

The interaction of G-proteins with their target enzymes can regulate the activity of the enzyme, either increasing or decreasing its activity. The change in activity of the target enzyme, in turn, results in downstream changes in other proteins in the cell, and alters the metabolic state of the cell. This is best understood by examining the well-studied response of cells to epinephrine, mediated through the β-adrenergic receptor, a type of G-protein coupled receptor.

Epinephrine (Figure 7.142), also known as adrenaline, is a catecholamine that plays an important role in the body's 'fight or flight' response. In response to stressful stimuli, epinephrine is secreted into the blood, to be carried to target organs whose cells will respond

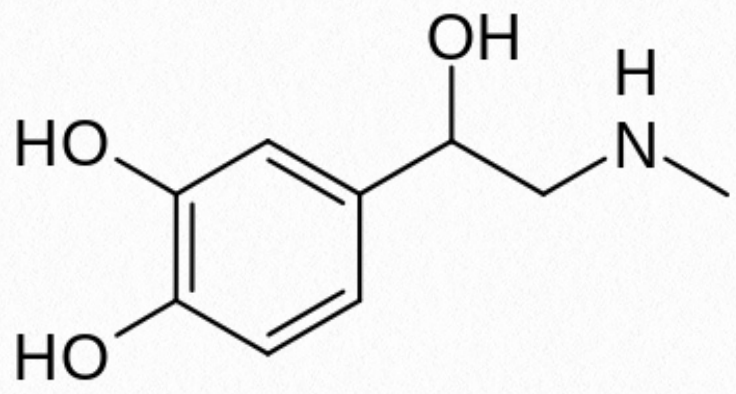

Figure 7.143 - Epinephrine

Wikipedia

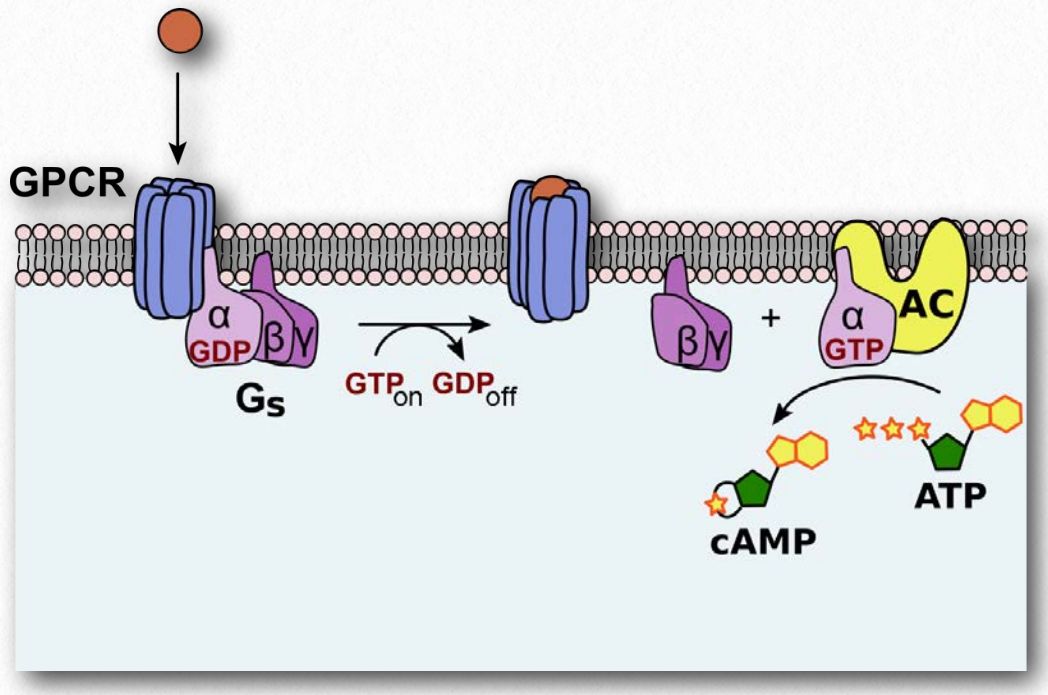

Figure 7.144 - G-protein coupled receptor. Signal starts with ligand binding (orange circle). G_s = G-protein; AC = adenylate cyclase.

Wikipedia

to this signal. If you were walking down a dark alley in an iffy neighborhood, and you heard footsteps behind you, your brain would respond to potential danger by sending signals that ultimately cause the adrenal cortex to secrete epinephrine into the blood stream. The epinephrine circulating in your system has many effects, including increasing your heart rate, but among its prime targets are your muscle cells. The reason for this is that your muscle cells store energy in the form of glycogen, a polymer of glucose. If you need to run or fight off an assailant, your cells will need energy in the form of glucose.

But how does epinephrine get your cells to break down the glycogen into glucose? Binding of epinephrine to the β-adrenergic receptor on the surface of the cells causes the receptor to activate a G-protein associated with its cytoplasmic tail. As described above, this leads to the α subunit exchanging its GDP for GTP and dissociating from the β-γ subunits. The activated α subunit then interacts with the enzyme adenylate cyclase (also known as adenylyl cyclase) stimulating it to produce cyclic AMP (cAMP) from ATP. Cyclic AMP is often described as a "second messenger", in that it serves to spread the

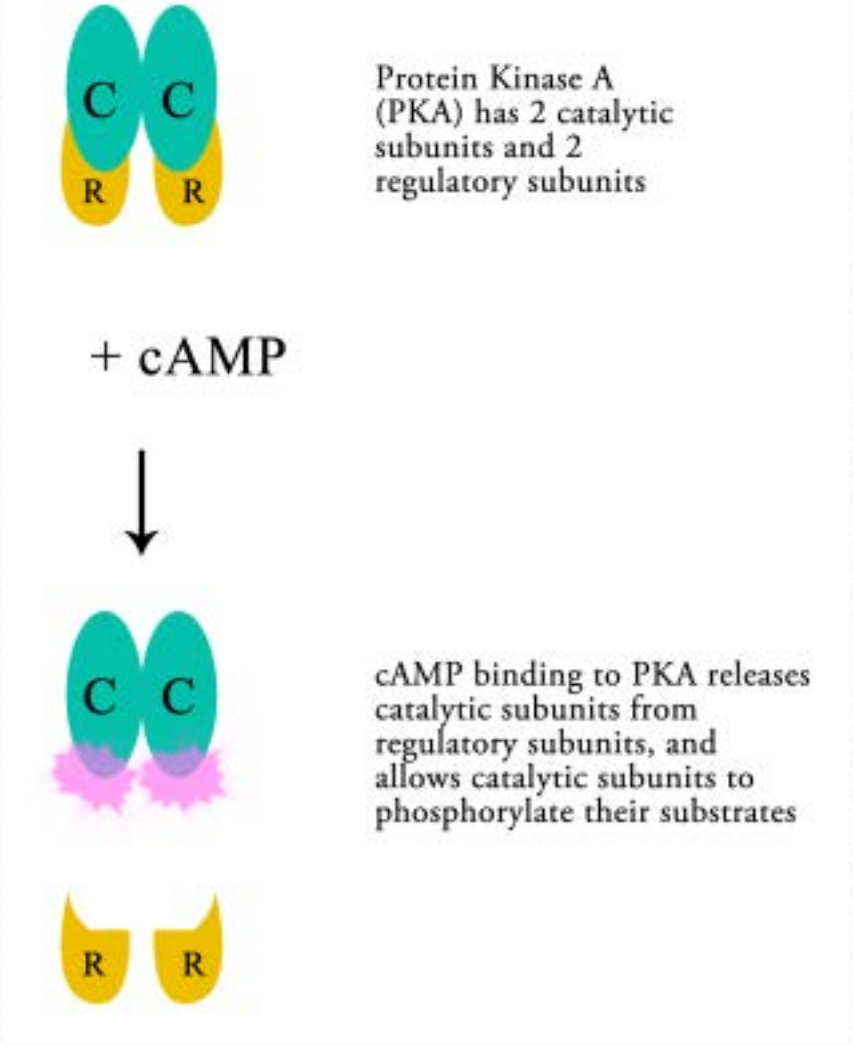

Figure 7.145 - Activation of Protein Kinase A by cAMP

Image by Martha Baker

signal received by the cell. How does cAMP accomplish this?

cAMP molecules bind to, and activate an enzyme, protein kinase A (PKA - Figure 7.145). PKA is composed of two catalytic and two regulatory subunits that are bound tightly together. Upon binding of cAMP, the catalytic subunits are released from the regulatory subunits, allowing the enzyme to carry out its function, namely phosphorylating other proteins. Thus, cAMP can regulate the activity of PKA, which in turn, by phosphorylating other proteins can change their activity. In this case, the relevant protein that is activated is an enzyme, phosphorylase kinase. This enzyme can then phosphorylate and activate glycogen phosphorylase, the enzyme ultimately responsible for breaking glycogen down into glucose-1-phosphate - readily converted to glucose. The activation of glycogen phosphorylase supplies the cells with the glucose they need, allowing you to fight or flee, as you might see fit. Simultaneously, PKA also phosphorylates another enzyme, glycogen synthase. In the case of glycogen synthase, phosphorylation inactivates it, and prevents free glucose from being used up for glycogen synthesis, ensuring that your cells are amply supplied with glucose (Figure 7.146).

Common pattern

Although the steps described above seem complicated, they follow the simple pattern outlined at the beginning of this section:

• Binding of signal to receptor

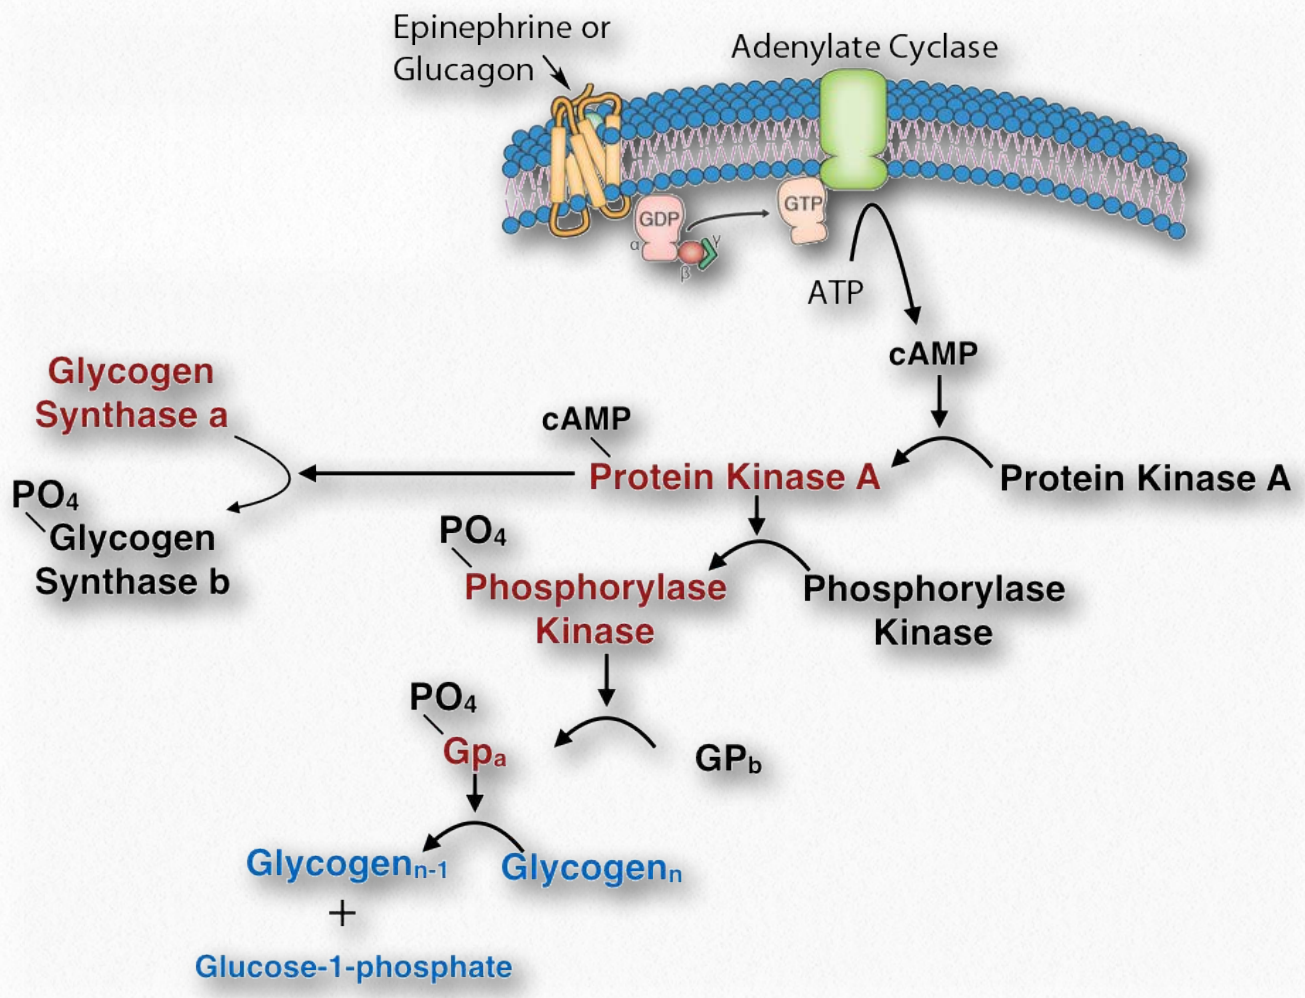

Figure 7.146 - Simultaneous activation of glycogen breakdown and inhibition of glycogen synthesis by epinephrine's binding of b-adrenergic receptor. Red enzyme names = activated forms; black enzyme names = inactivated forms; GPb = glycogen phosphorylase b; GPa = glycogen phosphorylase a.

Image by Penelope Irving

• Several steps where the signal is passed on through intermediate molecules (G-proteins, adenylate cyclase, cAMP, and finally, PKA)
• Phosphorylation of target proteins by the kinase, leading to changes in the cell. The specific changes depend on the proteins that are phosphorylated by the PKA.

Why so many steps? If you need to activate glycogen phosphorylase to break down glucose in a hurry, why not have a system in which binding of a signal to the receptor directly activated the target enzyme?

The answer to this puzzle is simple: there is amplification of the signal at every step of the pathway. A single signal molecule binding to a receptor sets in motion a cascade of reactions, with the signal getting larger at each step, so that binding of one epinephrine molecule to its receptor results in the activation of a million glycogen phosphorylase enzyme molecules!

Turning signals off

If the signal binding to the receptor serves as a switch that sets these events in motion, there must be mechanisms to turn the pathway off. The first is at the level of the receptor itself. A kinase called G-protein receptor kinase (GRK) phosphorylates the cytoplasmic tail of the receptor. The phosphorylated tail is then bound by a protein called arrestin, preventing further interaction with a G-protein.

The next point of control is at the G-protein. Recall that the α subunit of the G-protein is in its free and activated state when it has GTP bound, and that it associates with the β-γ subunits and has a GDP bound when it is inactive. We also

β-Adrenergic Signaling On Switches

1. Binding of Signal Molecule to Receptor
2. Passage of Signal Through Several Molecules (G-proteins, Adenylate Cyclase, cAMP, PKA)

3. cAMP Hydrolyzed by Phosphodiesterase
   PKA Becomes Inactive
4. Dephosphorylation of Phosphorylated Proteins by Phosphoprotein Phosphatase

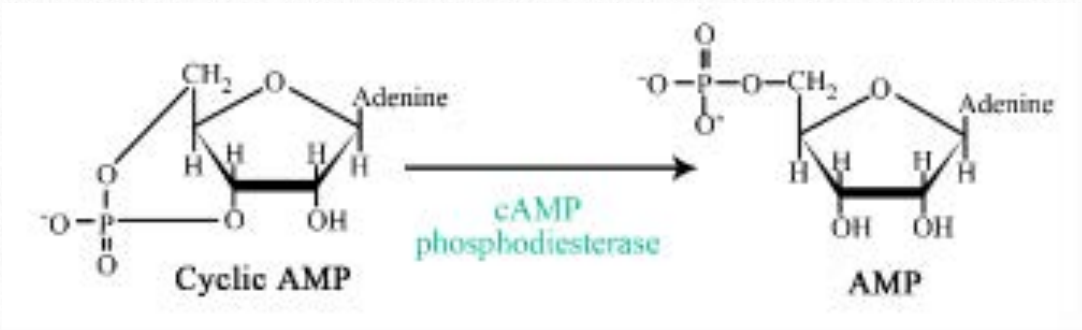

Figure 7.147 - Cyclic AMP is broken down by phosphodiesterase

know that the α subunit has an activity that enables it to hydrolyze GTP to GDP. This GTP-hydrolyzing activity makes it possible for the α subunit, once it has completed its task, to return to its GDP bound state, re-associate with the β-γ part and become inactive again.

A third "off switch" is further down the signaling pathway, and controls the level of cAMP. We just noted that cAMP levels increase when adenylate cyclase is activated. When its job is done, cAMP is broken down by an enzyme called phosphodiesterase (Figure 7.147). When cAMP levels drop, PKA returns to its inactive state, putting a halt to the changes brought about by the activation of adenylate cyclase by an activated G-protein.

Yet another way that the effects of this pathway can be turned off is at the level of the phosphorylated target proteins. These proteins, which are activated by phosphorylation, can be returned to their inactive state by the removal of the phosphates by phosphatases.

YouTube Lectures by Kevin

Receptor tyrosine kinases

Another major class of cell surface receptors are the receptor tyrosine kinases or RTKs. Like the GPCRs, receptor tyrosine kinases bind a signal, then pass the message on through a series of intracellular molecules, the last of which acts on target proteins to change the state of the cell.

As the name suggests, a receptor tyrosine kinase is a cell surface receptor that also has a tyrosine kinase activity. The signal binding domain of the receptor tyrosine kinase is on the cell surface, while the tyrosine kinase enzymatic activity resides in the cytoplasmic part of the protein (Figure 7.148). A transmembrane α helix connects these two regions of the receptor.

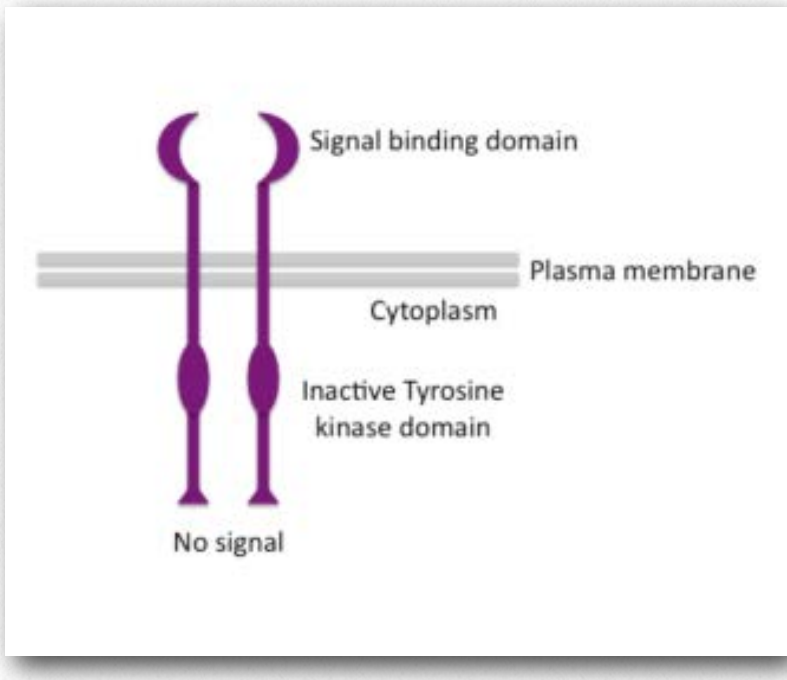

Figure 7.148 - Structure of a receptor tyrosine kinase

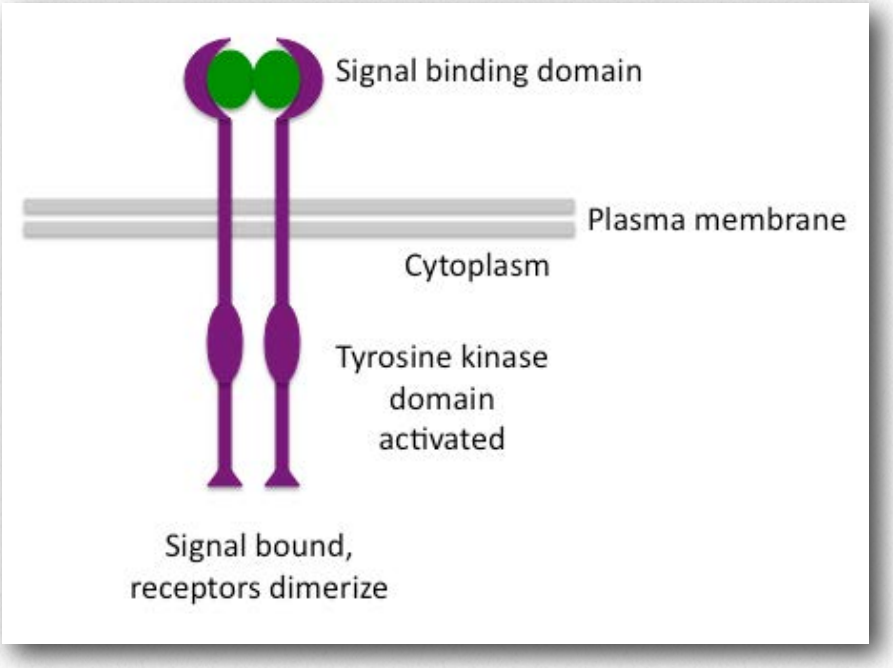

Figure 7.149 - Signal binding results in receptor dimerization and activation of tyrosine kinase activity

What happens when signal molecules bind to receptor tyrosine kinases? Binding of signal molecules to the extracellular domains of receptor tyrosine kinase proteins causes two receptor molecules to dimerize (come together and associate - Figure 7.149). This brings the cytoplasmic tails of the receptors close to each other and causes the tyrosine kinase activity of these tails to be turned on. The activated tails then phosphorylate each other on several tyrosine residues (Figure 7.150). This is called autophosphorylation.

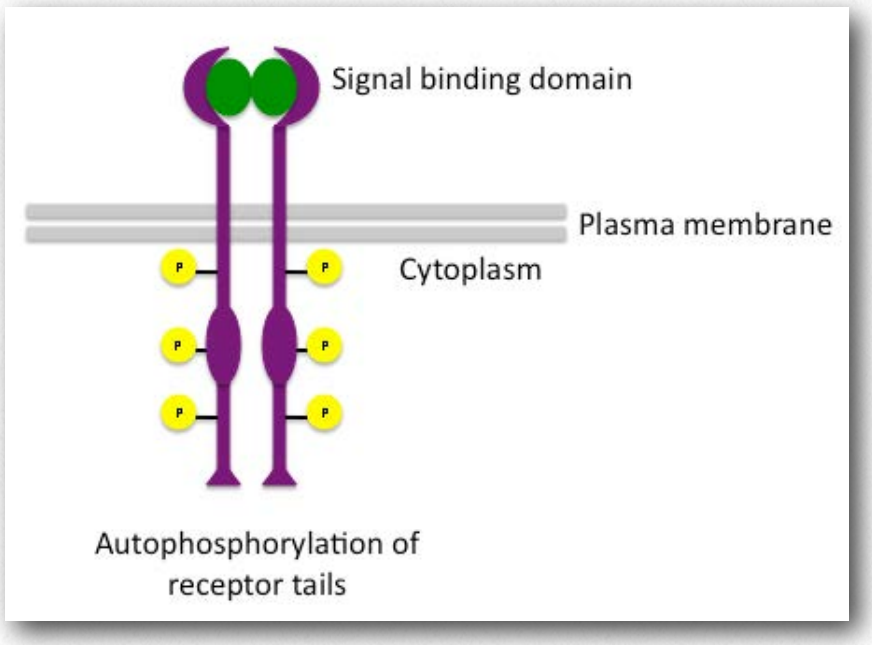

Figure 7.150 - Activated tyrosine kinases phosphorylate tyrosines on the receptor tails.

The phosphorylation of tyrosines on the receptor tails triggers the assembly of an intracellular signaling complex on the tails. The newly phosphorylated tyrosines serve as binding sites for a variety of signaling proteins that then pass the message on to yet other proteins to bring about changes in the cell. Receptor tyrosine kinases mediate responses to a large number of signals, including peptide hormones like insulin and growth factors like epidermal growth factor (EGF). We will examine how insulin

Wikipedia

and EGF act on cells by binding to receptor tyrosine kinases.

Insulin receptor

Insulin plays a central role in the uptake of glucose from the bloodstream. It increases glucose uptake by stimulating the movement of glucose receptor GLUT4 to the plasma membrane of cells.

How does insulin increase GLUT4 concentrations in the cell membrane? The binding of insulin to the insulin receptor (IR - Figure 7.151), results in dimerization of the receptor monomers and subsequent autophosphorylation of the cytosolic kinase domains. The activated tyrosine kinase domains also phosphorylate intracellular proteins called Insulin Receptor Substrates or IRS proteins. These proteins interact with, and activate another kinase called the PI_3-kinase. PI_3-kinase then catalyzes the formation of the lipid molecule PIP_3, which serves to activate yet another kinase, PDK1, which in turn, activates the Akt group of kinases. It is this group of enzymes that appears to increase the translocation of the GLUT4 to the plasma membrane (Figure 7.152), as cells that lack functional Akts exhibit poor glucose uptake and insulin resistance.

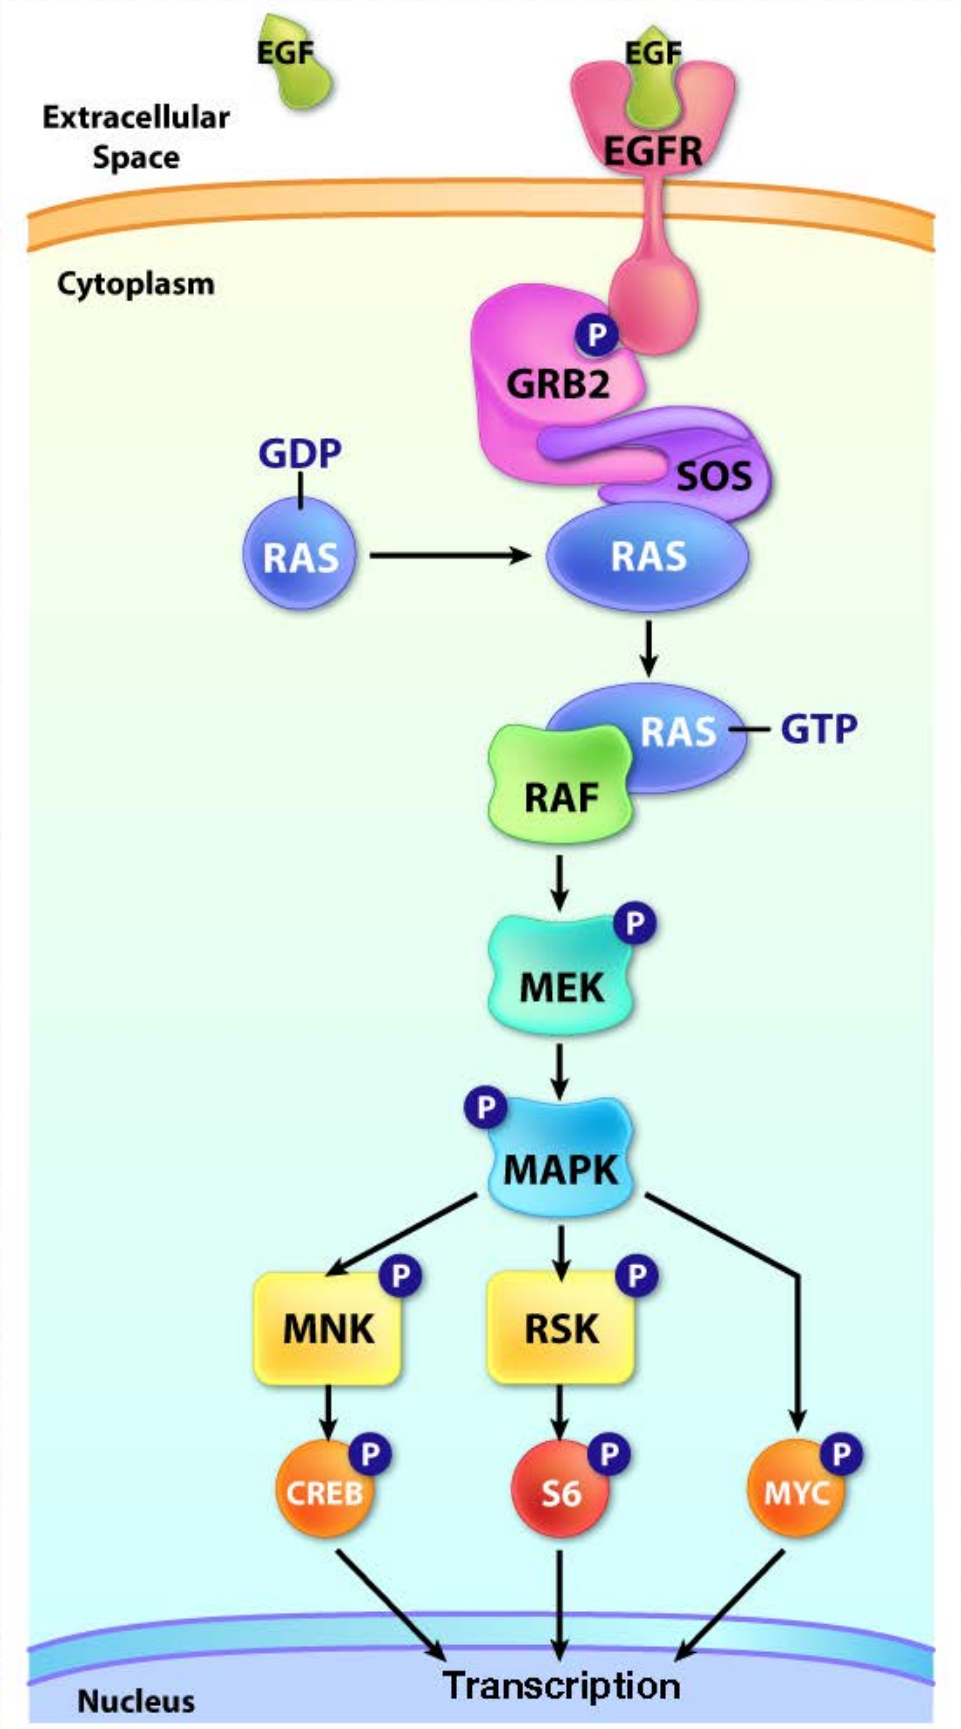

Figure 7.153 - EGFR signaling beginning at top with binding of EGF, dimerization of receptor, transmission of signal through proteins, activation of kinases, phosphorylation of transcription factors and effects on transcription

Image by Aleia Kim

EGFR pathway

Epidermal growth factor, EGF, is an important signaling molecule involved in growth, proliferation and differentiation in mammalian cells. EGF acts through the EGF receptor, EGFR, a receptor tyrosine kinase (Figure 7.153). Because of its role in stimulating cell proliferation and because overexpression of EGFR is associated with some kinds of cancers, EGFR is the target for many anti-cancer therapies. We can trace the signal transduction pathway from the binding of EGF to its receptor to the stimulation of cell division.

EGF binding to the EGFR is followed by receptor dimerization and stimulation of the tyrosine kinase activity of the cytosolic domains of the EGFR. Autophosphorylation of the receptor tails is followed by the assembly of a signaling

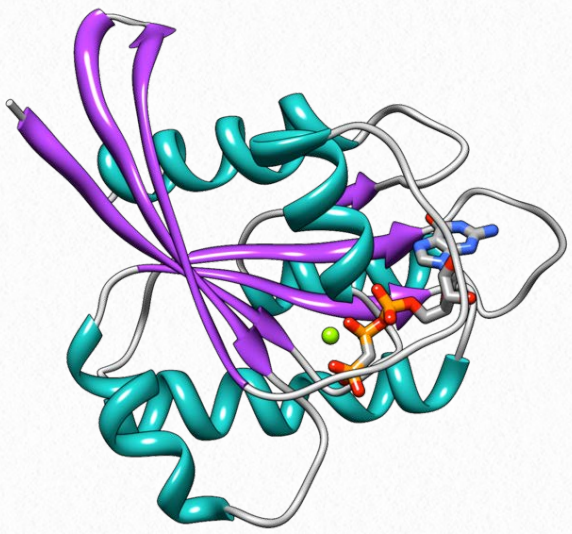

Figure 7.154 - Ras with GTP bound

Wikipedia

complex nucleated by the binding of proteins that recognize phosphotyrosine residues. An important protein that is subsequently activated by the signaling complexes on the receptor tyrosine kinases is called Ras (Figure 7.154). The Ras protein is a monomeric guanine nucleotide binding protein that is associated with the cytosolic face of the plasma membrane (in fact, it is a lot like the α subunit of trimeric G-proteins). Just like the α subunit of a G-protein, Ras is active when GTP is bound to it and inactive when GDP is bound to it. Also, like the α subunit, Ras can hydrolyze the GTP to GDP.

Ras activation

Activation of Ras accompanies the exchange of the GDP bound to the inactive Ras for a GTP. Activated Ras triggers a phosphorylation cascade of three protein kinases, which relay and distribute the signal. These protein kinases are members of a group called the MAP kinases (Mitogen Activated Protein Kinases). The final kinase in this cascade phosphorylates various target proteins, including enzymes and transcriptional activators that regulate gene expression.

YouTube Lectures by Kevin HERE & HERE

RTK Signal Transduction

1. Receptor binding of signal
2. Receptor dimerization
3. Autophosphorylation of cystosolic tails
4. Passing of message to proteins via signaling complex
5. Stimulation of kinase cascade
6. Terminal kinase acts on target proteins

The phosphorylation of various enzymes can alter their activities, and set off new chemical reactions in the cell, while the phosphorylation of transcriptional activators can change which genes are expressed. The combined effect of changes in gene expression and protein activity alter the cell's physiological state and promote cell division.

Once again, in following the path of signal transduction mediated by RTKs, it is possible to discern the same basic pattern of events: a signal is bound by the extracellular domains of receptor tyrosine kinases, resulting in receptor dimerization and autophosphorylation of the cytosolic tails, thus conveying the message to the interior of the cell.

The message is then passed on *via* a signaling complex to proteins that stimulate a series of kinases. The terminal kinase in the cascade acts on target proteins and brings about in changes in protein activities.

What is the OFF switch for RTKs? It turns out that RTKs with the signal bound can be endocytosed into the cell and broken down. That is, the region of the plasma membrane that the RTK is on can be internally pinched off into a vesicle containing the ligand-bound receptor which is then targeted for degradation.

Ras, which is activated by GTP binding, can also be deactivated by hydrolysis of the GTP to GDP. The importance of this mechanism for shutting down the pathway is evident in cells that have a mutant *ras* gene encoding a Ras protein with defective GTPase activity. Unable to shut off Ras, the cells continue to receive a signal to proliferate. The National Cancer Institute estimates that more than

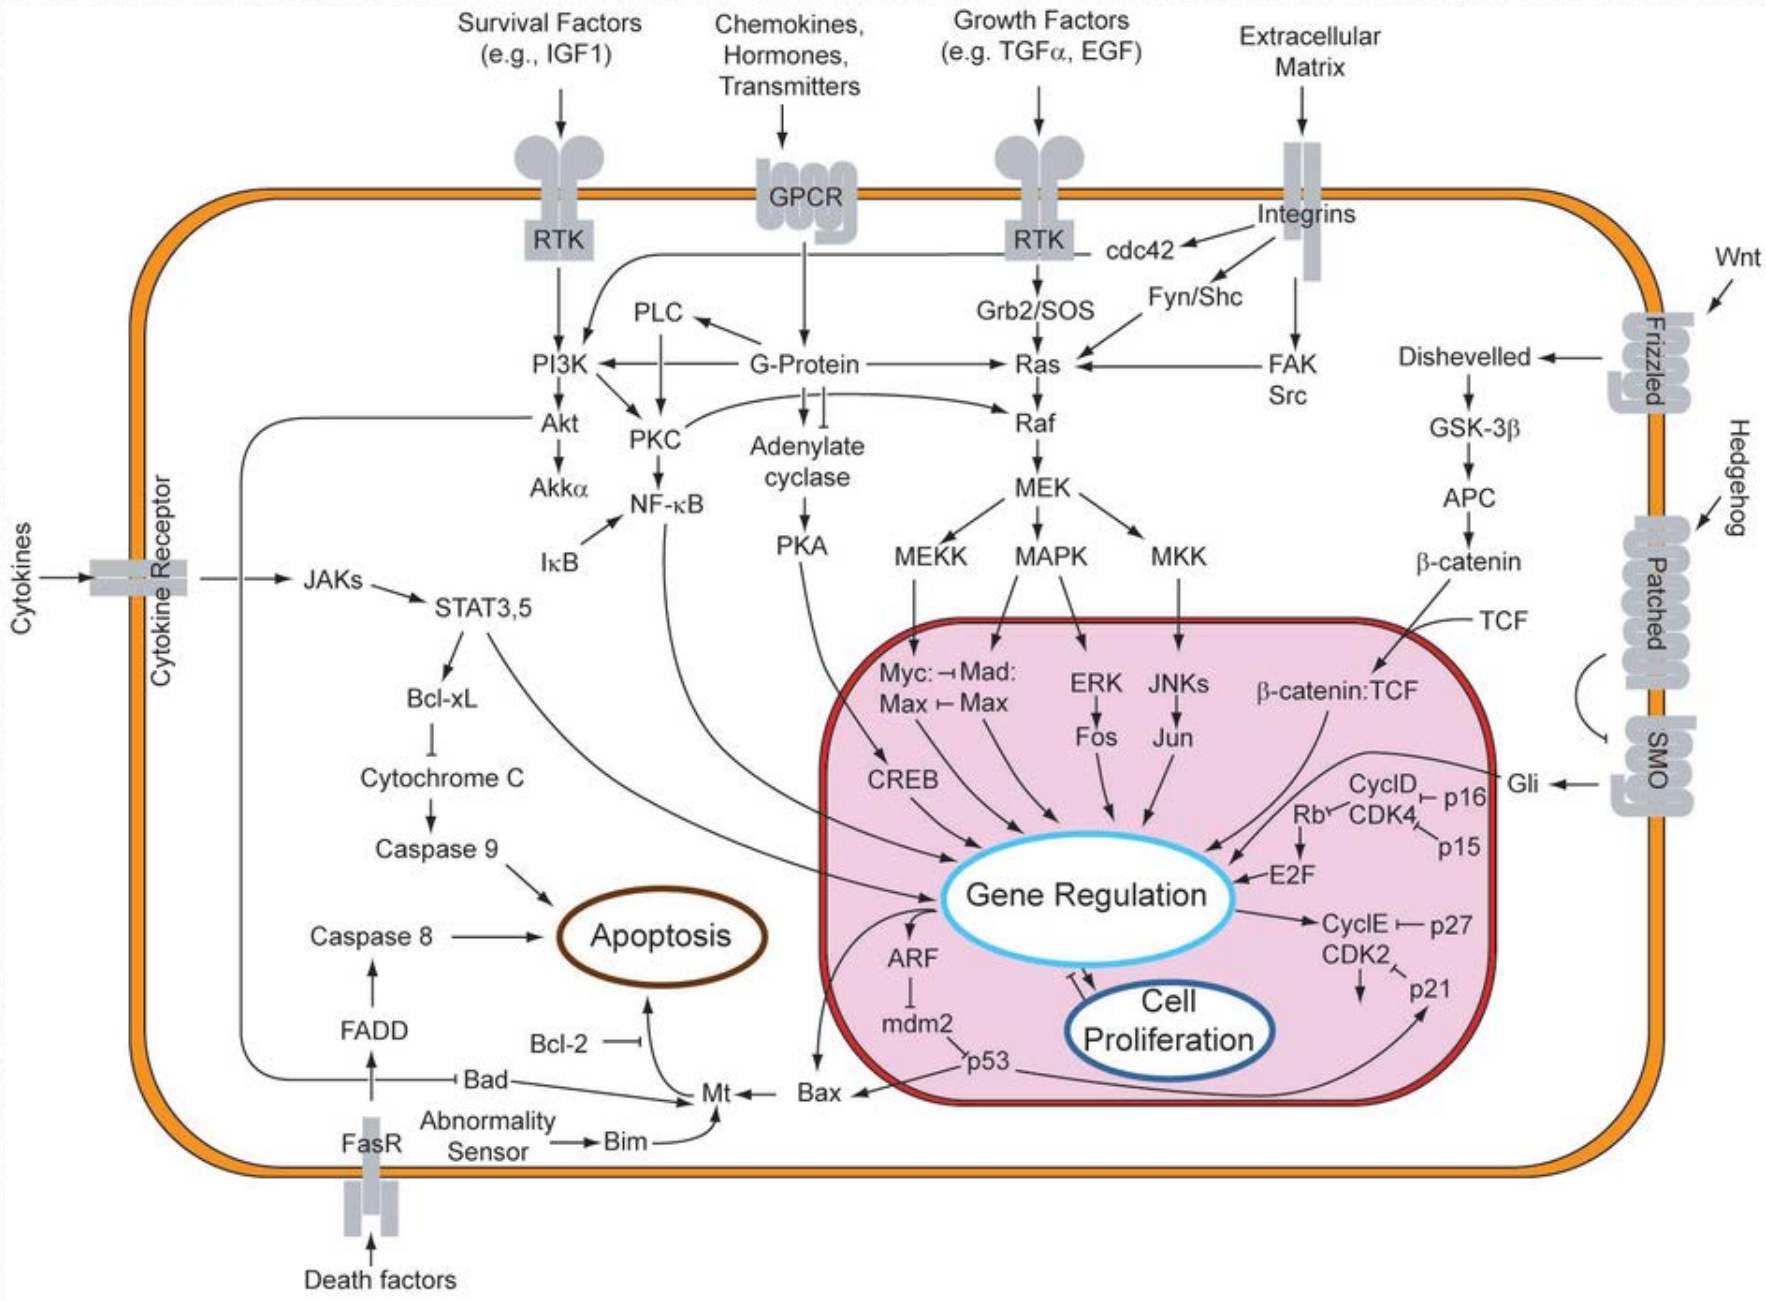

Figure 7.155 - Overview of some cellular signaling pathways

Wikipedia

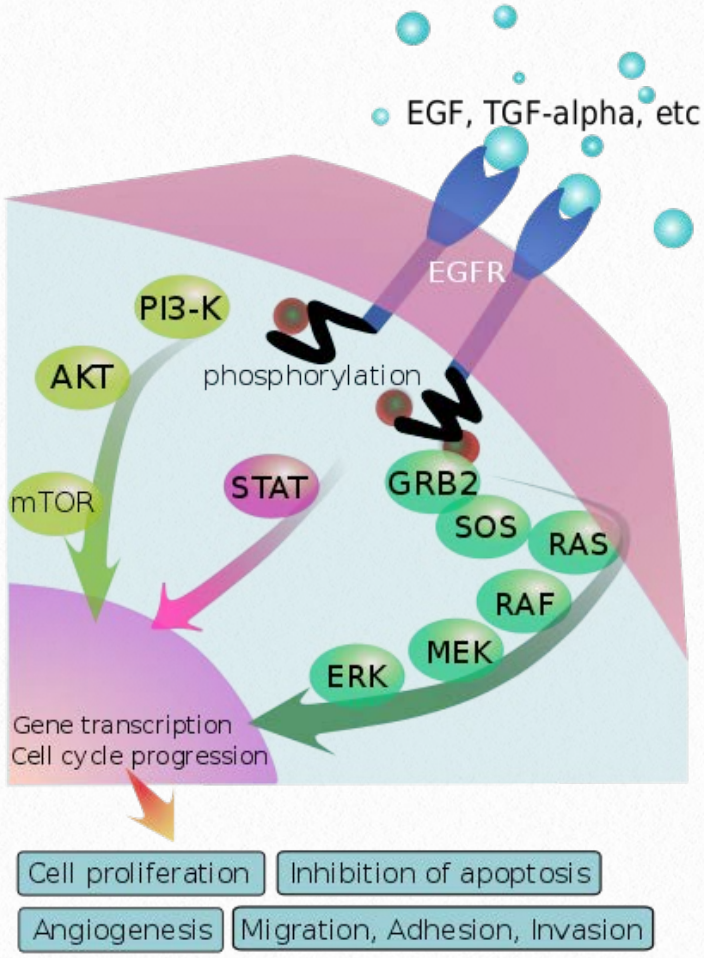

Figure 7.156 -Normal EGF Receptor signaling pathway
Wikipedia

30% of human cancers are driven by mutations in *ras* genes.

The descriptions above provide a very simple sketch of some of the major classes of receptors and deal primarily with the mechanistic details of the steps by which signals received by various types of receptors bring about changes in cells. A major take-home lesson is the essential similarity of the different pathways. Another point to keep in mind is that while we have looked at each individual pathway in isolation, a cell, at any given time receives multiple signals that set off a variety of different responses at once (Figure 7.155).

The pathways described above show a considerable degree of "cross-talk" and the response to any given signal is affected by the other signals that the cell receives simultaneously. The multitude of different receptors, signals, and the combinations thereof are the means by which cells are able to respond to an enormous variety of different circumstances.

RTKs, cancer and cancer therapies

As described above, binding of EGF to its receptor triggers a signaling pathway that results in the activation of a series of Mitogen Activated Protein Kinases (MAP kinases). These kinases are so-called because they are activated by a mitogen, a molecule, like EGF and other growth factors, that stimulates mitosis or cell division. The final kinase in the MAP kinase cascade phosphorylates a number of target proteins, many of them transcription factors, that when activated, increase the expression of genes associated with cell proliferation.

Given that the EGF-receptor pathway normally functions to stimulate cell division, it is not surprising that malfunctions in the pathway could lead to uncontrolled cell proliferation, or cancer. Next, we will take a brief look at some examples of such defects.

HER2

The human EGF receptor (HER) family has four members, HER1, HER2, HER3 and HER4. These are all receptor tyrosine ki-

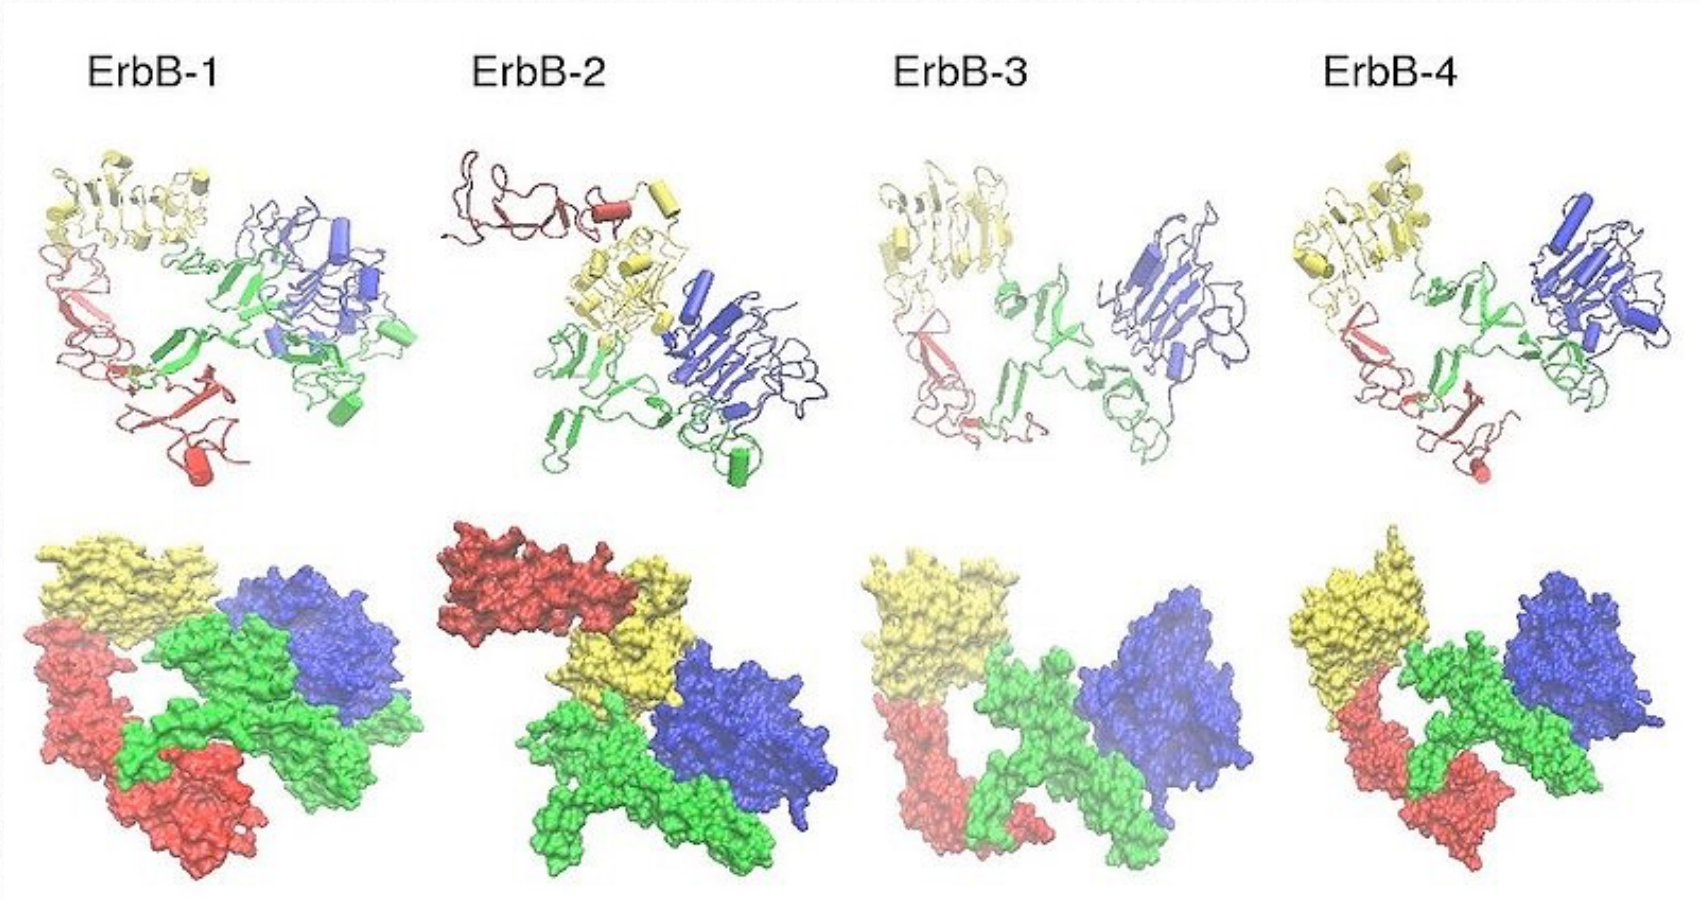

Figure 7.157 - The extracellular domains of the four members of the HER (ErbB) family

nases, cell surface receptors that bind EGF (Figure 7.157) and stimulate cell proliferation.

A crucial step in the signal transduction pathway is the dimerization of the receptors following binding of the signal, EGF, to the receptor. While HER1, HER3 and HER4 must bind the signal to dimerize, the structure of the HER2 receptor can, apparently, allow the receptor monomers to dimerize independently of EGF binding.

This means that the downstream events of the signaling pathway can be triggered even in the absence of a growth signal. In normal cells, only a few HER2 receptors are expressed at the cell surface, so this property of HER2 plays a relatively minor role in stimulating cell division. However, in about a quarter

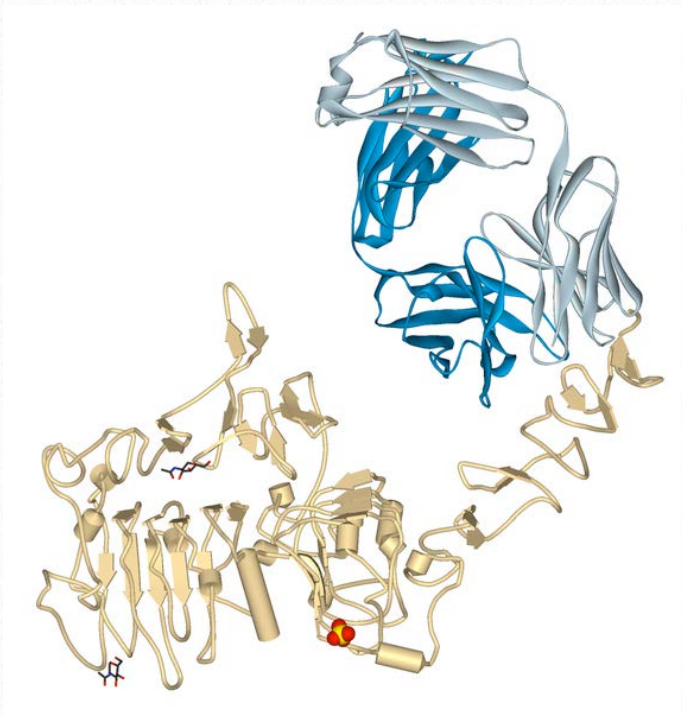

Figure 7.158 - Herceptin (blue) bound to the extracellular domain of HER2 (yellow)

Wikipedia

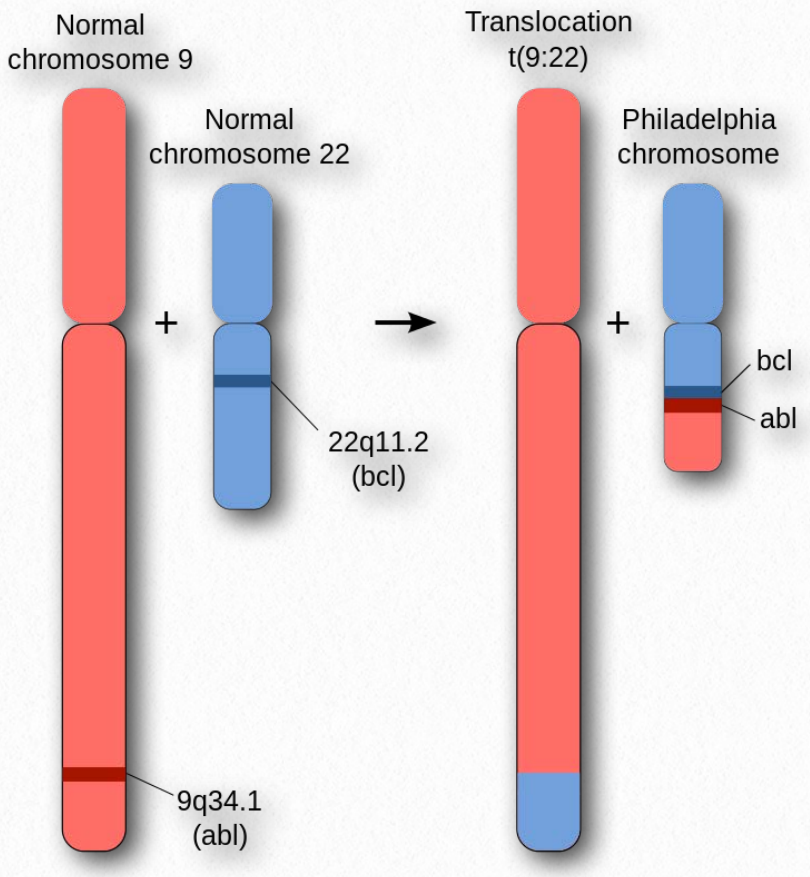

Figure 7.159 - Normal chromosomes (left) and altered chromosomes giving rise to the bcr-abl fusion (right)

Wikipedia

of breast cancer patients, HER2 receptors are overexpressed, leading to increased dimerization and subsequent uncontrolled cell proliferation.

Breast cancers that are HER2-positive can be more aggressive with a greater tendency to metastasize (spread) so therapy that blocks HER2 signaling is key in successful treatment of such cancers. Herceptin, a monoclonal antibody against the HER2 receptor, has been shown to be an effective treatment against Her2-positive breast cancers. Herceptin works by binding specifically to the extracellular domain of the HER2 receptor (Figure 7.158). This prevents dimerization of the receptor and thus blocks downstream signaling. Additionally, the binding of the Herceptin antibody to the receptor signals the immune system to destroy the HER2-positive cells.

Bcr-abl

Another example of a cancer caused by defects in an RTK signaling pathway is chronic myeloid leukemia (CML). Patients with CML have an abnormal receptor tyrosine kinase that is the product of a hybrid gene called bcr-abl, formed by the breakage and rejoining of chromosomes 9 and 22. This abnormal tyrosine kinase is constitutively dimerized, even when no signal is bound. As a result, it continuously signals cells to divide, leading to the massive proliferation of a type of blood cells called granulocytes.

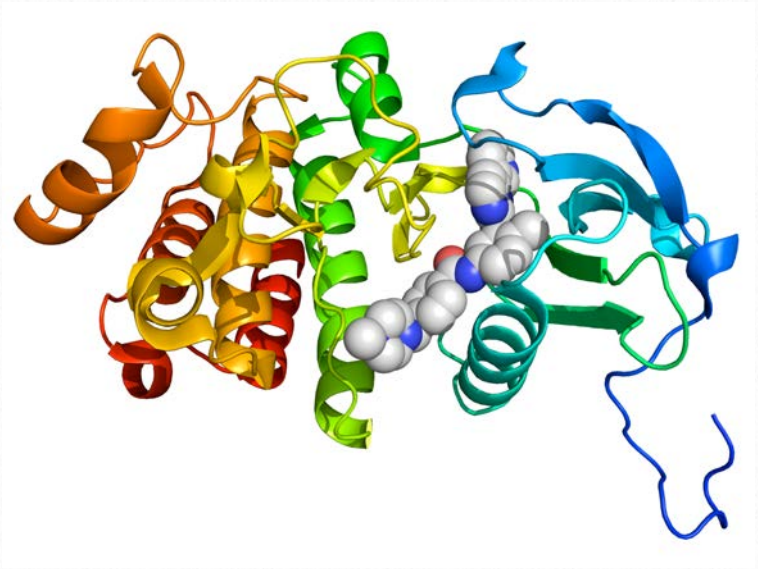

Figure 7.160 - Gleevec bound to the tyrosine kinase portion of abl

Wikipedia

As with HER2, the problem in CML is a receptor tyrosine kinase that dimerizes in the absence of a growth signal. The approach in this case was to target the next step in the signaling pathway. As you know, dimerization of RTKs activates the tyrosine kinase domain of the receptor, which results in the autophosphorylation of the cytoplasmic domains of both monomers. The phosphorylated tyrosines serve to recruit a number of other signaling proteins that pass the signal on within the cell.

In the case of the bcr-abl RTK, the drug Gleevec (imatinib) was designed to bind near the ATP-binding site of the tyrosine kinase domain. This "locks" the site in a conformation that inhibits the enzymatic activity of the tyrosine kinase and thus blocks downstream signaling. With no "grow" signal passed on, cells stop proliferating.

The Tao of Hormones

To the tune of "*The Sound of Silence*"

Metabolic Melodies Website HERE

Biochemistry my friend
It's time to study you again
Mechanisms that I need to know
Are the things that really stress me so
"Get these pathways planted firmly in your head,"
Ahern said
Let's start with ep-inephrine

Membrane proteins are well known
Changed on binding this hormone
Rearranging selves without protest
Stimulating a G alpha S
To go open up and displace its GDP
With GTP
Because of ep-inephrine

Active G then moves a ways
Stimulating ad cyclase
So a bunch of cyclic AMP
Binds to kinase and then sets it free
All the active sites of the kinases await
Triphosphate
Because of ep-inephrine

Muscles are affected then
Breaking down their glycogen
So they get a wad of energy
In the form of lots of G-1-P
And the synthases that could make a glucose chain
All refrain
Because of ep-inephrine

Now I've reached the pathway end
Going from adrenalin
Here's a trick I learned to get it right
Linking memory to flight or fright
So the mechanism that's the source of anxious fears
Reappears
When I make ep-inephrine

Recording by Tim Karplus

Glucagon is Coming Around

To the tune of "*Santa Claus is Coming to Town*"

Metabolic Melodies Website HERE

You've gotta admire
What molecules do
Their cellular fire
Is ready on cue
Glucagon is coming around

If hormone should bind
Receptor outside
G proteins find
G nucleotides
Glucagon is coming around

They activate cyclases
That make cAMPs
Which bind to Protein Kinase A
And pull the R's from C's

The glycogen shrinks
In liver quite fast
The glucose into
Your bloodstream is passed
Thanks to this you have energy

And muscles uptake
The glucose in turn
Obtaining a substrate
All of them burn
Thanks to this you have energy

The pool of phosphatidyl
Inositides in you
Can send two separate signals
When they get split in two

The muscles contract
When calcium's free
Lowering levels
Of Creatine-P
Now you're gonna need energy

Those little calcium ions
I hope you've learned them well
Are just like Martha Stewart
All locked up in a cell

This story's complete
I know it's a load
My hope is your head
Ain't gonna explode
You will need it in finals week

Toolbox

"In theory, there is no difference between theory and practice. But in practice, there is."

Yogi Berra

"The workman who would perfect his craft must first sharpen his tools"- Confucius.

The pace of discovery in biochemistry is astounding. It is hard to believe that the first demonstration that an enzyme was a protein was made only in 1926. The speed with which the field has grown is in no small part due to the development of the tools and techniques with which to study life at the molecular level.

Basic Techniques

Introduction

The environment of a cell is very complex, making it difficult to study individual reactions, enzymes, or pathways in situ. The traditional approach used by biochemists for the study of these things is to isolate molecules, enzymes, DNAs, RNAs, and other items of interest so they can be analyzed independently of the millions of other processes occurring simultaneously. Today, these approaches are used side by side with newer methods that allow us to understand events inside cells on a larger scale- for example, determining all the genes that are being expressed at a given time in specific cells. In this section we take a brief look at some commonly used methods used to study biological molecules and their interactions.

YouTube Lectures by Kevin HERE & HERE

Breaking cells open

To separate compounds from cellular environments, one must first break open (lyse) the cells. Cells are broken open, in buffered solu-

tions, to obtain a *lysate*. There are several ways of accomplishing this.

Osmotic shock and enzymes

One way to lyse cells is by lowering the ionic strength of the medium the cells are in. This can cause cells to swell and burst. Mild surfactants may be used to disrupt membranes. Most bacteria, yeast, and plant tissues are resistant to osmotic shocks, because of the presence of cell walls, and stronger disruption techniques are usually required. Enzymes may be useful in helping to degrade the cell walls. Lysozyme, for example, is very useful for breaking down bacterial walls. Other enzymes commonly employed include cellulase (plants), proteases, mannases, and others.

Figure 8.1 - A sonicator in use

Wikipedia

Mechanical disruption

Mechanical agitation may be employed in the form of beads that are shaken with a mixture of cells. In this method, cells are bombarded with tiny, glass beads that break the cells open. Sonication (20-50 kHz sound waves) provides an alternative type of agitation that can be effective. The method is noisy, however, and generates heat that can be problematic for heat-sensitive compounds.

Pressure disruption

Another means of disrupting cells involves using a “cell bomb”. In this method, cells are placed under very high pressure (up to 25,000 psi) and then the pressure is rapidly released. The rapid pressure change causes dissolved gases in cells to be released as bubbles which, in turn, break open cells.

Cryopulverization

Cryopulverization is often employed

for samples having a tough extracellular matrix, such as connective tissue, seed, and cartilage. In this technique, tissues are frozen using liquid nitrogen and then impact pulverization (typically, grinding, using a mortar and pestle or a powerful electric grinder) is performed. The powder so obtained is then suspended in the appropriate buffer.

Figure 8.2 - A high-speed centrifuge can be used to obtain different cell fractions from a crude lysate

Wikipedia

Whatever method is employed to create a lysate, crude fractions obtained from it must be further processed *via* fractionation.

Fractionation

Fractionation of samples, as the name suggests, is a process of separating out the components or fractions of the lysate. Fractionation typically begins with centrifugation of the lysate. Using low-speed centrifugation, one can remove cell debris, leaving a supernatant containing the contents of the cell. By using successively higher centrifugation speeds (and resulting g forces) it is possible to separate out different cellular components, like nuclei, mitochondria, etc., from the cytoplasm. These may then be separately lysed to release molecules that are specific to the particular cellular compartment. The soluble fraction of any lysate can, then, be further separated into its constituents using various methods.

Column chromatography

One powerful method used for this purpose is chromatography. We will consider several chromatographic approaches. Chromatography is used to separate out the components of a mixture based on differences in their size, charge or other characteristics. During chromatography, the mobile phase (buffer or other solvent) moves through the stationary phase (usually a solid matrix) carrying the components of the mixture. Separation of the components is achieved, because the different components move at different rates, for reasons that vary, depending on the type of chromatography used. We will consider several different kinds of chromatography to illustrate this process.

1. Ion exchange chromatography
2. Gel exclusion chromatography
3. Affinity chromatography
4. HPLC

These variations on chromatography are performed with the stationary phase held within so-called columns (Figure 8.3). These are

Figure 8.3 -- An ion exchange column apparatus

Wikipedia

tubes containing the stationary phase (also called the “support” or solid phase).

Supports are composed of tiny beads suspended in buffer (Figure 8.4) and are designed to exploit the chemistry or size differences of the components of the samples and thus provide a means of separation. Columns are “packed” or filled with the support, and a buffer or solvent carries the mixture of compounds to be separated through the support. Molecules in the sample interact differentially with the support and, consequently, travel through it at different speeds, thus enabling separation.

Figure 8.4 - Ion exchange beads

Wikipedia

Ion exchange chromatography

In ion exchange chromatography, the support consists of tiny beads to which are attached chemicals possessing a charge. Before use, the beads are equilibrated in a solution containing an appropriate counter-ion to the charged molecule on the bead. Figure 8.5 shows the repeating unit of polystyrolsulfonate, a compound used as a cation exchange resin. As you can see, this molecule is negatively charged, and thus the beads would be equilibrated in a buffer containing a positively charged ion, say sodium. In the suspension, the negatively charged polystyrolsulfonate is unable to leave the beads, due to its covalent attachment, but the counter-ions (sodium) can be “exchanged” for molecules of the same charge.

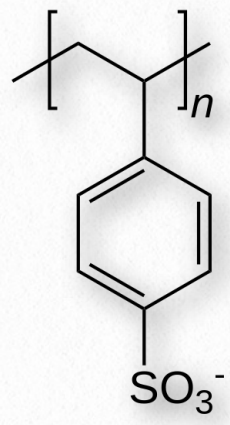

Figure 8.5 - Polystyrolsulfonate, a cation exchange resin

Wikipedia

Exchanges

Thus, a cation exchange column will have positively charged counter-ions and nega-

tively charged molecules covalently attached to the beads. Positively charged compounds from a cell lysate passed through the column will exchange with the counter-ions and "stick" to the negatively charged compounds covalently attached to the beads. Molecules in the sample that are neutral in charge or negatively charged will pass quickly through the column. At this point, only positively charged molecules from the original sample would be bound to the column. These may then be washed off, or eluted, by using buffers containing high concentrations of salt. Under these conditions, the interaction between the positively charged molecules and the polystyrosulfonate would be disrupted, allowing the molecules that were bound to the column to be recovered.

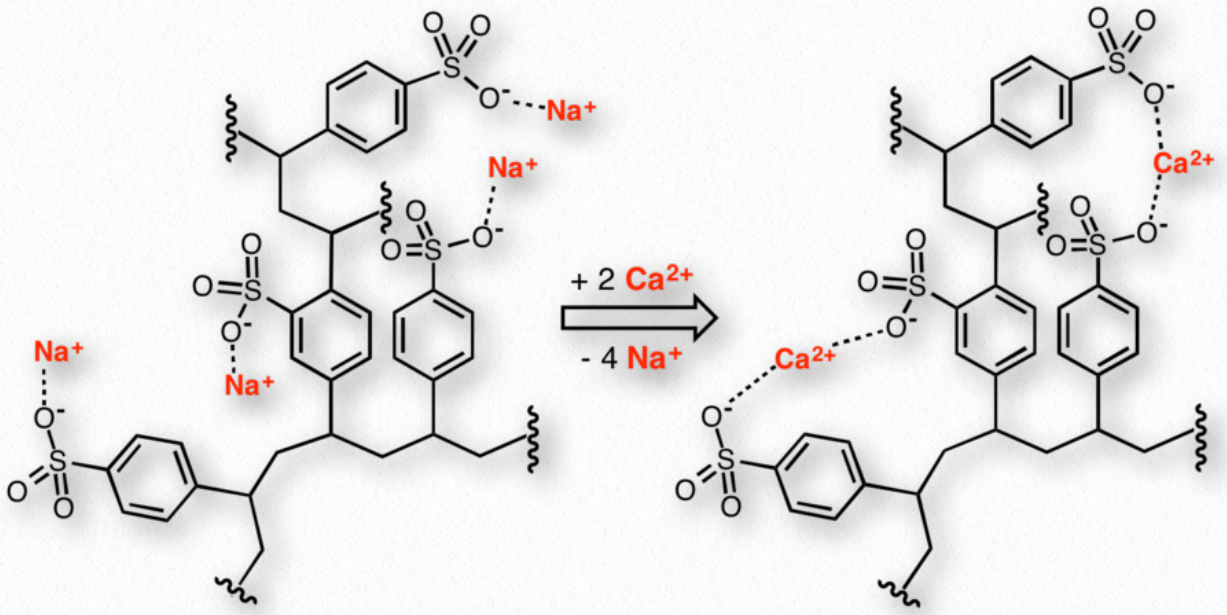

Figure 8.6 - Removal of calcium ions by an ion exchanger
Wikipedia

YouTube Lectures by Kevin HERE & HERE

Anion exchange

On the other hand, in anion exchange chromatography, the chemicals attached to the beads are positively charged and the counterions are negatively charged (chloride, for example). Negatively charged molecules in the cell lysate will "stick" and other molecules will pass through quickly. To remove the molecules "stuck" to a column, one simply needs to add a high concentration of counter-ions to release them.

Uses

Ion exchange resins are useful for separating charged from uncharged, or oppositely charged, biomolecules in solution. The resins have a variety of other applications, including water purification and softening. Figure 8.6 shows use of a polystyrolsulfonate polymer in removing calcium for water softening.

Interactive Learning Module HERE

Size exclusion chromatography

Size exclusion chromatography (also called molecular exclusion chromatography, gel exclusion chromatography, or gel filtration chromatography) is a low resolution separa-

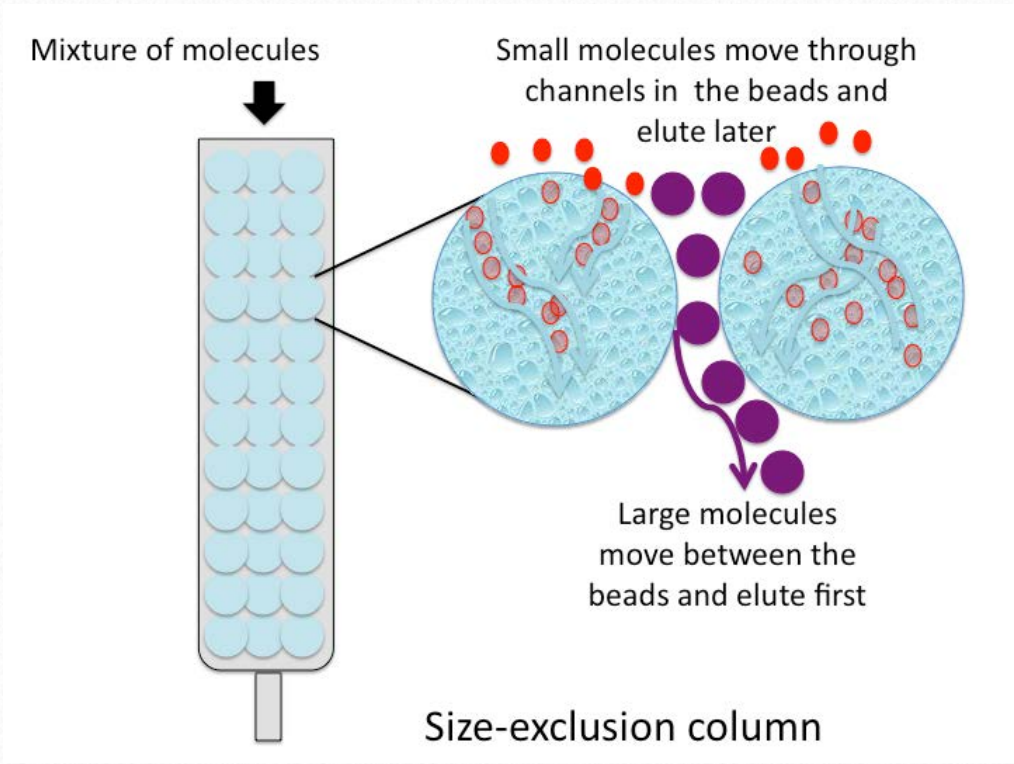

Figure 8.7 - Separation of molecules by size in a size-exclusion (aka gel filtration) column

tion method that employs beads with tiny "tunnels" in them that each have a precise opening. The size of the opening is referred to as an "exclusion limit," which means that molecules above a certain molecular weight will not be able to pass through the tunnels. Molecules with physical sizes larger than the exclusion limit do not enter the tunnels and pass through the column relatively quickly, in the spaces outside the beads. Smaller molecules, which can enter the tunnels, do so, and thus, have a longer path that they take in passing through the column and elute last (Figure 8.7).

Figure 8.8 shows a profile of a group of proteins separated by size exclusion chromatography using beads with an exclusion limit of about 30,000 Daltons. Proteins 30,000 in molecular weight or larger elute in the void volume (left) while smaller proteins elute later (middle and right).

Affinity chromatography

Affinity chromatography is a very powerful and selective technique that ex-

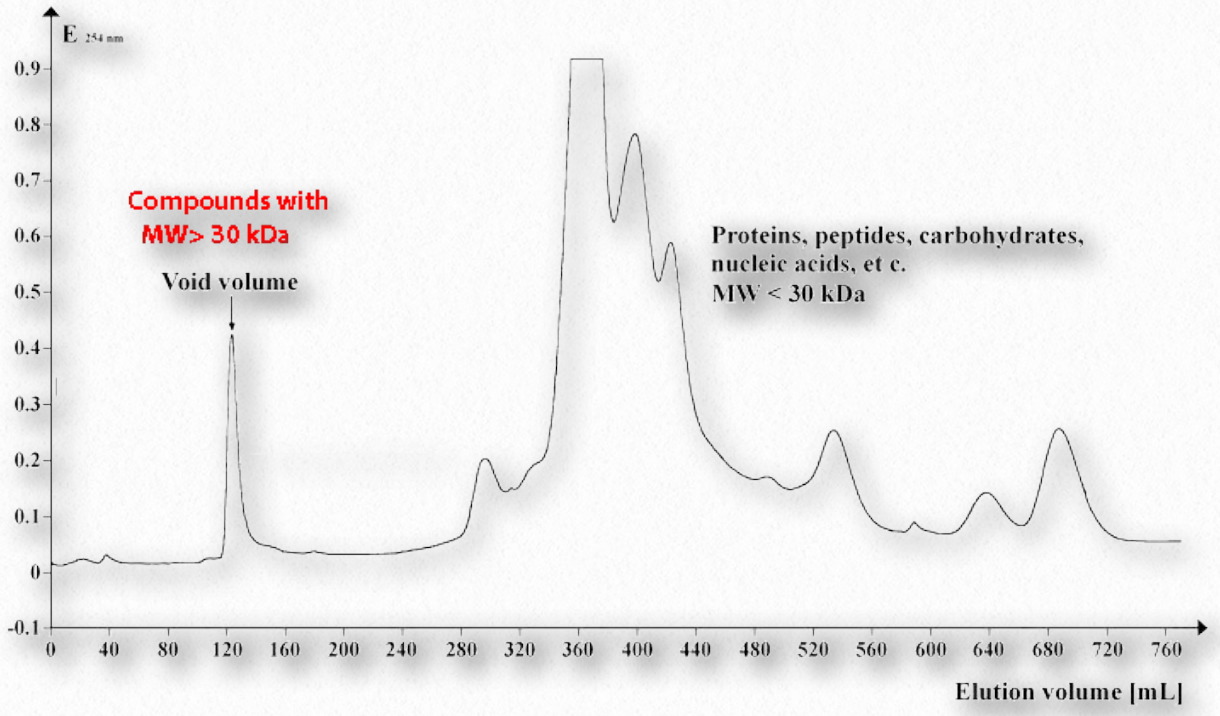

Figure 8.8 - Result of a size exclusion separation

Wikipedia

ploits the binding affinities of sample molecules (typically proteins) for molecules covalently linked to the support beads. In contrast to ion-exchange chromatography, where all molecules of a given charge would bind to the column, affinity chromatography exploits the specific binding of a protein or proteins to a ligand that is immobilized on the beads in the column.

Interactive Learning Module HERE

For example, if one wanted to separate all of the proteins in a cell lysate that bind to ATP from proteins that do not bind ATP, one could use a column that has ATP attached to the support beads and pass the sample through the column. All proteins that bind ATP will "stick" to the column, whereas those that do not bind ATP will pass quickly through it. The bound proteins may then be released from the column by adding a solution of ATP that will displace the bound proteins by competing, for the proteins, with the ATP attached to the column matrix.

Histidine tagging

Histidine tagging (His-tagging) is a special kind of affinity chromatography and is a

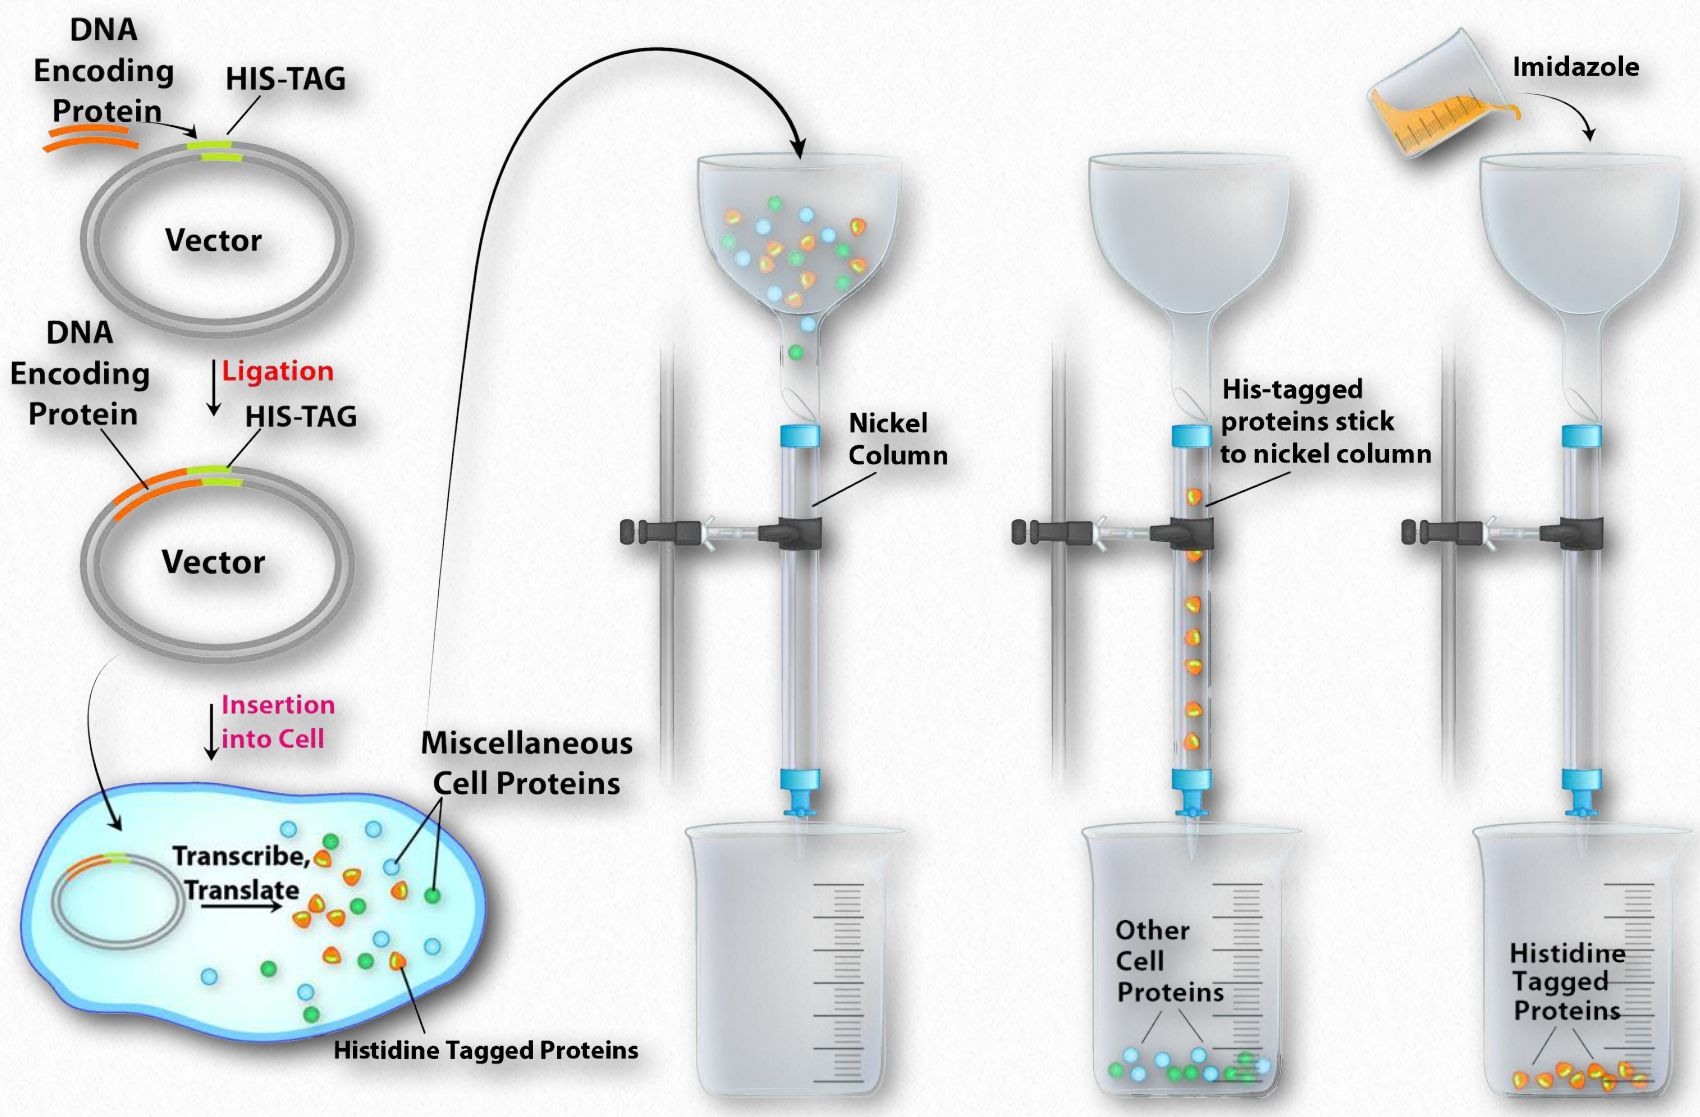

Figure 8.9 - Affinity chromatographic purification of a protein by histidine tagging

Image by Aleia Kim

powerful tool for isolating a recombinant protein from a cell lysate. His-tagging relies on altering the DNA coding region for a protein to add a series of at least six histidine residues to the amino or carboxyl terminal of the encoded protein. This "His-Tag" is useful in purifying the tagged protein because histidine side chains can bind to nickel or cobalt ions. Separation of His-tagged proteins from a cell lysate is relatively easy (Figure 8.9).

Figure 8.10 - HPLC: Pumps on left/Column in center/Detector on the right

Wikipedia

Passing the crude cell lysate through a column with nickel or cobalt attached to beads allows the His-tagged proteins to "stick," while the remaining cell proteins all pass quickly through. The His-tagged proteins are then eluted by addition of imidazole to the column. Imidazole, which resembles the side chain of histidine, competes with the His-tagged proteins and displaces them from the column. Although non-tagged proteins in the lysate may also contain histidine as part of their sequence, they will not bind to the column as strongly as the His-tagged protein and will, thus, be displaced at lower imidazole concentrations than needed to elute the His-tagged protein. Surprisingly, many His-tagged proteins appear to function normally despite the added histidines, but if needed, the histidine tags may be cleaved from the purified protein by treatment with a protease that excises the added histidines, allowing the recovery of the desired protein with its native sequence.

HPLC

High performance liquid chromatography (HPLC) is a powerful tool for separating a variety of molecules based on their differential polarities (Figure 8.10). A more efficient form of column chromatography, it employs columns with tightly packed supports and very tiny beads such that flow of solvents/buffers through the columns requires high pressures. The supports used may be polar (normal phase separation) or non-polar (reverse phase separation). In normal phase separations, non-polar molecules elute first followed by the more polar compounds. This order is switched in reverse phase chromatography. Of the two, reverse phase is much more commonly em-

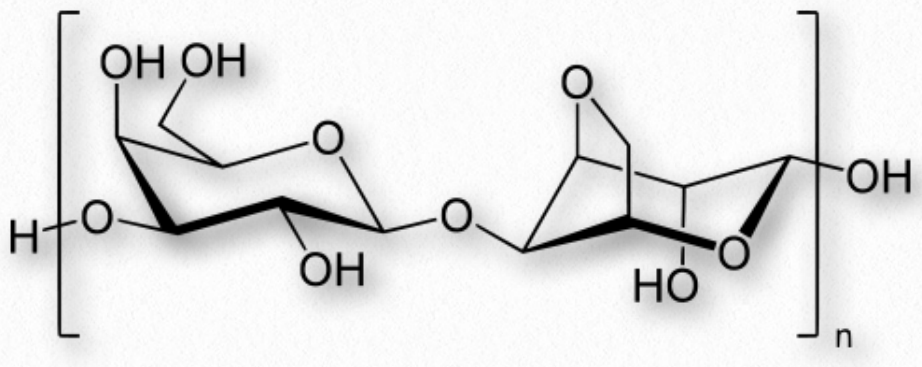

Figure 8.11 - Structure of the agarose polysaccharide

Wikipedia

ployed due to more reproducible chromatographic profiles (separations) that it typically produces.

Gel electrophoresis

Electrophoresis uses an electric field applied across a gel matrix to separate large molecules such as DNA, RNA, and proteins by charge and size. Samples are loaded into the wells of a gel matrix that can separate molecules by size and an electrical field is applied across the gel. This field causes negatively charged molecules to move towards the positive electrode. The gel matrix, itself, acts as a sieve, through which the smallest molecules pass rapidly, while longer molecules are slower-moving. For DNA and RNA, sorting molecules by size in this way is trivial, because of the uniform negative charge on the phosphate backbone. For proteins, which vary in their charges, a clever trick must be employed to make them mimic nucleic acids - see polyacrylamide gel electrophoresis (PAGE) below. Different kinds of gels have different pore sizes. Like sieves with finer or coarser meshes, some gels do a better job of separating smaller molecules while others work better for larger ones.

Gel electrophoresis may be used as a preparative technique (that is, when purifying proteins or nucleic acids), but most often it is used as an analytical tool.

Agarose gel electrophoresis

Agarose gel electrophoresis is a technique used to separate nucleic acids primarily by size. Agarose is a polysaccharide obtained

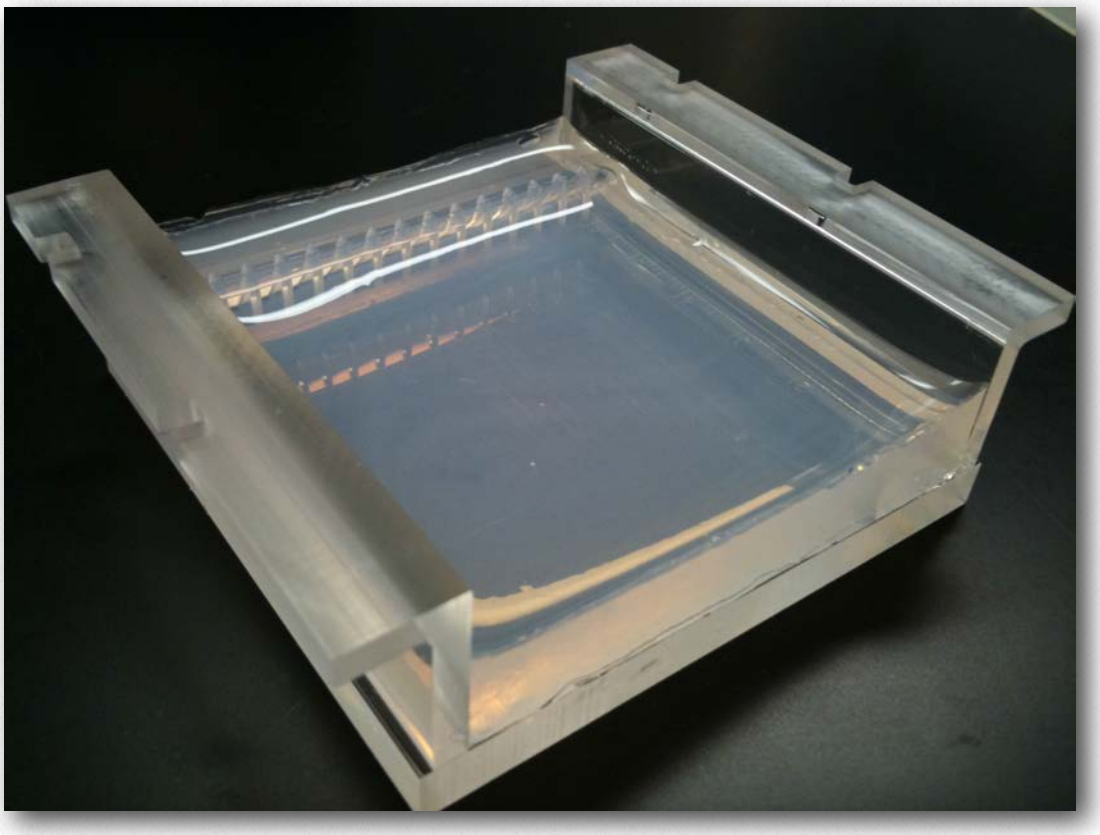

Figure 8.12 - Agarose gel electrophoresis separation of DNA - orange bands are DNA fragments

Wikipedia

from seaweeds (Figure 8.11). It can be dissolved in boiling buffer and poured into a tray, where it sets up as it cools (Figure 8.12) to form a slab. Agarose gels are poured with a comb in place to make wells into which DNA or RNA samples are placed after the gel has solidified. The gel is immersed in a buffer and a current is applied across the slab. Double-stranded DNA has a uniform negative charge that is independent of the sequence composition of the molecule. Therefore, if DNA fragments are placed in an electric field they will migrate from the cathode (-) towards the anode (+). The rate of migration is directly dependent on the ability of each DNA molecule to worm or wiggle its way through the sieving gel. The agarose matrix provides openings for macromolecules to move through. The largest macromolecules have the most difficult time navigating through the gel, whereas the smallest macromolecules slip through it the fastest.

YouTube Lectures by Kevin HERE & HERE

Because electrophoresis uses an electric current as a force to drive the molecules through the matrix, the molecules being separated must be charged. Since the size to charge ratio for DNA and RNA is constant for all sizes of these nucleic acids, the molecules simply sort on the basis of their size - the smallest move fastest and the largest move slowest.

Interactive Learning Module HERE

All fragments of a given size will migrate the same distance on the gel, forming the so-called “bands” on the gel. Visualization of the DNA fragments in the gel is made possible by addition of a dye, such as ethidium bromide, which intercalates between the bases and fluoresces when viewed under ultraviolet light (Figure 8.13) By running reference DNAs of known sizes alongside the samples, it is possible to determine the sizes of the DNA fragments in the sample. It is useful to note that, by convention, DNA fragments are not described by their molecular

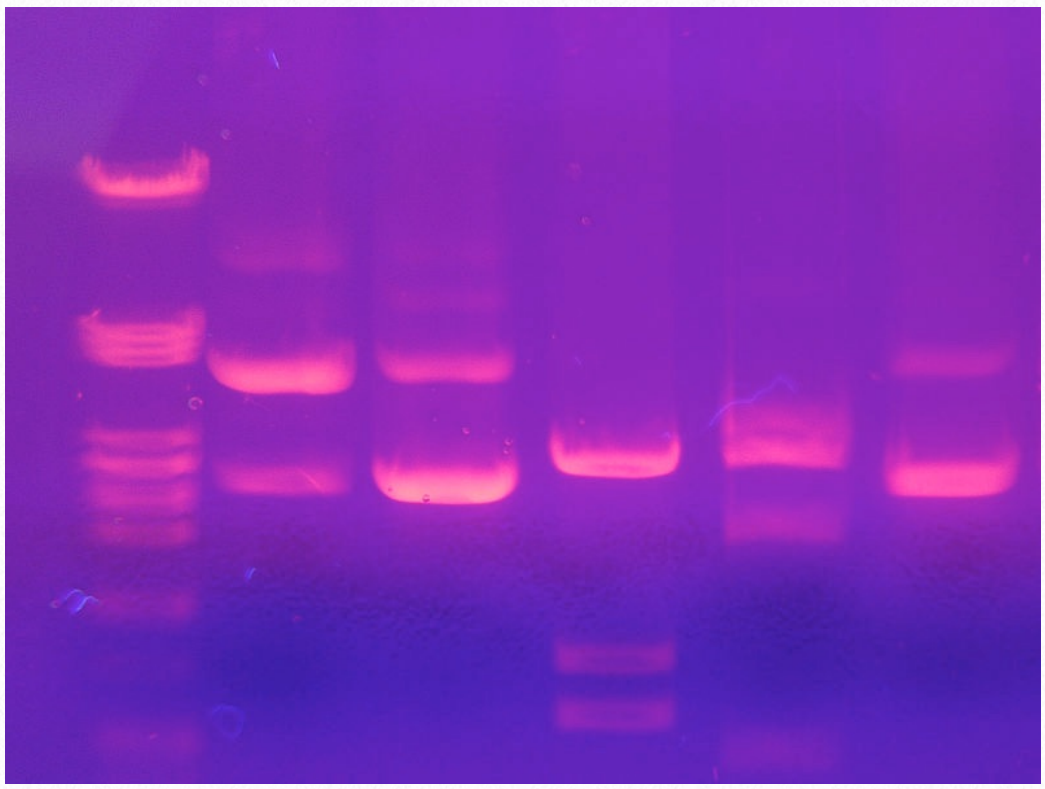

Figure 8.13 - DNA bands visualized with ethidium bromide staining

Wikipedia

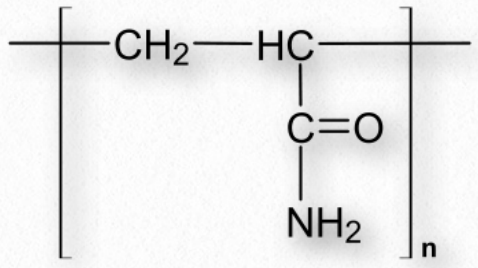

Figure 8.14 - Acrylamide monomer

Wikipedia

weights (unlike proteins), but by their length in base-pairs(bp) or kilobases (kb).

Polyacrylamide gel electrophoresis (PAGE)

Like DNA and RNA, proteins are large macromolecules, but unlike nucleic acids, proteins are not necessarily negatively charged. The charge on each protein depends on its unique amino acid sequence. Thus, the proteins in a mixture will not necessarily all move towards the anode.

Additionally, whereas double-stranded DNA is rod-shaped, most proteins are globular (folded). Further, proteins are considerably smaller than nucleic acids, so the openings of the matrix of the agarose gel are simply too large to effectively provide separation. Consequently, unaltered (native) proteins are not very good prospects for electrophoresis on agarose gels. To separate proteins by mass using electrophoresis, one must make several modifications.

Gel matrix

First, a matrix made by polymerizing and cross-linking acrylamide units is employed. A monomeric acrylamide (Figure 8.14) is polymerized and the polymers are cross-linked using N,N'-Methylene-bisacrylamide (Figure 8.15) to create a mesh-like structure. One can adjust the size of the openings of the matrix/mesh readily by changing the percentage of acrylamide in the reaction. Higher percentages of acrylamide give smaller openings and are more effective for separating smaller molecules, whereas lower percentages of acrylamide are used when resolving mixtures of larger molecules. (Note: polyacrylamide gels are also used to separate small nucleic acid fragments, with some acrylamide gels capable of separating pieces of DNA that differ in length by just one nucleotide.)

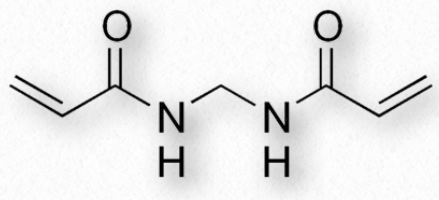

Figure 8.15 - N,N'-Methylenebisacrylamide - acrylamide crosslinking reagent

Wikipedia

Charge alteration by SDS

A second consideration is that proteins must be physically altered to "present" themselves to the matrix like the negatively charged rods of DNA. This is accomplished by treating the proteins with the anionic detergent, SDS (sodium dodecyl sulfate).

SDS denatures the proteins so they assume a rod-like shape and the SDS molecules coat the proteins such that the exterior surface is

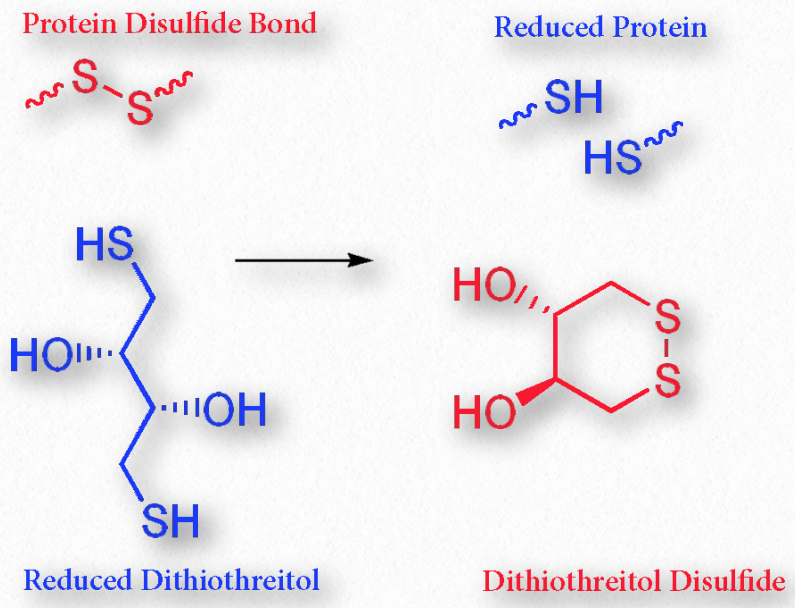

Figure 8.16 - Reduction of disulfide bonds by dithiothreitol

Wikipedia

loaded with negative charges, masking the original charges on the proteins and making the charge on the proteins more proportional to their mass, like the backbone of DNA.

Since proteins typically have disulfide bonds that prevent them from completely unfolding in detergent, samples are boiled with mercaptoethanol to break the disulfide bonds and ensure the proteins are as rod-like as possible in the SDS. Reagents like mercaptoethanol (and also dithiothreitol) are sulfhydryl-containing reagents that become oxidized as they reduce disulfide bonds in other molecules (see Figure 8.16)

Stacking gel

A third consideration is that a "stacking gel" may be employed at the top of a polyacrylamide gel to provide a way of compressing the samples into a tight band before they enter the main polyacrylamide gel (called the resolving gel).

Just like DNA fragments in agarose gel electrophoresis get sorted on the basis of size (largest move slowest and smallest move fastest), the proteins migrate through the gel matrix at velocities inversely related to their size. Upon completion of the electrophoresis, proteins may be visualized by staining with compounds that bind to proteins, like Coomassie Brilliant Blue (Figure 8.17) or silver nitrate.

Non-denaturing gel electrophoresis

The SDS_PAGE technique described above is the commonest method used for electrophoretic separation of proteins. In some situations, however, proteins may be resolved on so-called "native" gels, in the absence of SDS.

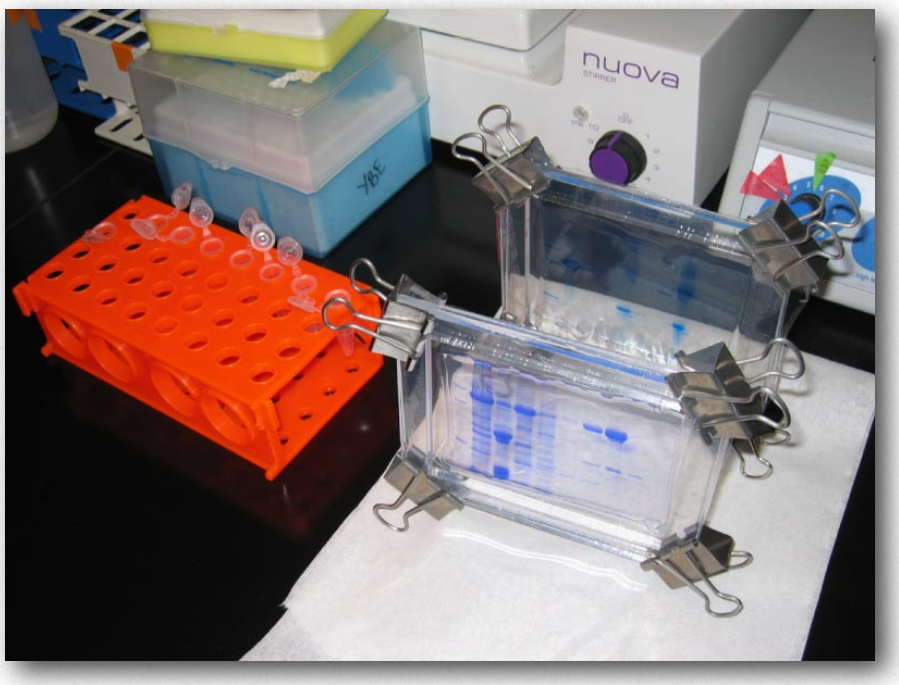

Figure 8.17 - Two SDS-PAGE gels - Proteins are the blue bands (stained with Coomassie Blue)

Wikipedia

Under these conditions, the movement of proteins through the gel will be affected not simply by their mass, but by their charge at the pH of the gel, as well. Proteins complexed with other molecules may move as single entity, allowing the isolation of the binding partners of proteins of interest.

Isoelectric focusing

Proteins vary considerably in their charges and, consequently, in their pI values (pH at which their charge is zero). This can be exploited to separate proteins in a mixture. Separating proteins by isoelectric focusing requires establishment of a pH gradient in a tube containing an acrylamide gel matrix. The pore size of the gel is adjusted to be large, to reduce the effect of sieving based on size. Molecules to be separated are applied to the gel containing the pH gradient and an electric field is applied.

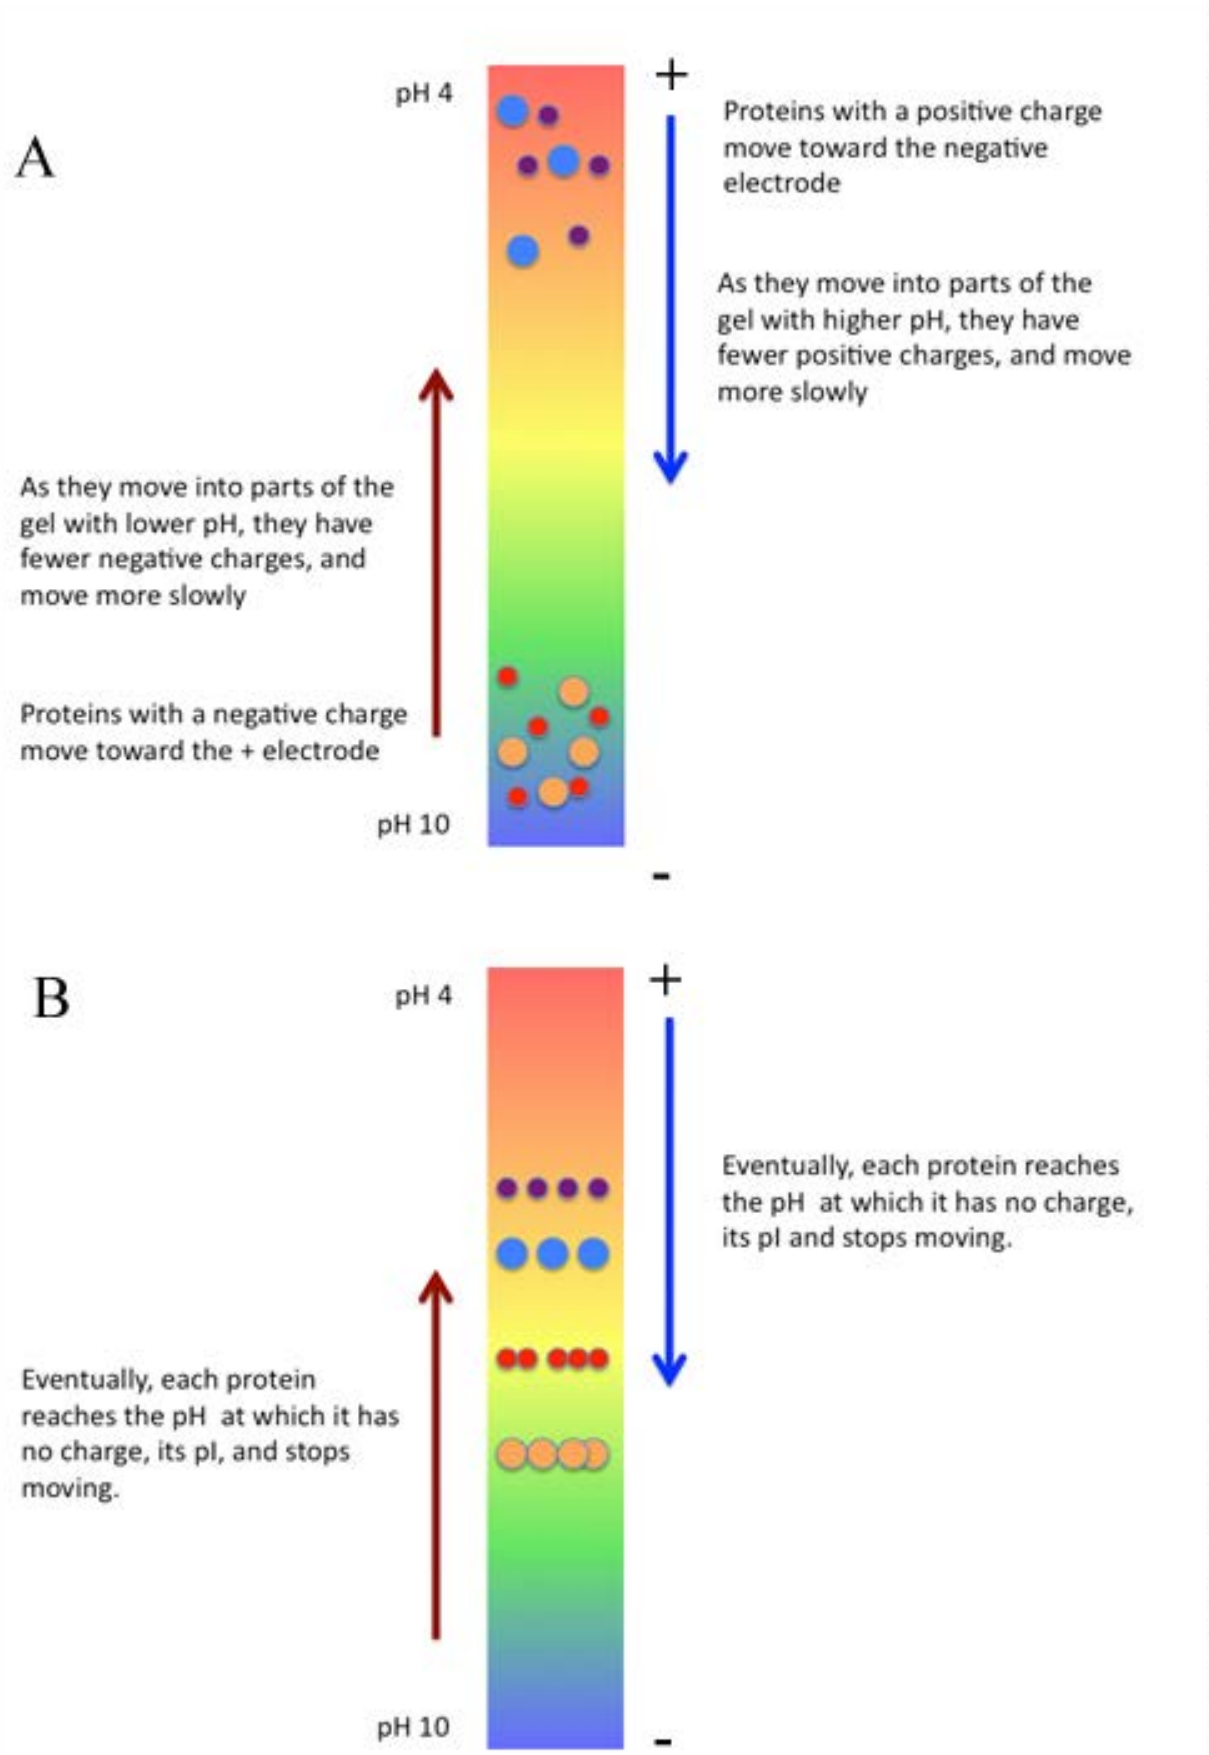

Figure 8.18 - Isoelectric focusing: A. At the start of the run; B. at the end of the run

Image by Indira Rajagopal

Under these conditions, proteins will move according to their charge.

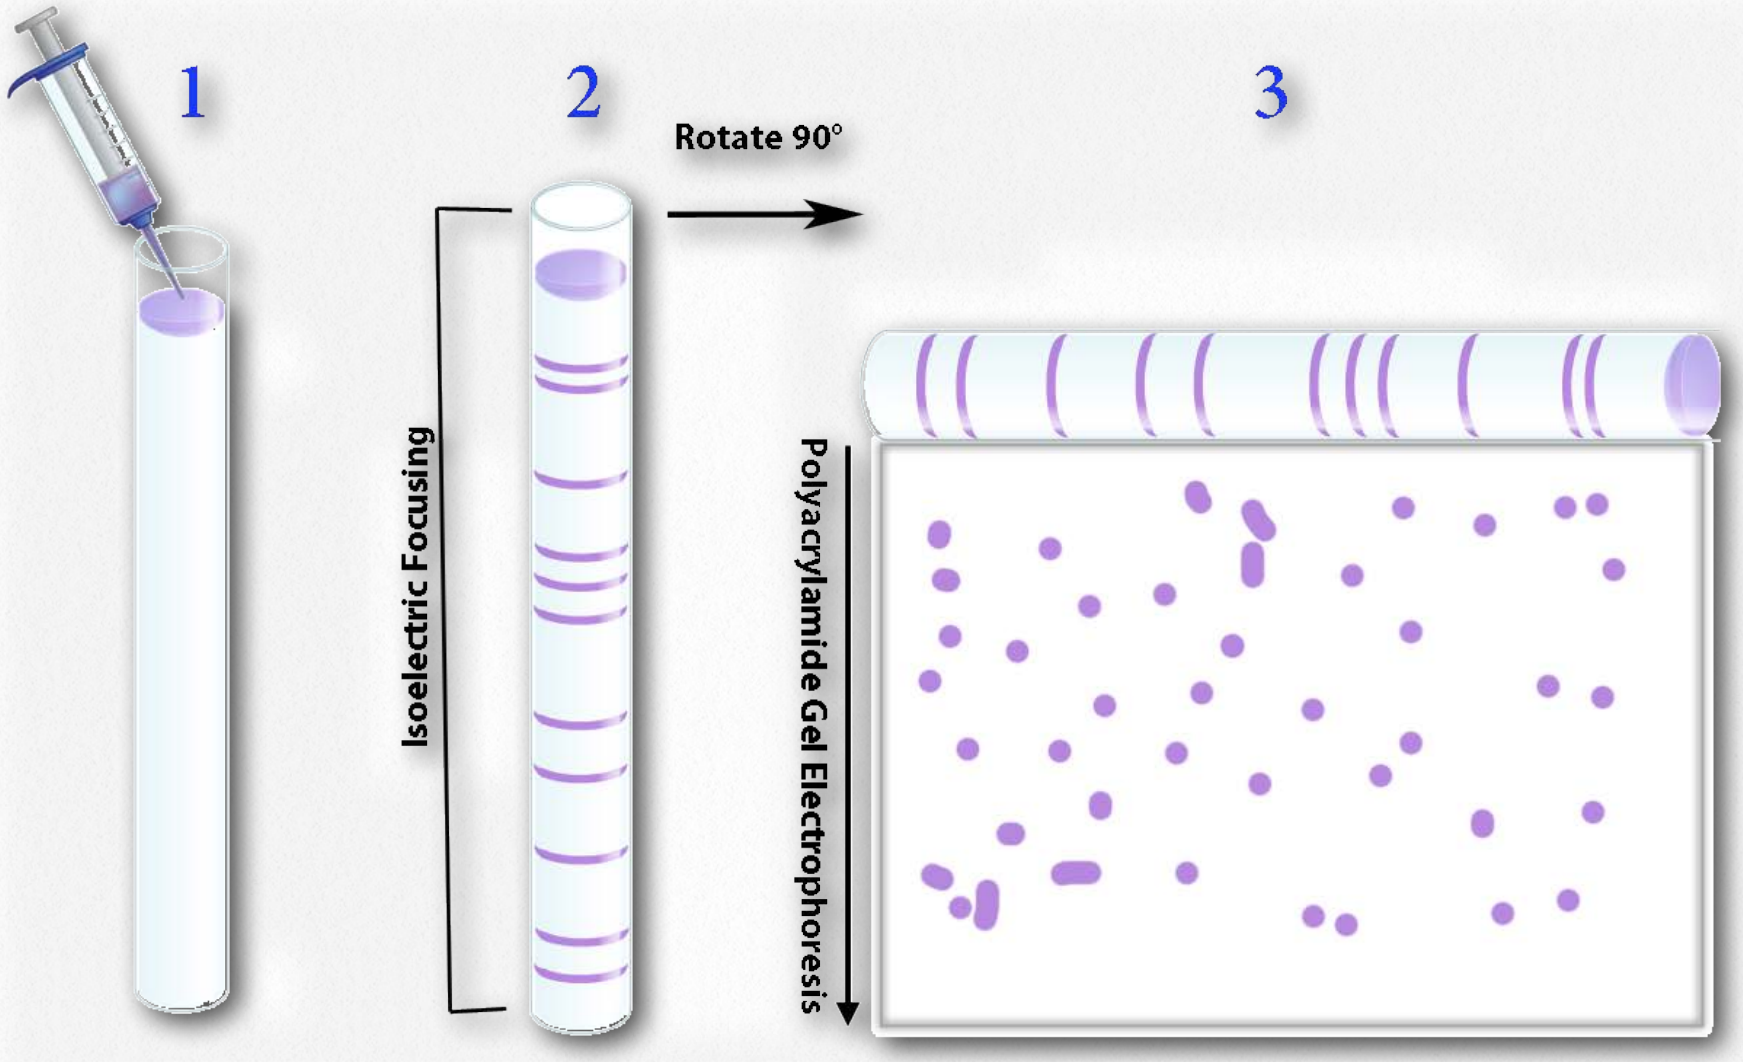

Figure 8.19 - Scheme for performing 2-D gel analysis

Image by Aleia Kim

Positively charged molecules, for example, move towards the negative electrode, but since they are traveling through a pH gradient, as they pass through it, they reach a region where their charge is zero and, at that point, they stop moving. They are at that point attracted to neither the positive nor the negative electrode and are thus "focused" at their pI (Figure 8.18). Using isoelectric focusing, it is possible to separate proteins whose pI values differ by as little as 0.01 units.

YouTube Lectures by Kevin HERE & HERE

2D gel electrophoresis

Both SDS-PAGE and isoelectric focusing are powerful techniques, but a clever combination of the two is a powerful tool of proteomics - the science of studying all of the proteins of a cell/tissue simultaneously. In 2-D gel electrophoresis, a lysate is first prepared from the cells of interest. The proteins in the lysate are separated first by their pI, through isoelectric focusing and then by size by SDS-PAGE.

The mixture of proteins is first applied to a

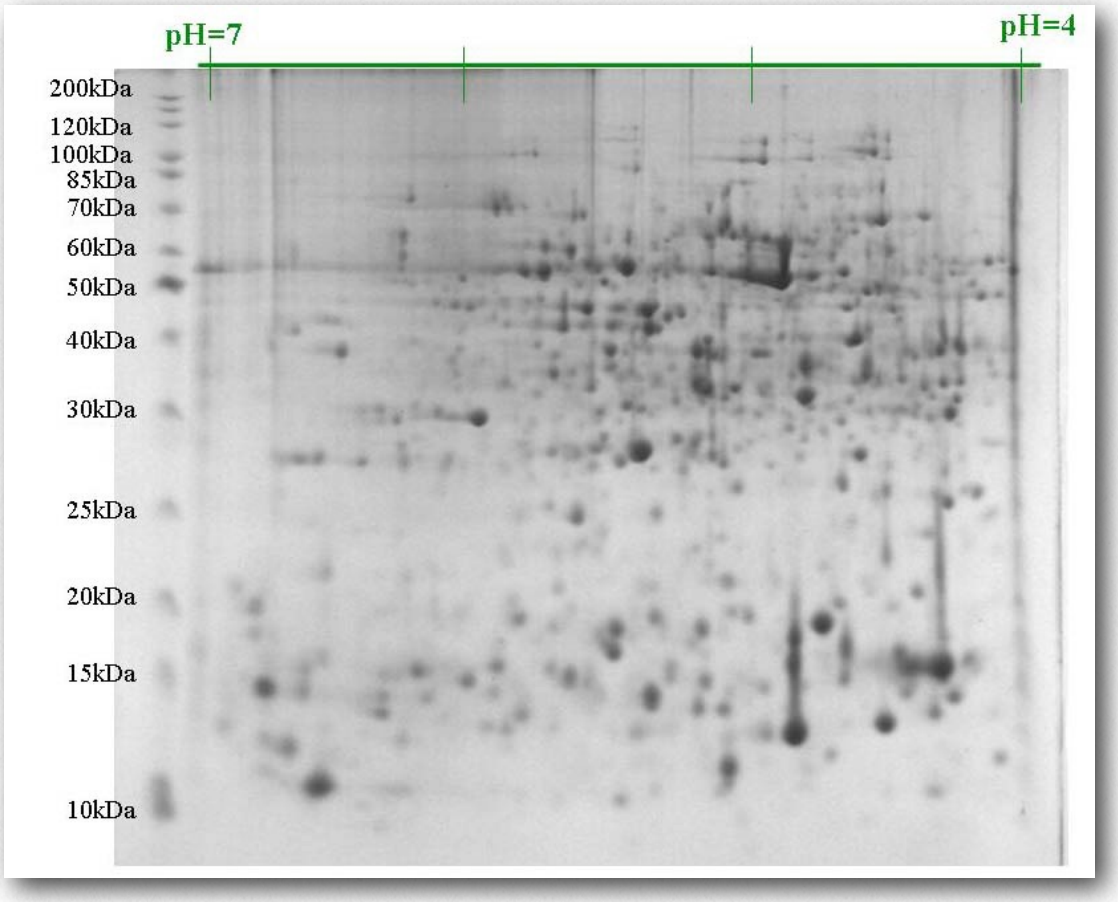

Figure 8.20 - Result of 2-D gel electrophoresis separation

Wikipedia

tube or strip (Figure 8.19, Step 1) where isoelectric focusing is performed to separate the proteins by their pI values (Step 2). Next, as shown in the figure, the gel containing the proteins separated by their pIs is turned on its side and applied along the top of a polyacrylamide slab for SDS-PAGE to separate on the basis of size (Step 3). The proteins in the isoelectric focusing matrix are electrophoresed into the polyacrylamide gel and separated on the basis of size. The product of this analysis is a 2-D gel as shown in Figure 8.20.

The power of 2-D gel electrophoresis is that virtually every protein in a cell can be separated and appear on the gel as a spot defined by its unique size and pI. In the figure, spots in the upper left correspond to large positively charged proteins, whereas those in the lower right are small negatively charged ones. Every spot on a 2-D gel can be eluted and identified by using high throughput mass spectrometry. This is particularly powerful when one compares protein profiles between different tissues or between control and treated samples of the same tissue.

Interactive Learning Module HERE

Protein profiles comparison

Comparison of 2-D gels of proteins from non-cancerous tissue and proteins from a cancerous tissue of the same type provides a quick identification of proteins whose level of expression differs between the two. Information such as this can be useful in designing treatments or in understanding the mechanism(s) by which the cancer develops.

Detection, identification and quantitation of specific nucleic acids and proteins

While gel electrophoresis can be used to resolve molecules in a mixture, by itself, the

technique does not permit the detection and identification of specific nucleic acid sequences or proteins. For example, the 2-D gel shown above clearly separates a large number of proteins in a sample into individual spots. However, if we wanted to know whether a specific protein was present, we could not tell by simply looking at the gel. Likewise, in an agarose gel, while bands of DNA could be assigned a size, one could not distinguish between two DNAs of different sequence if they were both the same length in base-pairs. One way to detect the presence of a particular nucleic acid or protein is dependent on transferring the separated molecules from the gels onto a membrane made of nitrocellulose or nylon to create a "blot" and probing for the molecule(s) of interest using reagents that specifically bind to those molecules. The next section will discuss how this can be done for nucleic acids as well as for proteins.

Southern and northern blots

The Southern blot is named for its inventor, Oxford professor, Edwin Southern, who came up with a protocol for transferring DNA fragments from a gel onto a nitrocellulose sheet and detecting a specific DNA sequence among the bands on the blot.

As shown in Figure 8.21, the method works as follows. A mixture of DNA molecules (often DNA that has been cut into smaller fragments using restriction endonucleases) is loaded on an agarose gel, as usual. After the gel run is complete, the DNA bands are transferred from the gel onto a membrane. This can be achieved by capillary transfer, where the gel is placed in contact with a piece of membrane and buffer is pulled through the gel by wicking it up into a stack of absorbent paper placed above the mem-

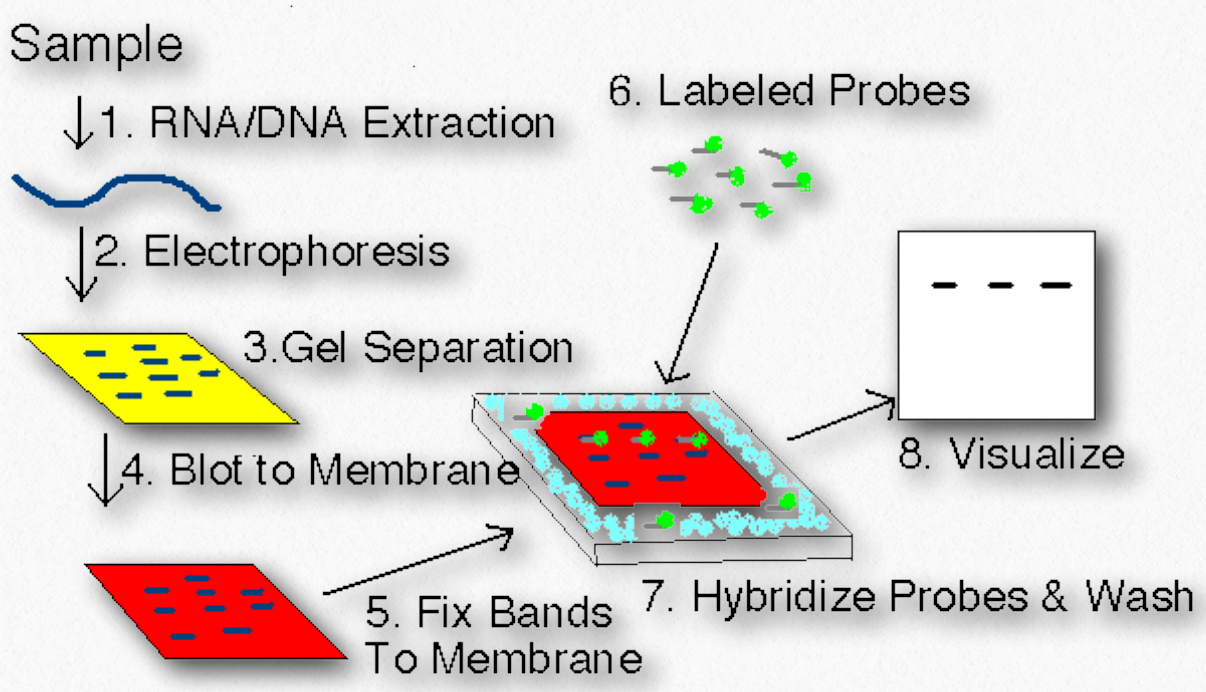

Figure 8.21 - Northern or Southern blot scheme. Southern blotting adds strand denaturation between steps 4 and 5.
Wikipedia

brane. As the buffer moves, it carries with it the DNA fragments. The DNA binds to the membrane leaving a “print” of DNA fragments that exactly mirrors their positions in the gel. The blotting membrane may be treated with UV light, heat, or chemicals to firmly attach the DNA to the membrane.

Next, a probe, or visualizing agent specific for the molecule of interest is added to the membrane. In Figure 8.21, this is called a labeled probe. The probes in a Southern blot are pieces of DNA designed to be complementary to the desired target sequence. If the sequence of interest is present on the blot, the probe, which is complementary to it, can base-pair (hybridize) with it. The blot is then washed to remove all unbound probe. Probes are labeled with radioactivity or with other chemical reagents that allow them to be easily detected when bound to the blot, so it is possible to visually determine whether the probe has bound to any of the DNA bands on the blot. Given that the Southern blot relies on specific base-pairing between the probe and the target sequence, it is easy to adapt the technique to detect specific RNA molecules, as well. The modification of this method to detect RNAs was jokingly named a “northern” blot.

Western blots

Proteins cannot, for obvious reasons, be detected through base-pairing with a DNA probe, but protein blots, made by transferring proteins, separated on a gel, onto a membrane, can be probed using specific antibodies against a particular protein of interest.

Protein detection usually employs two antibodies, the first of which is not labeled. The label is on the second antibody, which is designed to recognize only the first antibody in a piggyback fashion. The first antibody specifically binds to the protein of interest on the blot and the second antibody recognizes and binds the first antibody.

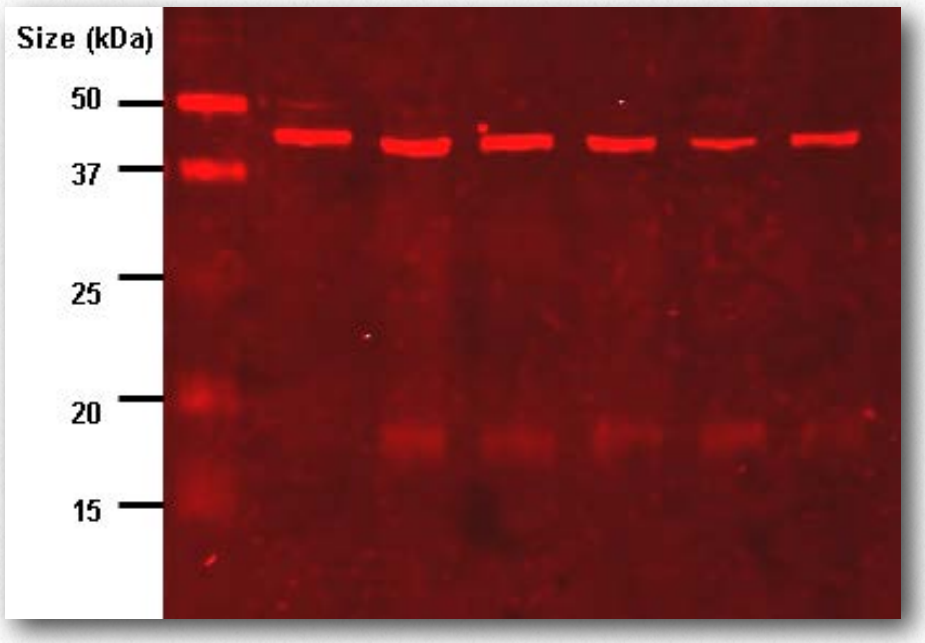

Figure 8.22 - Result of a western blot analysis

Wikipedia

The second antibody commonly carries an enzyme or reagent which can cause a reaction to produce a color upon further treatment. In the end, if the molecule of interest is in the original mixture, it will “light” up and reveal itself on the blot. This variation on the blotting theme was dubbed a western blot (Figure 8.22).

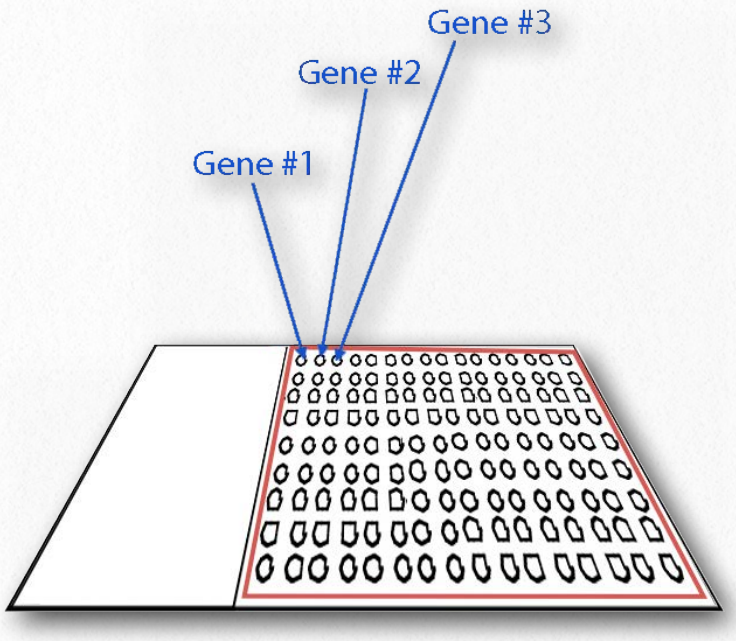

Figure 8.23 - Microarray design
Image by Taralyn Tan

In each of the blots described above, binding of the probe to the target molecule allows one to determine whether the target sequence or protein was in the sample. Although blots are designed to be used for detection, rather than for precise quantitation, it is possible to obtain estimates of the abundance of the target molecule from densitometry measurements of signal intensity.

Microarrays

2-D gels are a way of surveying a broad spectrum of protein molecules simultaneously. One approach to doing something similar with DNA or RNA involves what are called microarrays. Microarrays are especially useful for monitoring the expressions of thousands of genes, simultaneously. Where a northern blot would allow the identification of a single mRNA from a mixture of mRNAs, a microarray experiment can allow the simultaneous identification of thousands of mRNAs that may be made by a cell at a given time. It is also possible to perform quantitation much more reliably than with a blot.

Microarrays employ a glass slide, or chip, to which are attached short sequences of single-stranded DNA, arranged in a grid, or matrix (Figure 8.23) Each position in the grid corresponds to a unique gene. That is, the DNA sequence at this spot is part of the sequence of a specific gene. Each spot on the grid has multiple identical copies of the same sequence.

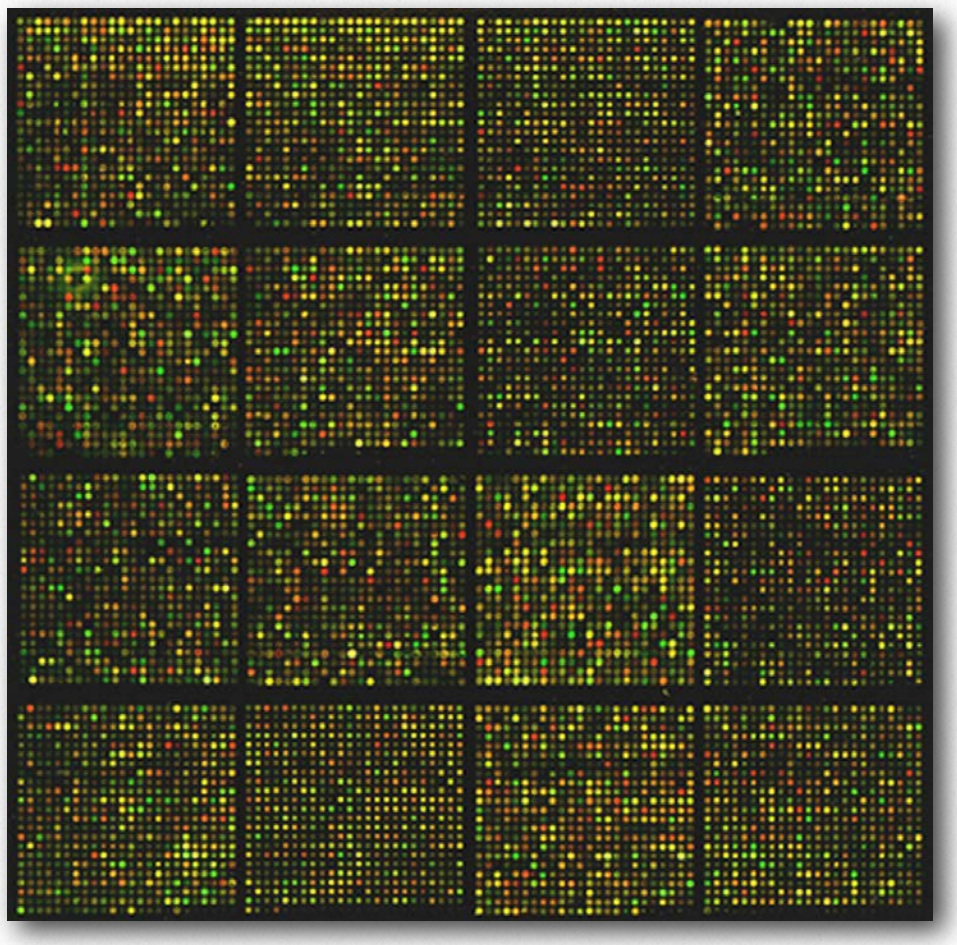

Figure 8.24 - Large scale microarray analysis of mouse transcriptome
Wikipedia

The gene sequence immobilized at each position in the grid is recorded.

Adding samples

To the slide are added a mixture of sample molecules, some of which will recognize and bind specifically to the sequences on the slide. Binding between the sample molecules and the sequences attached to the slide occurs by base pairing, in the case of DNA microarrays. The slide is then washed to remove sample molecules that are not specifically bound to the sequences in the grid.

Sample molecules are tagged with a fluorescent dye, allowing the spots where they bind to be identified. The grid is analyzed spot by spot for binding of the sample molecules to the immobilized sequences. The more sample molecules are bound at a spot, the greater the intensity of dye fluorescence that will be observed. Information from this analysis can give information about the presence/absence/abundance of molecules in the sample that bind to the sequences in the grid.

YouTube Lectures by Kevin
HERE & HERE

Transcriptomics

For example, consider a matrix containing all of the known gene sequences in a genome. To make such a matrix for analysis, one would need to make copies of every gene, either by chemical synthesis or by using the polymerase chain reaction. The strands of the resulting DNAs would then be separated to obtain single-stranded sequences that could be attached to the chip. Each box of the grid would contain sequence from one gene. With this grid, one could analyze the transcriptome - all of the mRNAs being made in selected cells at a given time. For a simple analysis, one could take a tissue (say liver) and extract all the mRNAs from it. This mRNA population represents all the genes that were being expressed in the liver cells at the time the RNA was extracted. These RNAs should be able to hybridize (base-pair) with their corresponding genes on the microarray. Genes that were not being expressed would have no mRNAs to bind to their corresponding genes on the grid.

In practice, the mRNAs are not used directly, but are copied into single-stranded DNA copies called cDNAs. The cDNAs are tagged with a fluorescent dye and added to the microarray under conditions that allow base pairing so that the cDNAs can find and base pair with complementary sequences on the matrix (Figure 8.26). The matrix is then washed to remove unhybridized cDNAs. The presence/absence/abundance of each mRNA is then readily determined by measuring the amount of dye at each box of the grid.

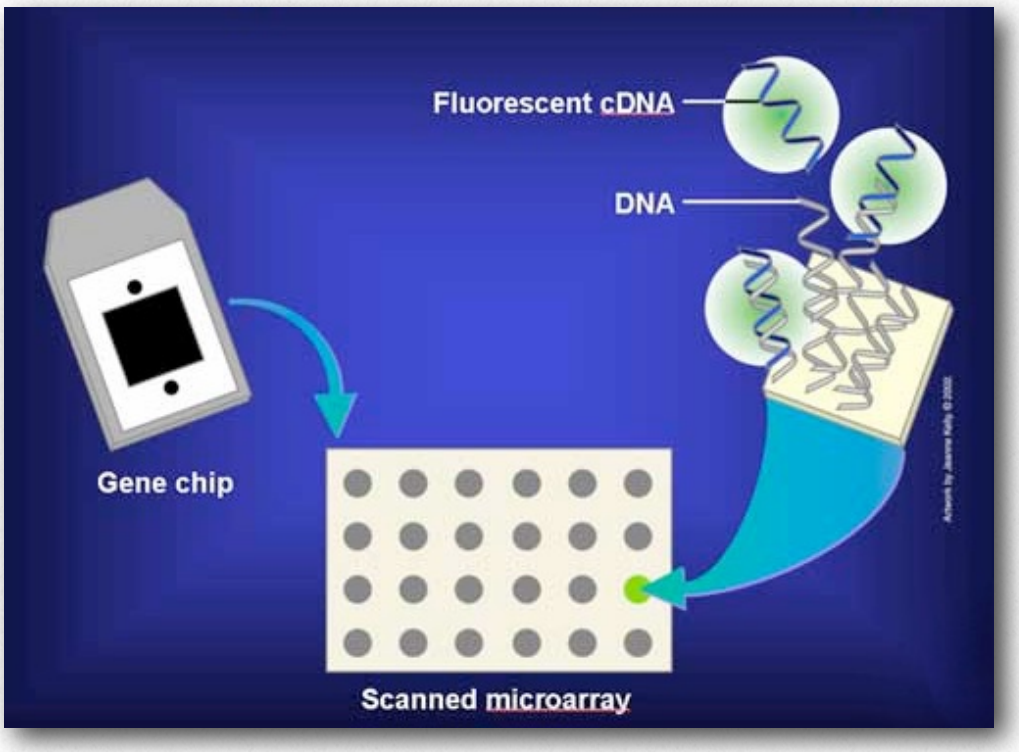

Figure 8.27 - Binding of a fluorescent cDNA copy of a specific mRNA to DNA immobilized on one spot in a microarray

Wikipedia

In Figure 8.27, a fluorescent cDNA has bound to the spot on the far right in the third row of the grid. This means that the sequence of the cDNA was complementary to the sequence of the gene sequence immobilized at that spot. Because the identity of the genes at each position on the grid is known, we then know that the sample contained mRNA that corresponded to that particular gene. In other words, that gene was being expressed in the cells from which the mRNAs were obtained.

A more powerful analysis could be performed with two sets of mRNAs simultaneously. . One set of cDNAs could come from a cancerous tissue and the other from a non-cancerous tissue, for example. The cDNAs derived from each sample is marked with a different color (say green for normal and red for cancerous) (Figure 8.25). The cDNAs are mixed and then added to the matrix and complementary sequences are once again allowed to form

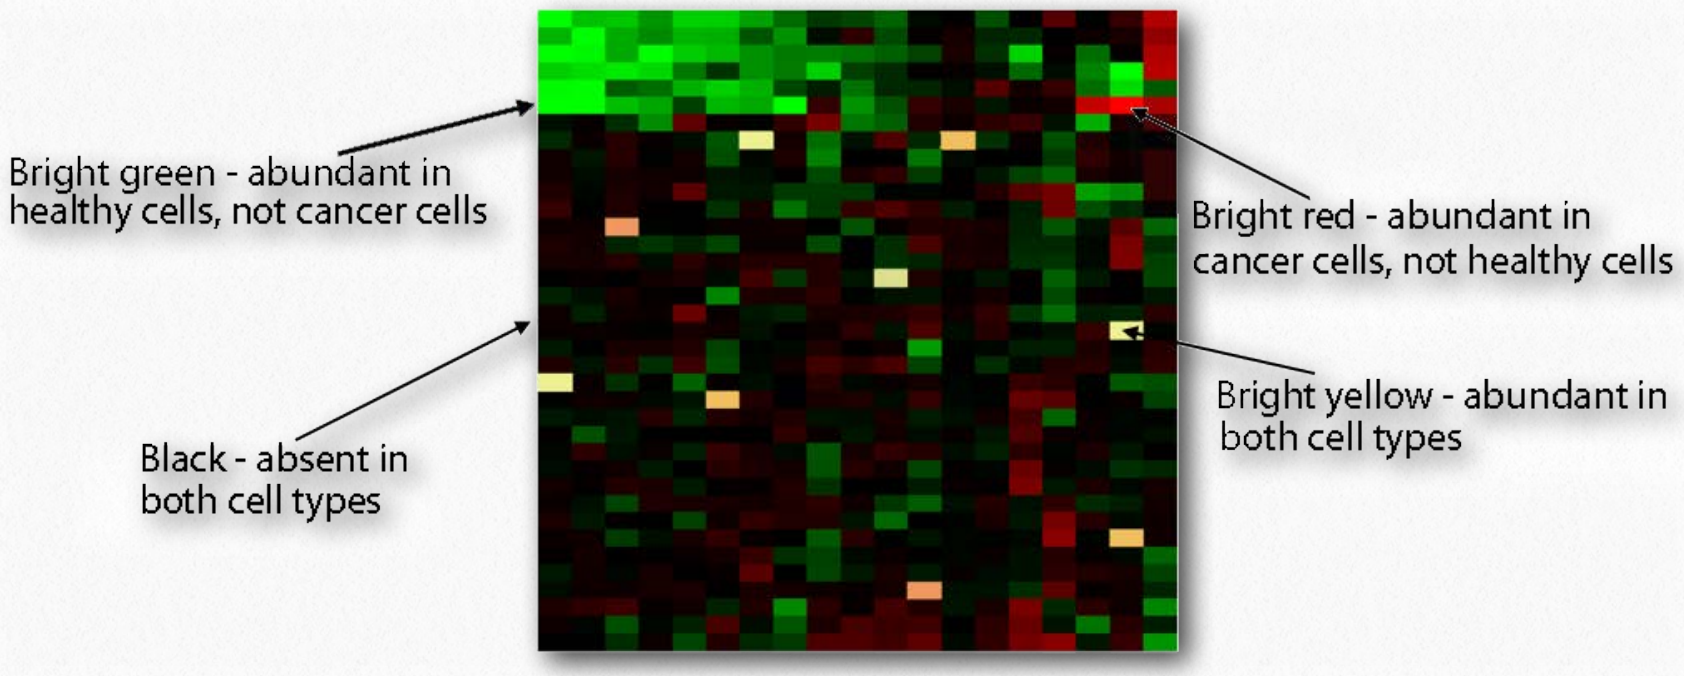

Figure 8.28 - Microarray analysis comparing gene expression in normal and cancer cells

Wikipedia

duplexes (Figure 8.27). Unhybridized cDNAs are washed away and then the plate is analyzed. Red grid boxes correspond to an mRNA present in the cancerous tissue, but not in the non-cancerous tissue. Green grid boxes correspond to an mRNA present in the non-cancerous tissue, but not in the cancerous tissue. Yellow would correspond to mRNAs present in equal abundance in the two tissues (Figure 8.28). The intensity of each spot also gives information about the relative amounts of each mRNA in each tissue.

Protein microarrays

The same principle used for nucleic acid microarrays can be adapted for analyzing other molecules. For example, polypeptides could be bonded to the glass slide instead of DNA to create a protein chip. Protein chips are useful for studying the interactions of proteins with other molecules as well as for diagnostics.

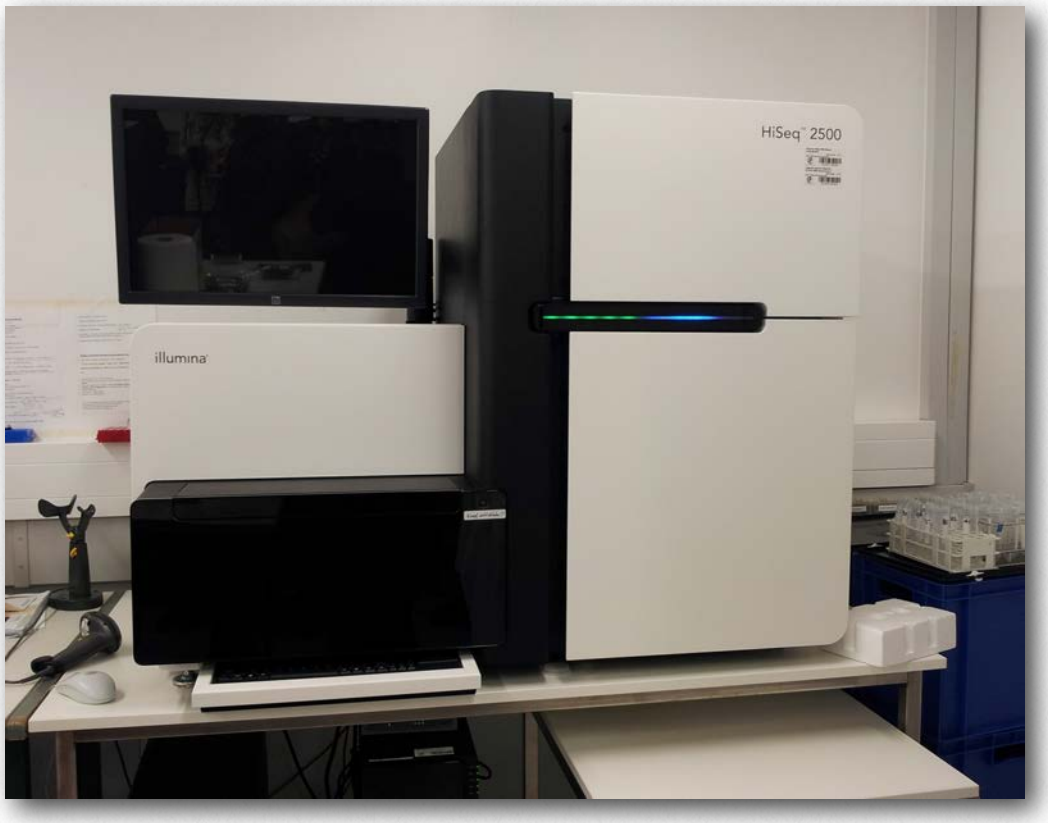

Figure 8.29 - Automated high throughput sequencer
Wikipedia

RNA-Seq

Like microarrays, a newer method called RNA-Seq, is a tool for simultaneously detecting and quantitating all of the transcripts in a given sample. This method relies on recently developed sequencing technologies called next-generation sequencing, or deep sequencing. These techniques allow for rapid, parallel sequencing of millions of DNA fragments and can, thus, be used not only for genomic DNA, but also to sequence all of the reverse-transcribed RNAs from a given sample.

To determine all the protein-coding genes that were being expressed in a particular set of cells under specific physiological conditions, all of the mRNA would first be extracted and reverse-transcribed into cDNA. This step is similar to the preparation of samples for microarrays. However, at this point, the cDNAs are fragmented into smaller pieces, and have small sequencing adapters attached at either end. The fragments are

then subjected to high-throughput sequencing, to obtain short sequences from all of the fragments. These data are aligned against the genome sequence and used to measure the level of expression of different genes. RNA-Seq offers some advantages over microarrays. With microarrays, an RNA can only be detected if the gene sequence corresponding to it is present on the grid. In RNA-Seq every RNA present in the sample is sequenced, so detection of RNAs is not limited by the probes on a chip. RNA-Seq is more sensitive than microarrays and offers a much larger range over which gene expression can be measured accurately.

YouTube Lectures by Kevin HERE & HERE

Isolating genes

Earlier in this chapter, we discussed methods such as column chromatography that are used to purify proteins of interest. Using combinations of these methods, it is possible to isolate a protein to a high degree of purity, thus enabling us to study the protein's activity and properties. This problem is harder to solve for nucleic acids. Genomic DNA can be readily obtained from cells, but is too complex to be analyzed as a whole. Individual genes are the units of DNA that correspond to proteins, and thus, it makes more sense to isolate specific genes for study. Methods to isolate genes were not available till the 1970s, when the discovery of restriction enzymes and the invention of molecular cloning provided, for the first time, ways to obtain large quantities of specific DNA fragments, for study. Although, for purposes of obtaining large amounts of a specific DNA fragment, molecular cloning has been largely replaced by direct amplification using the polymerase chain reaction described later, cloned DNAs are still very useful for a variety of reasons. The development of molecular cloning was dependent on the discovery of restriction endonucleases, described below.

Restriction enzymes

Restriction enzymes, or restriction endonucleases, are enzymes made by bacteria. These enzymes protect bacteria by degrading foreign DNA molecules that are carried into their cells by, for example, an invading bacteriophage. Each restriction enzyme recognizes a specific sequence, usually of four or six nucleotides in the DNA. These sequences, when they occur in the bacterium's own DNA, are chemically modified by methylation, so that they are not recognized and degraded. Where these sequences occur in foreign DNA, they are cut by the restriction enzyme.

The utility and importance of restriction enzymes lies in their ability to recognize specific sequences in DNA and cut near or (usually) at the site they recognize. Over 3000 such enzymes are known. Sequences recognized by these enzymes are typically 4-8 base pairs long and the most commonly used enzymes

Figure 8.30 -A restriction enzyme bound to its recognition sequence on DNA

Wikipedia

which is the same as the bottom strand (read in the same 5' to 3' direction).

While all restriction enzymes must recognize and bind to particular DNA sequences, the exact spot at which they cut the DNA varies. Some enzymes leave a staggered sequence after cutting that has an overhang at the 5' end of one strand of the duplex; some leave a staggered sequence after cutting that has an overhang at the 3' end; and some cut both strands in the same place, leaving no overhanging sequence - called blunt end cutters.

Consider cutting a DNA sequence that contains the Hind III recognition site, which is recognize sequences described as palindromic.

Palindrome

In molecular biology, the term palindrome means that the sequence of the recognition site when read in the 5' to 3' direction for the top strand is exactly the same as that of the bottom strand. Consider the sequence recognized by the restriction enzyme known as Hind III (pronounced hin-dee-three). It is

5' -A-A-G-C-T-T-3'
3' -T-T-C-G-A-A-5'

On the top strand, the recognition sequence is

5' AAGCTT 3'

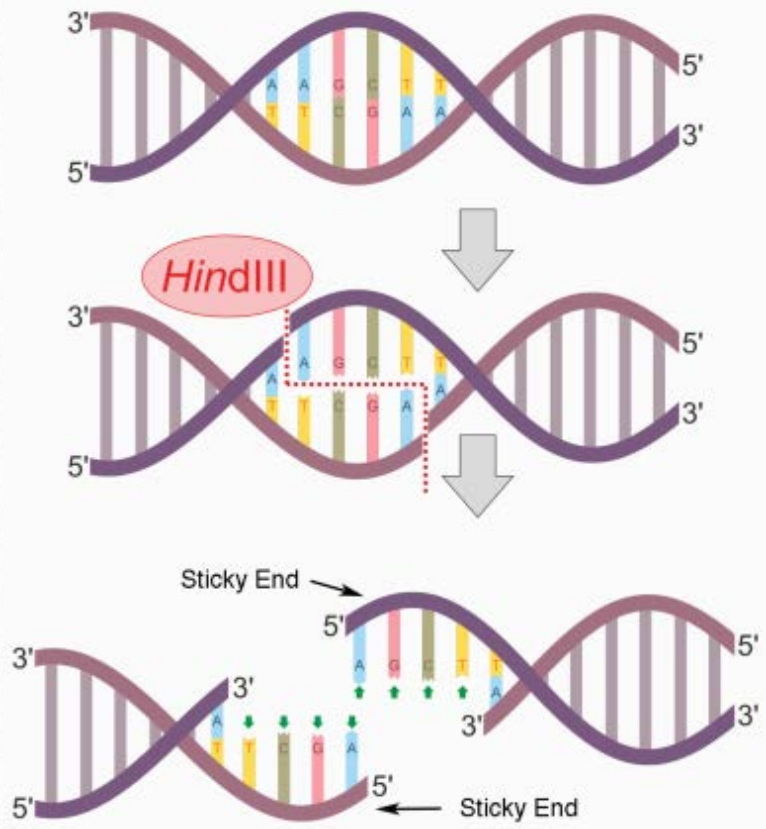

Figure 8.31 - Result of cutting DNA with Hind III

Wikipedia

5’ -A-A-G-C-T-T-3’
3’ -T-T-C-G-A-A-5’

Embedded within a DNA sequence, the Hind III sequence would look like this (Ns correspond to any base and represent all of the DNA around the recognition site).

5’ -N-N-N-A-A-G-C-T-T-N-N-N-3’
3’ -N-N-N-T-T-C-G-A-A-N-N-N-5’

After cutting with Hind III, it would look as follows:

5’ -N-N-N-A 3‘ 5’A-G-C-T-T-N-N-N-N-3’
3’ -N-N-N-T-T-C-G-A-5‘
3’ A-N-N-N-N-5’

where gaps have been inserted to illustrate where cutting has occurred. Hind III cuts between the two ‘A’ containing nucleotides near the 5’ end of the recognition sequence and thus leaves 5’ overhangs (Figure 8.31).

and cuts between the A and the G near the 3’ end of the recognition sequence.

5’ -N-N-N-C-T-G-C-A 3‘ 5’G-N-N-N-N-N 3’
3’ -N-N-N-G 5‘ 3’ A-C-G-T-C-N-N-N-N-N 5’

As you can see, cutting a DNA with Pst I leaves 3’ overhangs of the recognition sequence. The ends left after cutting by a restric-

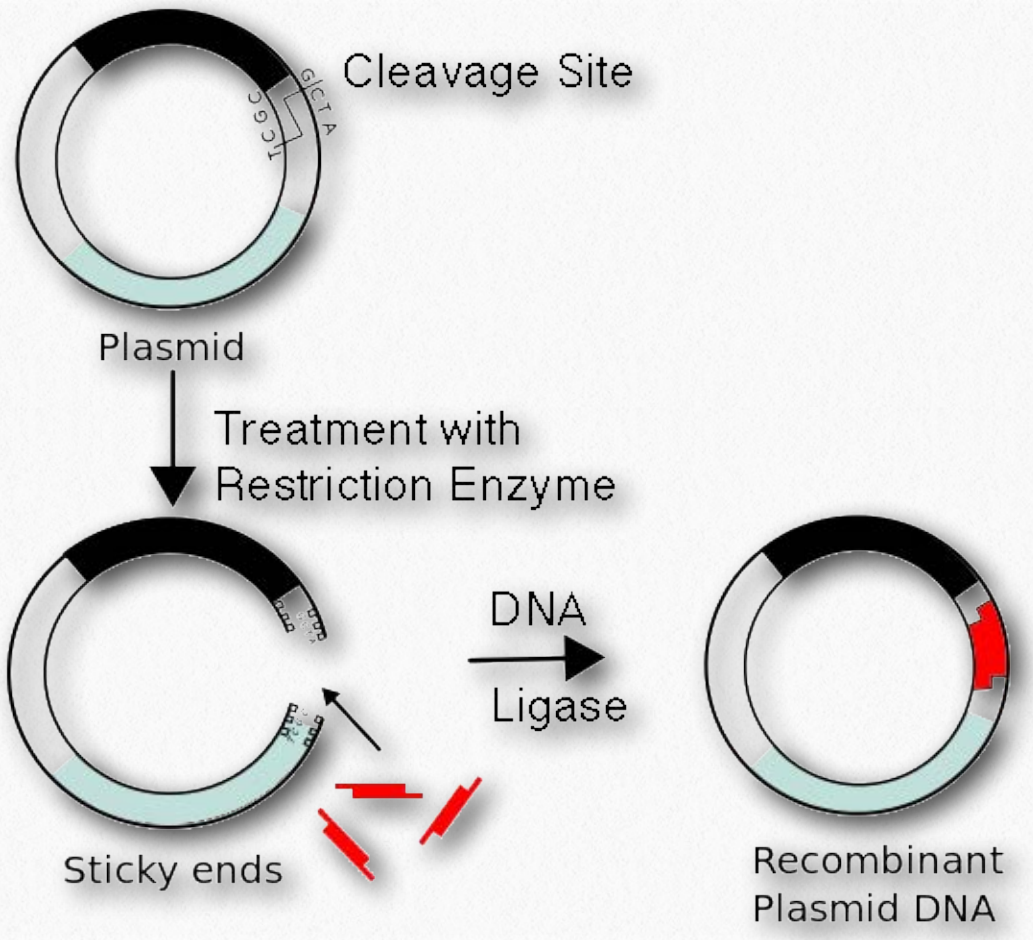

Figure 8.32 - Recombinant DNA construction

Wikipedia

The restriction enzyme Pst I, on the other hand, recognizes the following sequence

5’ -N-N-N-C-T-G-C-A-G-N-N-N-N-3’
3’ -N-N-N-G-A-C-G-T-C-N-N-N-N-5’

tion enzyme that overhang either at the 5’ end or the 3’ end are referred to as being “sticky” because they can form proper base pairs and more readily be joined to a similarly “sticky end”. This means that you can take two unrelated pieces of DNA, cut them with the same restriction enzyme so that they have

compatible sticky ends, and then "paste" them together using DNA ligase to form a new hybrid molecule, or recombinant.

Making recombinant DNAs

Joining together of DNA fragments from different sources creates recombinant DNA. The ability to cut and paste DNA might seem like purely a technical feat, but one key application that arose out of this is molecular cloning. In molecular cloning a gene of interest can be inserted into a vector, usually a plasmid, by cutting both the vector and the gene (called the insert) with the same enzyme to generate sticky ends and joining the two pieces together to generate a recombinant (Figure 8.32). A plasmid is a type of autonomously replicating, extrachromosomal DNA. It is quite simple to extract plasmids from the cells, engineer them to contain the gene of interest and re-introduce the recombinant plasmid into the bacteria. The idea was that when the plasmid DNA was replicated, the extra inserted gene would also be copied. Thus, by growing up a lot of the bacteria carrying the plasmid, many copies of the gene of interest could be obtained, to provide sufficient amounts of the gene to use in experiments. While we now have easier methods to accomplish this goal, cloned DNAs remain very useful. For example, it is possible to clone a gene that encodes a protein of interest so that it can be expressed at high levels in the cells into which the recombinant plasmid is introduced.

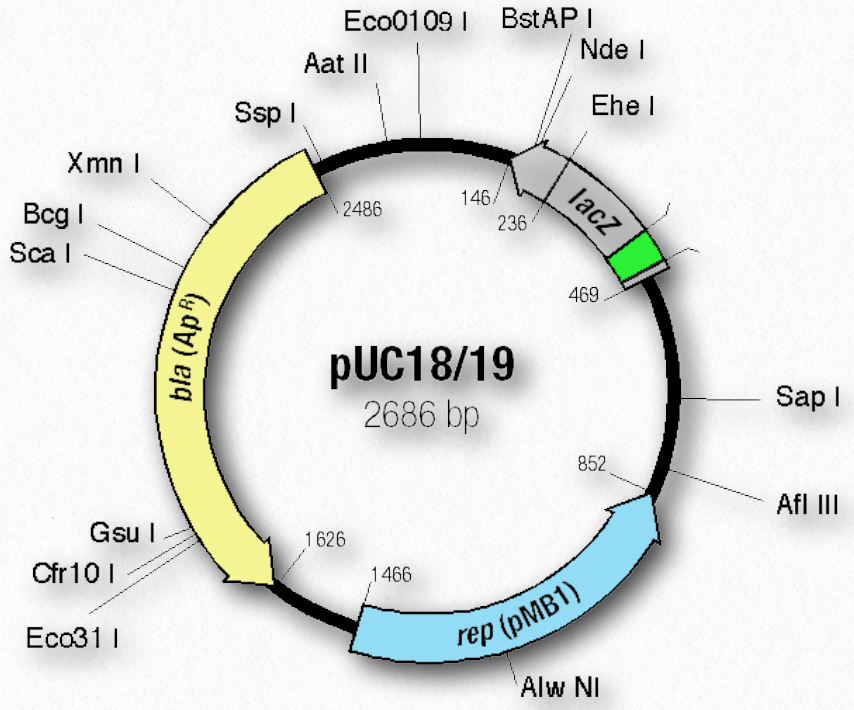

Figure 8.33 - Restriction site map for the pUC 18/19 plasmids, a classic plasmid vector. Genes identified by arrows. Numbers correspond to the pUC 18/19 numbering convention

Whatever the purpose for which the recombinant plasmid is made, it typically carries an antibiotic resistance gene (or genes), called a *selectable marker*. Cells that take up the plasmid will be able to grow in the presence of the antibiotic. If bacterial cells to which the plasmid has been added are plated on agar containing the antibiotic, the cells which took up the plasmid will be able to grow, while the others will not.

Expression cloning

As mentioned above, a gene of interest may be inserted into a vector and the recombinant plasmid be placed into a cell where the gene can be expressed. For instance, one might desire to clone the gene coding for human growth hormone or insulin or other medically important proteins and have a bacterium or yeast make large quantities of it very cheaply. Remember that these are human proteins, and thus it is not feasible to extract the proteins in any quantity from human subjects.

Expression vectors

To clone a gene so that it can be expressed, one needs to set up the proper conditions in order for the human protein to be made in the bacterial cells. This typically involves the use of specially designed plasmids. These plasmids have been engineered to 1) replicate in high numbers; 2) carry markers that allow researchers to identify cells carrying them (antibiotic resistance, for example) and 3) contain sequences (such as a promoter and Shine Dalgarno sequence) necessary for expression of the desired protein, with convenient sites for insertion of the gene of interest in the appropriate place relative to the control sequences. A plasmid which has all of these features is referred to as an expression vector. In addition to plasmids that can be used for expression in bacterial cells, expression vectors are also available that allow protein expression in a variety of eukaryotic cells.

Many sophisticated variations on such vectors have been created that have made it easy to produce and purify large amounts of any pro-

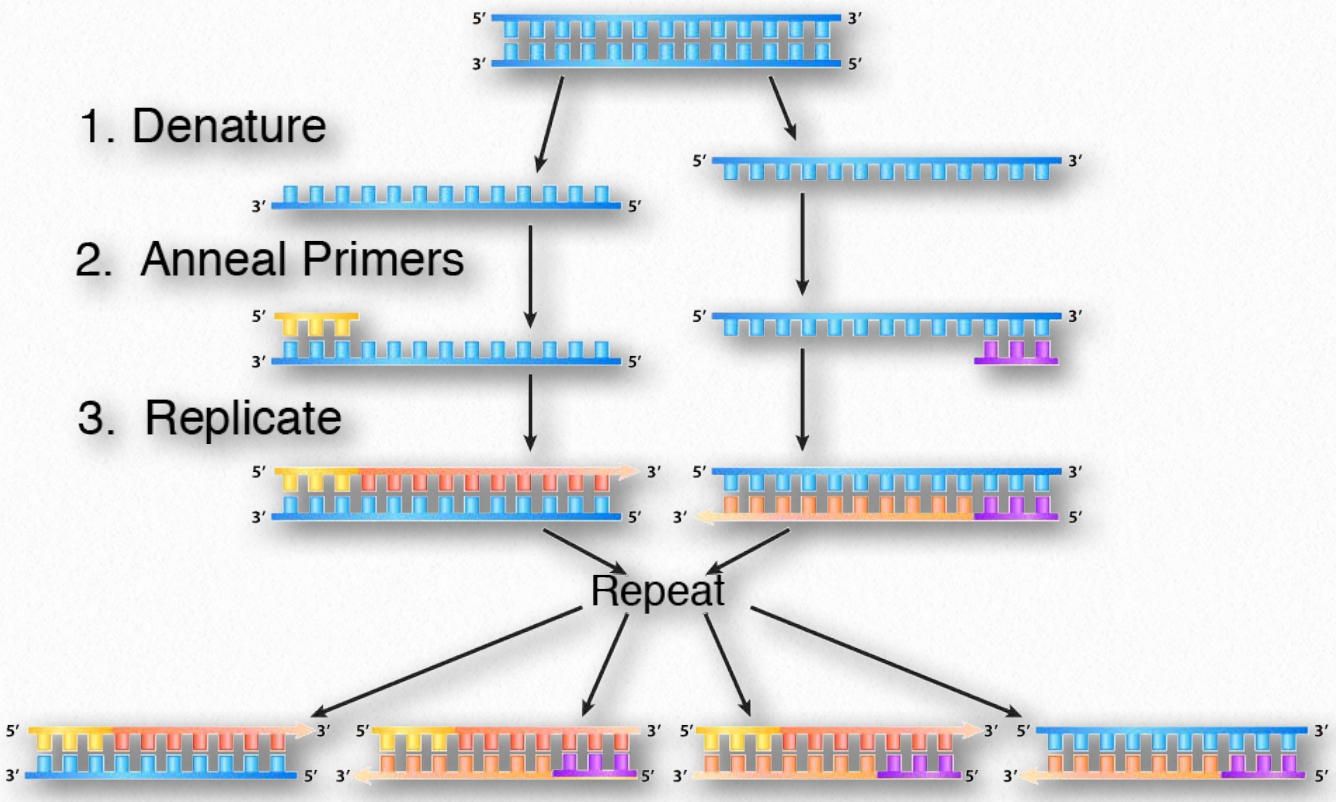

Figure 8.34 - Steps in the polymerase chain reaction

Image by Aleia Kim

tein of interest for which the gene has been cloned. A handy feature in some expression vectors is a sequence encoding an affinity tag either up- or downstream of the gene being expressed. This sequence allows a short affinity tag (such as a run of histidine residues) to be fused onto the encoded protein. The tag can be used to readily purify the protein, as described in the section on affinity chromatography.

Figure 8.35 - PCR tubes with DNA samples ready for reaction

Wikipedia

Polymerase chain reaction (PCR)

As we just saw, molecular cloning was the first method available to isolate a gene of interest and make many copies of it to obtain sufficient amounts of the DNA to study. Today, there is a faster and easier way to obtain large amounts of a DNA sequence of interest -the polymerase chain reaction, or PCR.

PCR allows one to use the power of DNA replication to amplify DNA enormously in a short period of time. As you know, cells replicate their DNA before they divide, and in doing so, double the amount of the cell's DNA. PCR essentially mimics cellular DNA replication in the test tube, repeatedly copying the target DNA over and over, to produce large quantities of the desired DNA.

YouTube Lectures by Kevin HERE & HERE

Selective replication

In contrast to cellular DNA replication, which amplifies all of a cell's DNA during a replication cycle, PCR does targeted amplification to replicate only a segment of DNA bounded by the two primers that determine where DNA polymerase begins replication. Figure 8.34 illustrates the process. Each cycle of PCR involves three steps, denaturing, annealing and extension, each of which occurs at a different temperature.

The starting materials

Since PCR is, basically, replication of DNA in a test-tube, all the usual ingredients needed for DNA replication are required:

A template (the DNA containing the target sequence that is being copied)

Primers (to initiate the synthesis of the new DNA strands)

Thermostable DNA polymerase (to carry out the synthesis). The polymerase needs to be heat stable, because heat is used to separate the template DNA strands in each cycle.

dNTPs (DNA nucleotides to build the new DNA strands).

The template is the DNA that contains the tar-

get you want to amplify (the "target" is the specific region of the DNA you want to amplify). The primers are short synthetic single-stranded DNA molecules whose sequence matches a region flanking the target sequence. It is possible to chemically synthesize DNA molecules of any given base sequence, to use as primers. To make primers of the correct sequence that will bind to the template DNA, it is necessary to know a little bit of the template sequence on either side of the region of DNA to be amplified. DNA polymerases and dNTPs are commercially available from biotechnology supply companies.

Figure 8.36 - A PCR thermocycler system

Wikipedia

First, all of the reagents are mixed together. Primers are present in millions of fold excess over the template. This is important because each newly made DNA strand starts from a primer. The first step of the process involves separating the strands of the target DNA by heating to near boiling.

Interactive Learning Module HERE

Next, the solution is cooled to a temperature that favors complementary DNA sequences finding each other and making base pairs, a process called annealing. Since the primers are present in great excess, the complementary sequences they target are readily found and base-paired to the primers. These primers direct the synthesis of DNA. Only where a primer anneals to a DNA strand will replication occur, since DNA polymerases require a primer to begin synthesis of a new strand.

Extension

In the third step in the process, the DNA polymerase replicates DNA by extension from the 3' end of the primer, making a new DNA strand. At the end of the first cycle, there are twice as many DNA molecules, just as in cellular replication. But in PCR, the process is repeated, usually for between 25 and 30 cycles. At the end of the process, there is a theoretical yield of 2^{30} (over 1 billion times) more DNA than there

was to start. (This enormous amplification power is the reason that PCR is so useful for forensic investigations, where very tiny amounts of DNA may be available at a crime scene.)

The temperature cycles are controlled in a thermocycler, which repeatedly raises and lowers temperatures according to the set program. Since each cycle can be completed in a couple of minutes, the entire amplification can be completed very rapidly. The resulting DNA is analyzed on a gel to ensure that it is of the expected size, and depending on what it is to be used for, may also be sequenced, to be certain that it is the desired fragment.

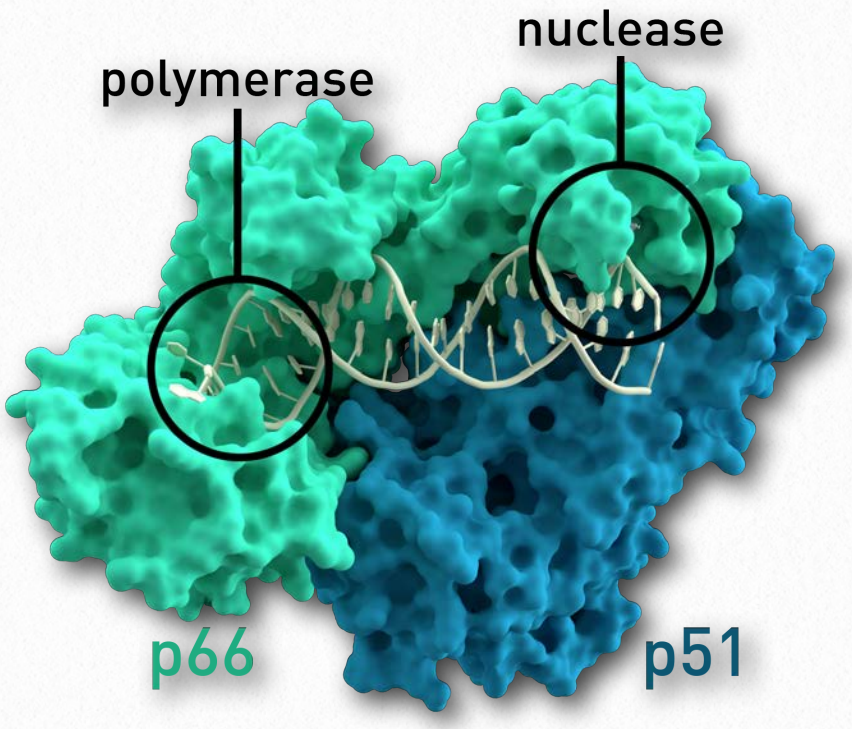

Figure 8.37 - Reverse transcriptase of HIV. The nuclease function is needed for the viral life cycle, but not for lab use.

Wikipedia

Mutagenesis

PCR is frequently used to obtain gene sequences to be cloned into vectors for protein expression, for example. Besides simplicity and speed, PCR also has other advantages. Because primers can be synthesized that differ from the template sequence at any given position, it is possible to use PCR for site-directed mutagenesis. That is, PCR can be used to mutate a gene at a desired position in the sequence. This allows the proteins encoded by the normal and mutant genes to be expressed, purified and compared.

Analysis of gene expression

PCR can also be used to measure gene expression. Where in PCR the amount of amplified product is not determined till the end of all the cycles, a variation called quantitative real-time PCR is used, in which the accumulation of product is measured at each cycle. This is possible because real-time PCR machines have a detector module that can measure the levels of a fluorescent marker in the reaction, with the amount of fluorescence proportional to the amount of amplified product. By following the accumulation of product over the cycles it is possible to calculate the amount of starting template. To measure gene expression, the template used is mRNA reverse-transcribed into cDNA (see below). This coupling of reverse transcription with quantitative real-time PCR is called qRT-PCR.

Reverse transcription

In the central dogma, DNA codes for mRNA, which codes for protein. One known exception to the central dogma is exhibited by retroviruses. These RNA-encoded viruses have a phase in their life cycle in which their genomic RNA is converted back to DNA by a virally-encoded enzyme known as reverse transcriptase. The ability to convert RNA to DNA is a method that is desirable in the laboratory for numerous reasons. For example, converting RNAs of interest to cDNA is used in RT-PCR as well as in other applications like microarray analysis.

Process

First, one creates a DNA oligonucleotide to serve as a primer for reverse transcriptase to use on a target RNA. The primer must, of course, be complementary to a segment (near the 3' end) of the RNA to be amplified. The RNA, reverse transcriptase, the primer, and four dNTPs are mixed. With one round of replication, the RNA is converted to a single strand of DNA. Denaturation frees the single stranded cDNA, which can be used as is, or converted to double-stranded cDNA, depending on the application.

Detecting molecular interactions

The study of biochemistry is basically the study of the interactions of cellular molecules. Methods for detecting interactions among biomolecules are, for this reason, very useful to biochemists. We will now discuss a couple of very different methods for detecting these inter-molecular interactions.

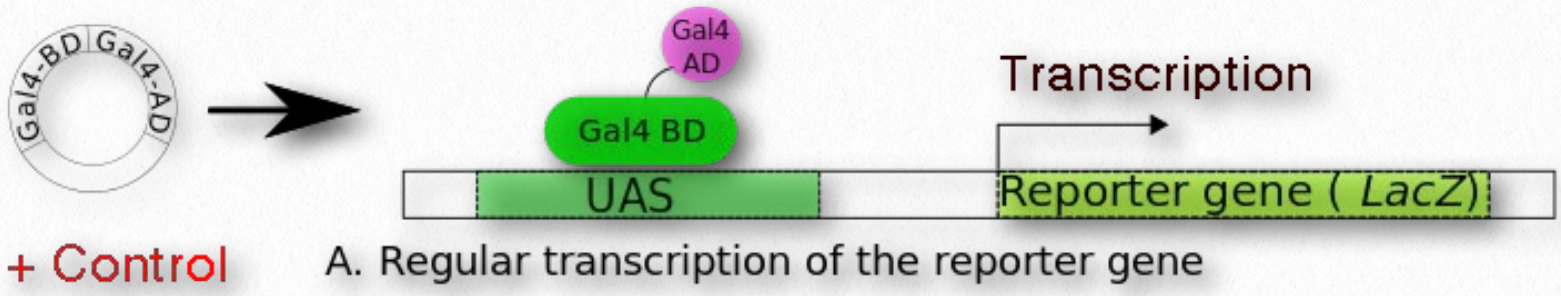
Yeast two-hybrid system (Y2H)

Yeast two-hybrid screening is a sophisticated technique for identifying which protein(s), out of a collection of all of a cell's proteins, interacts with a specific protein of interest. The method relies on the interaction between two proteins to reconstitute a functional transcriptional activator within yeast cells. You may remember that many transcriptional activators are modular proteins that have a domain that binds to DNA and another domain that activates transcription (Figure 8.38).

Figure 8.38 - Structure of a eukaryotic transcriptional activator, showing the DNA-binding domain (DBD) and transcriptional activation domain (TAD).

Wikipedia

If the transcription factor is split, so that the binding domain is attached to one protein, and the activation domain to another protein, a functional transcriptional activator can only be re-created if the two "carrier"proteins come into close proximity - that is, they inter-



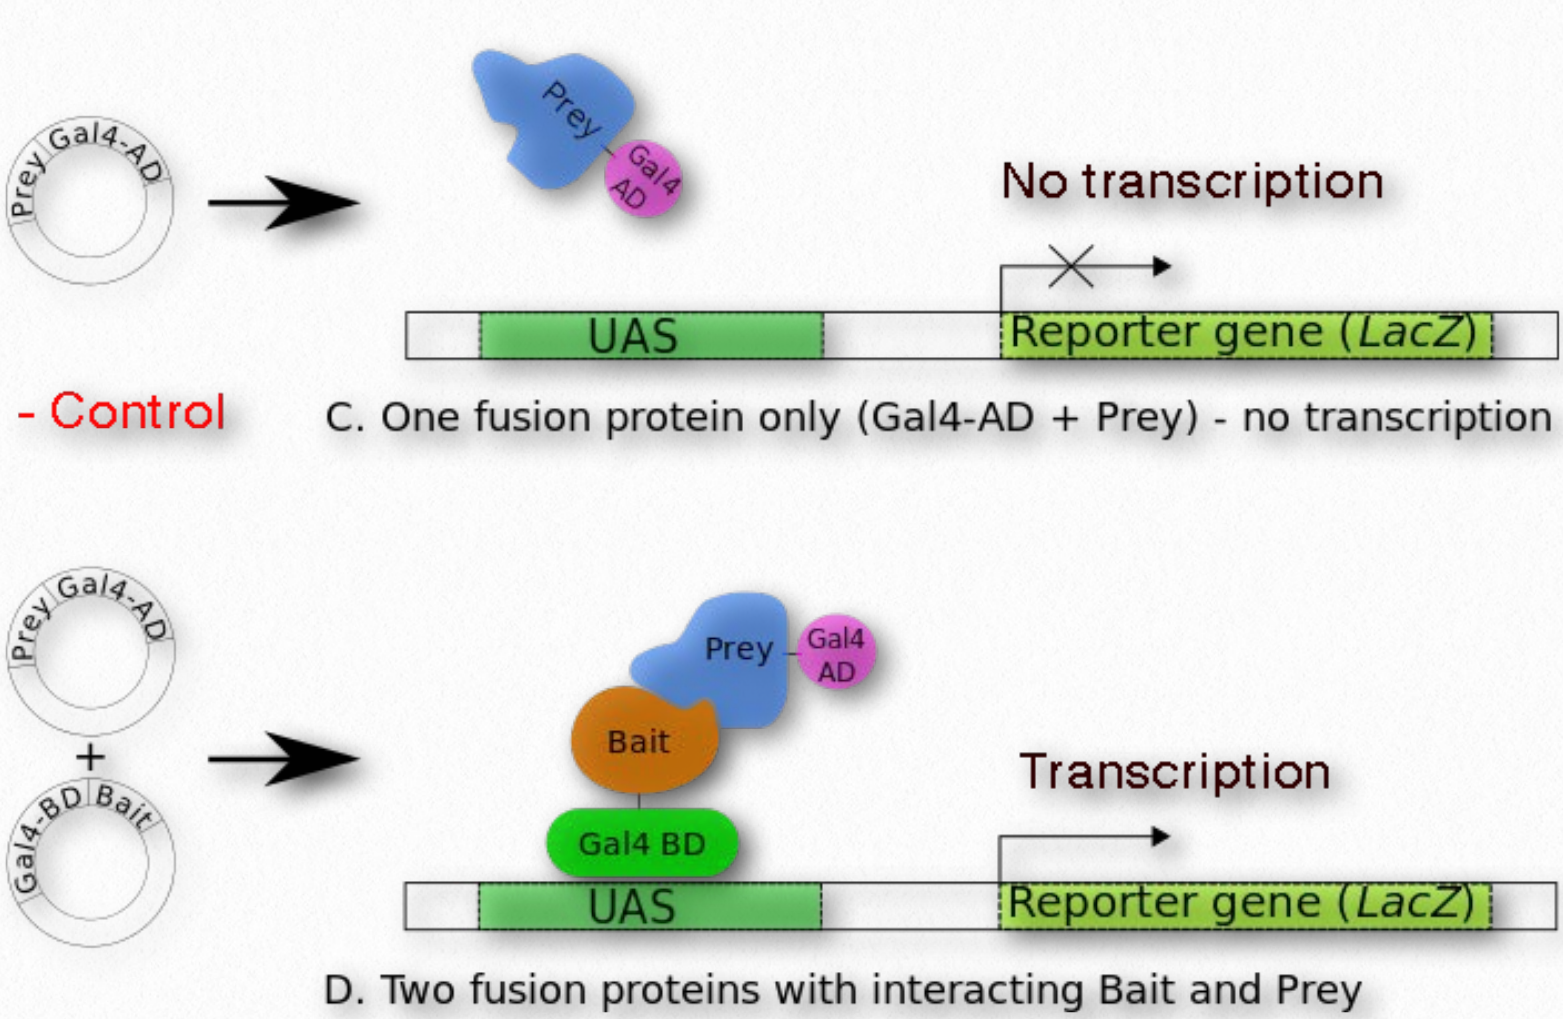


Figure 8.39 - Four scenarios for the yeast two-hybrid system. UAS = Upstream Activator Sequences - acts like a promoter. Scenario A shows that the two transcription factors start out as one protein

Wikipedia

act. The presence of this functional activator can be detected by the expression of a reporter gene.

A simple way to understand this idea is by thinking of a transcriptional activator as a device, like a flashlight, that has two parts, the battery and the lamp, that must be together in order to function. Neither a person who has just a battery nor one who has only the lamp will be able to see in a dark room. But if the two interact by coming close enough to insert the battery in the flashlight, their interaction can be detected by the fact that the flashlight will now be functional as evidenced by the light produced.

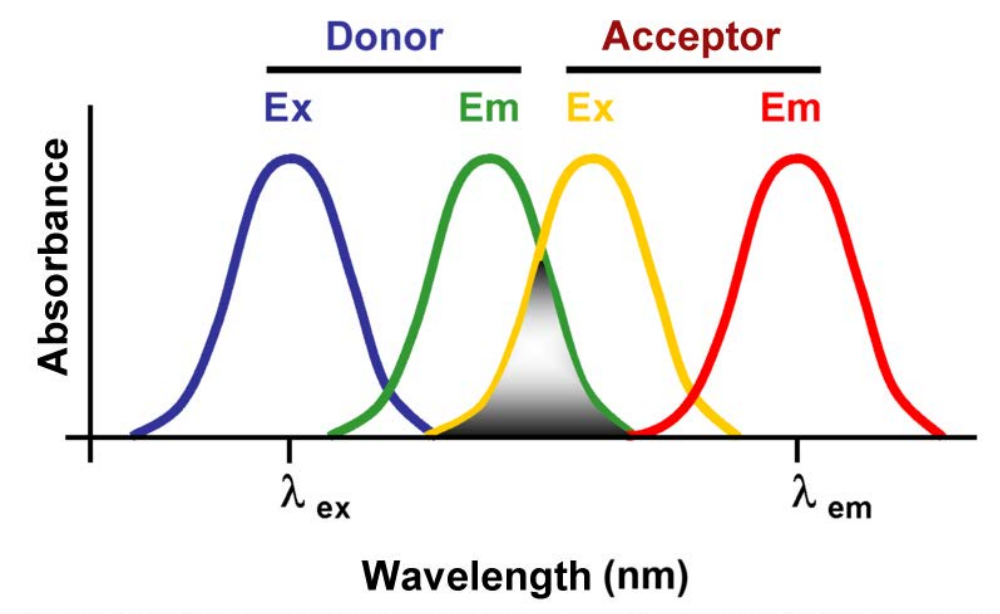

Figure 8.40 - Excitation and emission spectra for donor and acceptor fluorophores in FRET

Wikipedia

It takes two to tango

Figure 8.39 (A) shows the normal yeast transcriptional activator, GAL4, with both the DNA-binding (DBD) and Activation domains (AD). It is able to stimulate transcription of the downstream reporter gene, *lac z*. Panels B and C show constructs that produce the GAL4 DBD and AD, respectively, fused to other proteins, one of which is termed the "bait" and the other as "prey". Neither of these fusion proteins can stimulate transcription of the *lac z* gene. When constructs encoding both the bait and prey are in the same yeast cell, if the bait protein interacts with the prey, the DBD and AD of the GAL4 will be brought together to reconstitute a functional GAL4. The presence of functional GAL4 is readily detectable because it will stimulate expression of the l*ac z* reporter gene. If the bait and prey proteins do not interact, then there will be no lac z expression.

When interaction is detected through expression of the reporter gene, the specific prey protein can then be identified.

YouTube Lectures by Kevin HERE & HERE

The yeast two-hybrid system allows for simultaneous screening of many prey proteins, by constructing large collections of fusion constructs, with each potential protein partner of the bait protein fused to the GAL4 activation domain.

FRET

Another method for detecting molecular interactions is Fluorescence resonance energy transfer (FRET) - also called Förster reso-

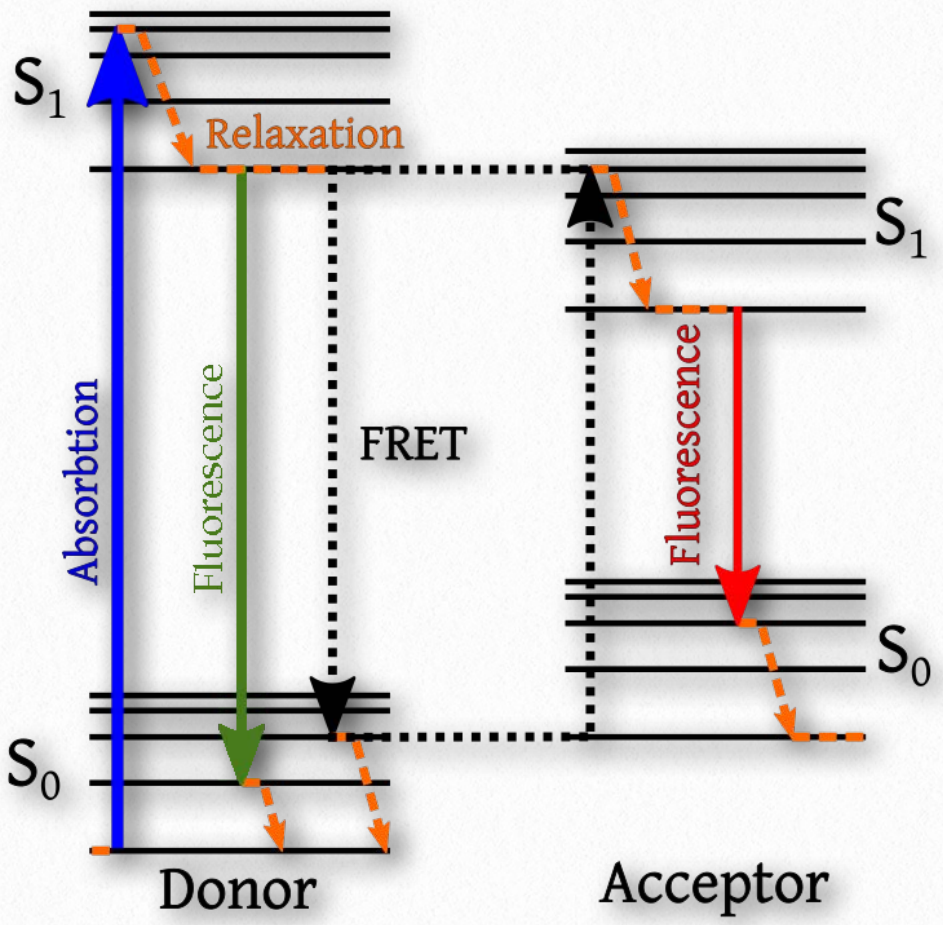

Figure 8.41 - Fluorescence resonance energy transfer between donor and acceptor chromophores

Image by Pehr Jacobson

nance energy transfer, resonance energy transfer (RET) or electronic energy transfer (EET). The technique is based on the observation that a molecule excited by the absorption of light can transfer energy to a nearby molecule if the emission spectrum of the first molecule overlaps with the excitation spectrum of the second (Figure 8.40) This transfer of energy can only take place if the two molecules are sufficiently close together (no more than a few nanometers apart).

Design

In the technique, a donor fluorophore or an acceptor fluorophore is covalently attached to two molecules of interest. The acceptor fluorophore is designed to accept energy from the donor molecule (orange dotted line in Figure 8.41) and fluoresce at a unique wavelength (red arrow) when it receives that energy from the donor.

Further, the wavelength of light that the donor absorbs is uniquely tailored for the donor fluorophore and has no effect on the acceptor fluorophore. The only way the acceptor can fluoresce is if it is close enough to receive energy transferred from the donor (red arrow). This fluorescence will have a unique wavelength, as well. If the donor and acceptor are not close enough together, the donor fluoresces and emits light corresponding to the green or black arrow. These are different wavelengths than that of the red arrow.

The experiment begins in the cell with one protein with a donor fluorophore and the other protein with an acceptor fluorophore. Light of a wavelength that excites the donor fluorophore is shined on the cell. If a protein with a donor interacts with the protein carrying an acceptor, then energy transfer occurs from the donor fluorophore to the acceptor and the unique fluorescence (red line) of the acceptor is detected. If the two proteins do not interact, then little or no fluorescence from the acceptor is detected.

Genome editing

The development of tools that would allow scientists to make specific, targeted changes in the genome has been the Holy Grail of molecular biology. An ingenious new tool that is both simple and effective in making precise changes is poised to revolutionize the field, much as PCR did in the 1980s. Known as the CRISPR/Cas9 system, and often abbreviated simply as CRISPR, it is based on a sort of bacterial immune system that allows bacteria to recognize and inactivate viral invaders.

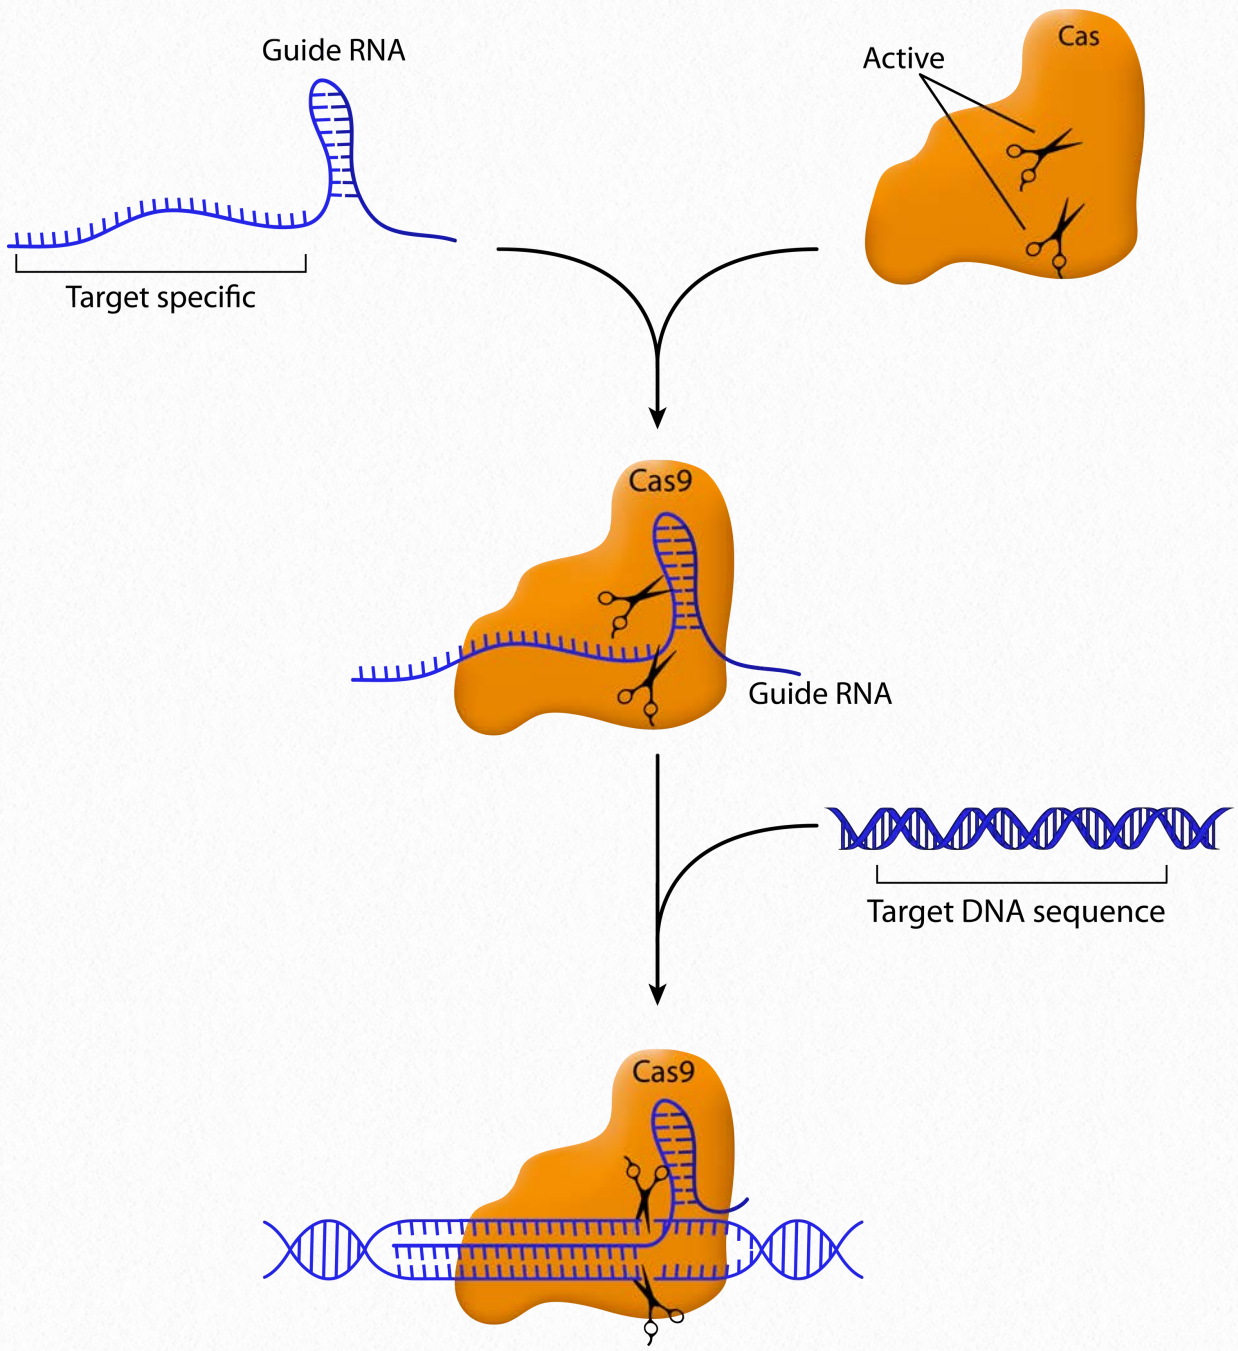

Figure 8.42 - A guide RNA directs the Cas9 nuclease to its target gene

Image by Pehr Jacobsen

CRISPR stands for Clustered Regularly Interspaced Short Palindromic Repeats, short repeated sequences found in prokaryotic DNA, separated by spacer sequences derived from past encounters with, for example, a bacteriophage. Like the glass slipper left behind by Cinderella that was later used to identify her, the pieces of the invader's sequences are a way for the bacteria to identify the virus if it attacks again. Inserted into the bacterial genome, these sequences can later be transcribed into a guide RNA that matches, and base-pairs with, sections of the viral genome if it was encountered again. A nuclease associated with the guide RNA then cleaves the sequence base-paired with the guide RNA. (The nucleases are named Cas for CRISPR-associated.)

The essential elements of this system are a guide RNA that homes in on the target sequence and a nuclease that can make a cut

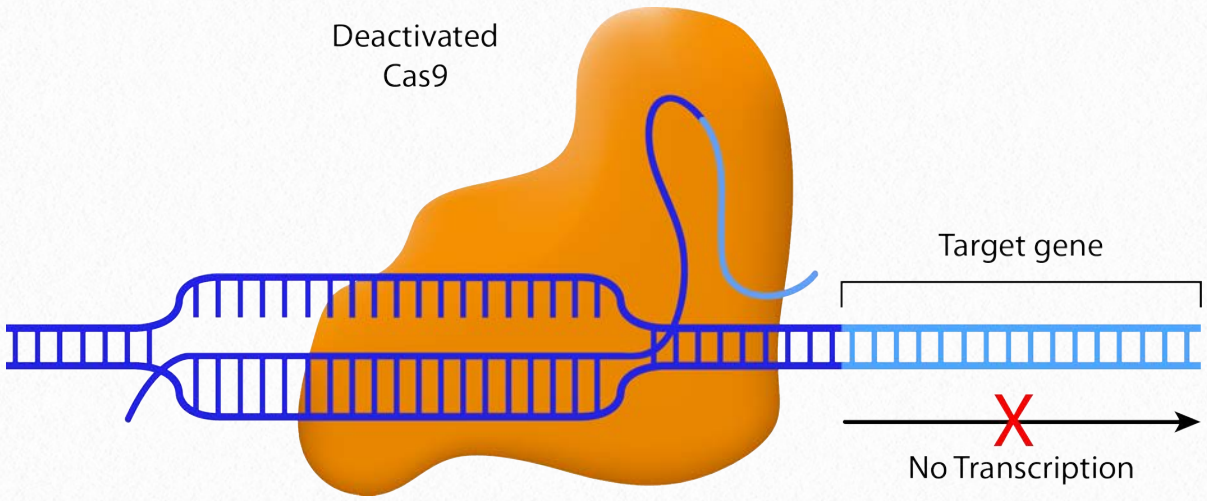

Figure 8.43 - Inactive Cas9 can block transcription of a target gene

Image by Pehr Jacobsen

in the sequence that is bound by the guide RNA. By engineering guide RNAs complementary to a target gene, it is possible to target the nuclease to cleave within that gene. In the CRISPR/Cas9 system, the Cas9 endonuclease cuts both strands of the gene sequence targeted by the guide RNA (Figure 8.42). This generates a double-strand break that the cell attempts to repair.

As you may remember, double-strand breaks in DNA can be repaired by simple, non-homologous end joining (NHEJ) or by homologous recombination. When a break is fixed by NHEJ, there is good chance that there will be deletions or insertions that will inactivate the gene they are in. Thus, targeted cleavage of a site by CRISPR/Cas9 can easily and specifically inactivate a gene, making it easy to characterize the gene's function.

Interactive Learning Module HERE

But, what if you wished to simply mutate the gene at a specific site to study the effect of the mutation? This, too, can be achieved. If a homologous sequence bearing the specific mutation is provided, homologous recombination can repair the break, and at the same time insert the ex-

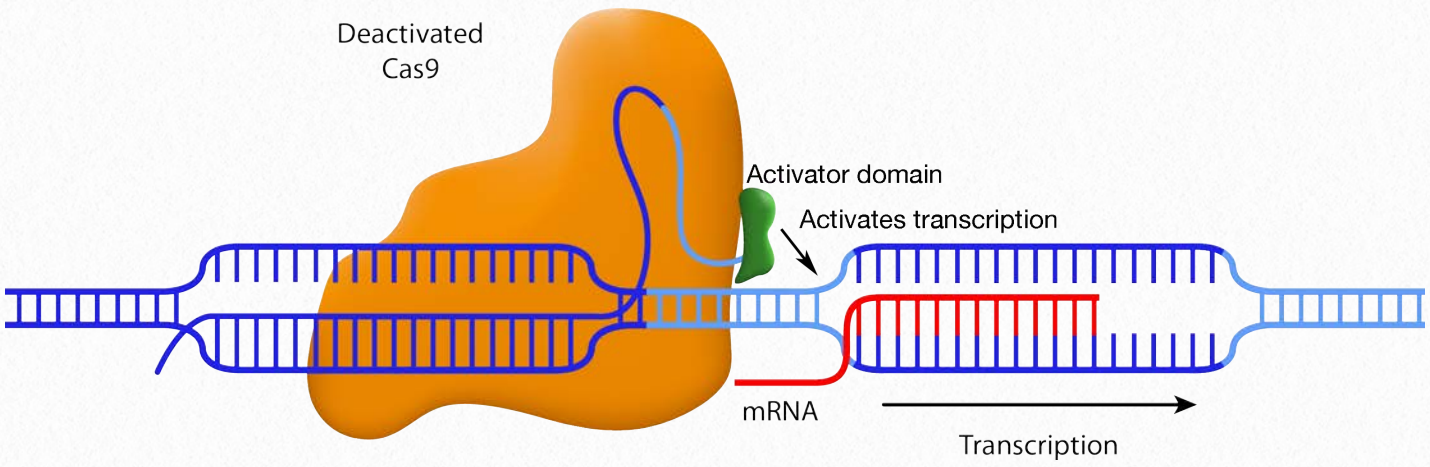

Figure 8.44 - A Cas9-activator domain fusion can activate transcription of a target gene

Image by Pehr Jacobsen

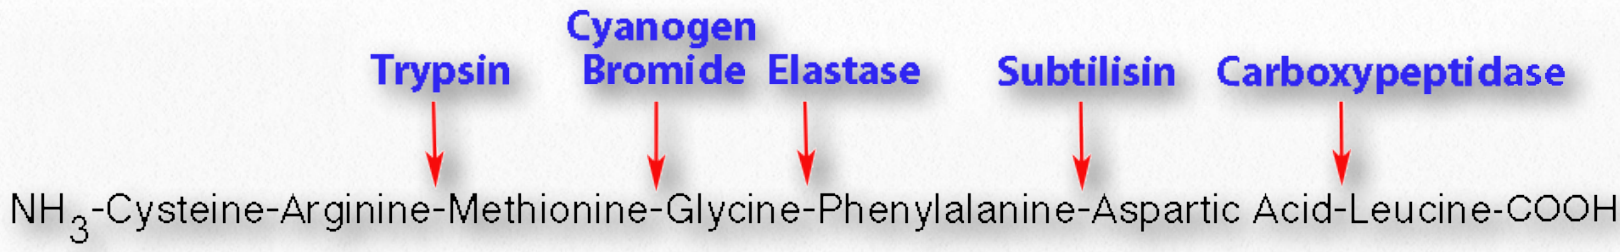

Figure 8.45 - Protease cleavage sites on a polypeptide

act mutation desired. It is obvious that if you can insert a mutation as just described, it should be possible to correct a mutation in the genome by cleaving at the appropriate spot and providing the correct sequence as a template for repair by homologous recombination. The simplicity of the system holds great promise for curing genetic diseases.

Scientists have also come up with some creative variations on the CRISPR/Cas9 system. For instance, one variant inactivates the nuclease activity of Cas9. The guide RNA in this system pairs with the target sequence, but the Cas9 does not cleave it. Instead, the Cas9 blocks the transcription of the downstream gene (Figure 8.43) This method allows specific genes to be turned off without actually altering the DNA sequence.

Another variation also uses a disabled Cas9, but this time, the Cas9 is fused to a transcriptional activation domain. In this situation, the guide RNA positions the Cas9-activator domain in a place where it can enhance transcription from a specific promoter (Figure 8.44). Other variations on this theme attach histone-modifying enzymes or DNA methylases to the inactive Cas9. Again, the guide RNA positions the Cas9 in the desired spot, and the enzyme attached to Cas9 can methylate the DNA or modify the histones in that region.

Protein Cleavage Agent Cut Sites

Subtilisin - C-terminal side of large uncharged side chains

Chymotrypsin - C terminal side of aromatics (Phe, Tyr, Trp)

Trypsin - C-terminal side of lysine and arginines (not next to proline)

Carboxypeptidase - N-terminal side of C-terminal amino acid

Elastase - Hydrolyzes C-side of small AAs (Gly, Ala)

Cyanogen Bromide (chemical) - Hydrolyzes C-side of Met

CRISPR has already been used to edit genomes in a wide variety of species (and in human cell cultures). It may not be long before the technique is approved for clinical use. In the meanwhile, CRISPR is transforming molecular biology.

Protein cleavage

Because of their large size, intact proteins can be difficult to study using analytical techniques, such as mass spectrometry. Consequently, it is often desirable to break a large polypeptide down into smaller pieces. Proteases are enzymes that typically break peptide bonds by binding to specific amino acid sequences in a protein and catalyzing their hydrolysis.

Chemical reagents, such as cyanogen bromide, which cleaves peptide bonds on the C-terminal side of a methionine residue can also be used to cut larger proteins into smaller peptides. Common proteins performing this activity are found in the digestive system and are shown in the yellow box below.

Determining mass and protein sequence

Mass spectrometry, as its name suggests, is a method that can be used to determine the masses of molecules. Once limited to analyzing small molecules, it has since been adapted and improved to allow the analysis of biologically important molecules like proteins and nucleic acids. Mass spectrometers use an electrical field to accelerate an ionized molecule toward a detector. The time taken by an ionized molecule to move from its point of ionization to the detector will depend on both its mass and its charge and is termed its time of flight (TOF).

Figure 8.46 - A desktop MALDI-TOF system

MALDI-TOF

MALDI-TOF (Matrix-assisted Laser Desorption Ionization - Time of Flight) is an analytical technique allowing one to determine the molecular masses of biologically relevant

molecules with great precision. It is commonly used in proteomics and determination of masses of large biomolecules, including nucleic acids. The development of MALDI, which permits the production of ionic forms of relatively large molecules, was crucial to the successful use of mass spectrometry of biomolecules. Figure 8.46 shows a compact MALDI-TOF system.

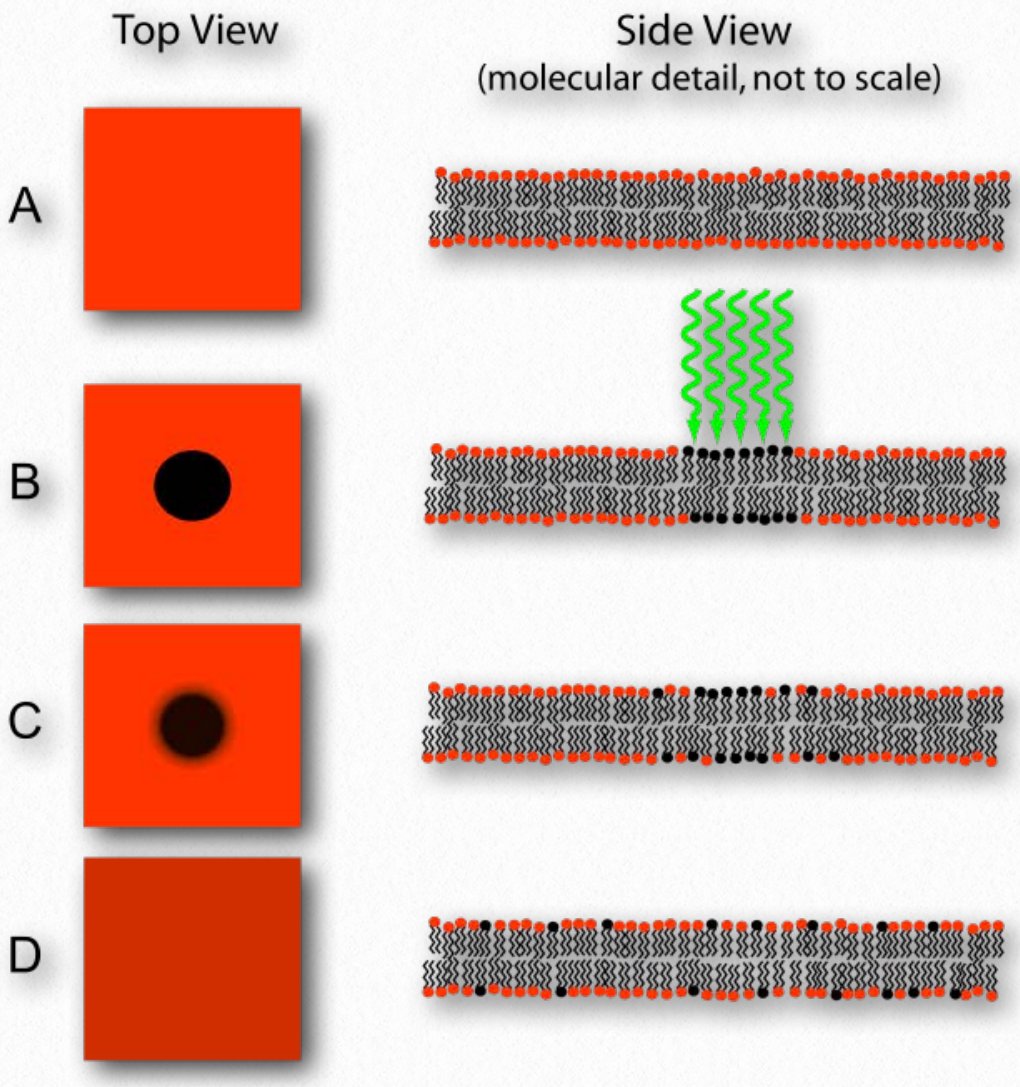
The MALDI-TOF process involves three basic steps. First, the material to be analyzed is embedded in solid support material (matrix) that can be volatilized in a vacuum chamber by a laser beam. In the second part of the process, a laser focused on the matrix volatilizes the sample, causing the molecules within it to vaporize and, in the process, to form ions by either gaining or losing protons. Third, the ions thus created in the sample are accelerated by an electric field towards a detector. Their rate of movement towards the detector is a function of the ratio of their mass to charge (m/z). An ion with a mass of 100 and a charge of +1 will move twice as fast as an ion with a mass of 200 and a charge of +1 and at the same rate as an ion with a mass of 200 and a charge of +2. Thus, by precisely determining the time it takes for an ion to go from ionization (time zero of the laser treatment) to being detected, the mass to charge ratio for all of the molecules in a sample can be readily determined.

Ionization may result in destabilization of larger molecules, which fragment into smaller ones in the MALDI-TOF detection chamber. The size of each of the sub-fragments of a larger molecule allows one to determine its identity if this is not previously known. This fragmentation can be intentionally enhanced by having the accelerated ions collide with an inert gas, like argon.

Fragmentation of a molecule may also be carried out prior to analysis, as for example, by cleaving a protein into smaller peptides by the use of enzymes or chemical agents. The amino acid sequence of a protein may be determined by using MALDI-TOF by analyzing the precise molecular masses of the many short peptide fragments obtained from a protein. When one amino acid, for example, fragments from a larger peptide, this can be detected as the difference in mass between the fragment with and without the amino acid, since each amino acid will have a characteristic molecular mass. By peptide mass fingerprinting and analysis of smaller fragments of individual peptides, the entire sequence of a polypeptide can, thus, be determined.

Membrane dynamics

Understanding the dynamics of movement in the membranes of cells is the province of the Fluorescence Recovery After Photobleaching (FRAP) technique (Figure 8.47). This optical technique is used to measure the two dimensional lateral diffusion of mole-



bleached using a laser (Step B). The spread of the bleached molecules is followed using a microscope (Step C). Information obtained in this manner provides data about the rate of lateral diffusion occurring in a lipid bilayer (Step D).

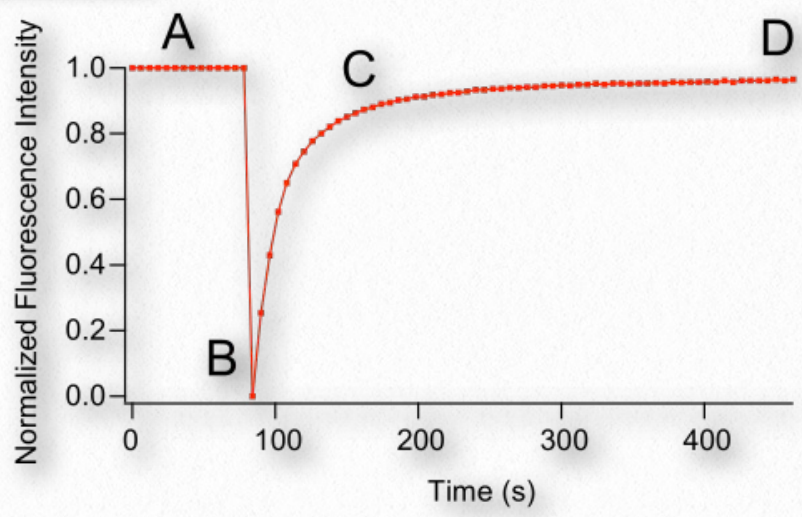


Figure 8.47 - FRAP analysis

Wikipedia

cules in thin films, like membranes, using fluorescently labeled probes. It also has applications in protein binding.

In the method, a lipid bilayer is uniformly labeled with a fluorescent tag (Figure 8.47, Step A) and then a subset of the tag is

The Restriction Enzyme Song

To the tune of "*Chim Chim Cher-ee*"

Metabolic Melodies Website HERE

I'm obsessed with A-A-G-C-T-T
Cuz it is the binding site of Hin-d-III
Cutting up DNA most readily
The ends are not blunt when they're cut up you see

Five prime overhangs of A-G-C-T

Bacteria don't have an immune system so
They must fight off phages or they will not grow
Protection by chopping is their strategy
And one of the cutters we call Hin-d-III

On binding to A-A-G-C-T-T
The site recognition site's bent easily
Phosphodiester attacking meanwhile
Has water behaving as nucleophile

To stave off the phage for a little while

Why don't these enzymes cut cell DNAs?
The answer's provided by their methylase
Adding a methyl group on top of what
The sequence these enzymes would otherwise cut

So cells get protected in this simple way
From nuclease chewing of their DNA
The phage is not lucky in most every case
Unless methylases win the enzyme race

If that happens then, the cell gets erased

Lyrics by Kevin Ahern

No Recording Yet For This Song

I’ve Just Run a Gel

To the tune of “*I Just Saw a Face*”

Metabolic Melodies Website HERE

I’ve just run a gel. I do not think it went too well
I may have used a bit much SDS.
The stacker’s looking like a mess. It’s true
Oh now what will I do?

The protein sample’s my last one. To purify it was not fun
I spent three weekends working late.
The middle lanes aren’t looking great. I’m screwed
Good God what will I do?

Crawling.
I’m almost bawling
The boss is calling to follow through

I just loaded all I’ve got to make this final western blot
My fingers are both crossed for sure
I hope my protein product’s pure. I do
Then my thesis is through

Hating.
All of the waiting
I’m contemplating what I should do

Staining.
My eyes are straining
There’s no complaining. I say ‘wahoo’

‘Cuz it has the band I need
I’ll go and have it scanned to speed
The writing of my thesis and
Proceed onto the post-doct’ral plan
Oh that will be so grand

Pieces make up my thesis.
No more ‘phoresis. The promised land.

Writing so unexciting.
But no more biting. My nails again.

Writing is coinciding.
With reference citing. I’m at the end.

Lyrics by Kevin Ahern

The Proteins Marching One by One

To the tune of "*The Ants Go Marching One by One*"

Metabolic Melodies Website HERE

Oh there's a method you should know that's very huge
It's spinning round and round inside the centrifuge
The supernatant, pellet too
You choose the one that's right for you
And from there we pu-ri-fy
What's inside

To size exclude filtration is the way to go
The beads have pores small proteins can go in you know
The largest ones, they come out fast
The smallest ones eluting last
And the proteins purified
By their size

Electrons power gel e-lec-tro-pho-re-sis
The protein is denatured thanks to SDS
Proteins in a minus state
Get sorted by atomic weight
Smaller ones in speedy mode
To the anode

Ion exchange is special chromatography
To switch cations, you must have a minus bead
Upon this bead, the proteins bind
They're positive, not any kind
And the others wash right through
Out to you

Oh my this song has given you a mighty list
Perhaps we'll just skip over ol' dialysis
So study HPL and C
If you have questions, talk to me
You will get through protein hell
You'll do well.

Recording by David Simmons
Lyrics by Taralyn Tan

Point by Point

“It is not how much we have, but how much we enjoy, that makes happiness.”

-Charles Spurgeon

Students always ask us for study guides so when we designed this book, we decided to build in chapter and section summaries to help in this capacity. That’s what follows in this chapter. We hope you find them helpful in your studies.x

Point by Point: In the Beginning

Basic Biology

- Cells are the fundamental units of life
- Three main branches of cells - prokaryotes, eukaryotes, and archaeans
- All cells have 1) plasma membrane; 2) ribosomes; 3) cytoplasm
- The plasma membrane has a lipid bilayer, proteins, and cholesterol
- Phototrophs get energy from light
- Chemotrophs get energy from oxidation of chemicals
- Autotrophs synthesize their own organic compounds from CO2
- Heterotrophs get organic compounds from other organisms
- Eukaryotic cells contain numerous organelles not found in prokaryotes and archaeans
- Eukaryotic organelles include nucleus, lysosomes, mitochondria, chloroplasts (plants), endoplasmic reticulum, nu-

cleolus, Golgi apparatus, endosomes, plastids (plants), and vacuoles.

- Archaeans similar to bacteria, but often found in extreme environments
- All bacteria are unicellular
- Most eukaryotes are multicellular
- Unicellular eukaryotes include yeast and protists
- Bacteria have a peptidoglycan cell wall not found in eukaryotes
- Eukaryotes have a cytoskeleton containing microtubules, microfilaments, and intermediate filaments.
- Eukaryotic DNAs are generally much bigger than in prokaryotes
- Eukaryotic DNAs are arranged in chromatin with histone proteins. Prokaryotic DNAs arranged in nucleoids
- The cytoskeleton has roles in signaling, endocytosis, chromosome segregation, cell division.
- Microtubules arise from polymerization of **α**- and **β**-tubulin
- Epithelial tissues line the cavities and surfaces of blood vessels and organs in the body ad are categorized by their shapes: squamous, columnar, and cuboidal.
- The underlying connective tissue is known as the basement membrane.
- Four types of tissue in animals - epithelium, connective tissue, nerve tissue, and muscle tissue.
- Connective tissue is the glue that holds all together.
- Nerve tissue has central nervous system (brain and spinal cord) and peripheral nervous system (nerves and ganglia)
- Nerve cells = neurons
- Muscle tissue - 3 types - 1) skeletal/striated muscle; 2) smooth, non-striated muscle; and 3) cardiac muscle
- Secretory pathways move proteins out of cells

Basic Chemistry

- Single bonds can rotate. Double bonds cannot
- Double-bonded carbons create a planar structure with angles of 120°
- Single-bonded carbons create tetrahedral structures with angles of 109.5°
- Important organic structures needed to understand biochemistry include alkanes, alkenes, alcohols, esters, amines, thiols, aldehydes, ketones, carboxylic acids, amides, and esters.
- Molecules or chemical groups that mix or interact well with water are called hydrophilic.
- Molecules or chemical groups that do not mix or interact well with water are called hydrophobic.

- Oxidation is the loss of electrons. Reduction is the gain of electrons.
- For every oxidation, there is also a reduction.
- Electronegativity is a measure of the "pull" a nucleus has for electrons. High electronegativity means stronger pull
- Covalent bonds involving hydrogen in which the electronegaties are not very equal give rise to unequal sharing of electrons and hydrogen bonds.
- Carboxyl groups can gain or lose a proton. When the proton is on, the charge is zero When the proton is off, the charge is -1
- Amine groups can gain or lose a proton. When the proton is on, the charge is +1 When the proton is off, the charge is 0.
- Carbons having bonds to four different chemical groups can have those groups arranged in three-dimensional space around it in two different ways. These different arrangements are called stereoisomers. Such carbons are called asymmetric centers.
- The Gibbs free energy (G) for a system is equal to the enthalpy (H) minus the absolute temperature (T) times the entropy (S) -> G = H - TS
- For a process, the change in Gibbs free energy is $\Delta G = \Delta H - T\Delta S$
- For a reaction aA + bB <=> cC + dD, the equilibrium constant, K_{eq} is equal to $\{[C]^c_{eq}[D]^d_{eq}]\} / \{[A]^a_{eq}[B]^b_{eq}\}$
- For a biological system, the standard Gibbs free energy ($\Delta G°'$) is equal to $-RT\ln K_{eq}$
- For a biological system, the change in Gibbs free energy for a process is
- $\Delta G = \Delta G°' + RT\ln K_{eq}$
- Changes in Gibbs free energy for two processes are additive.
- Changes in standard Gibbs free energy for two processes are additive
- Catalysts speed reactions without being changed.
- The change in Gibbs free energy for a catalyzed process is the same as for an uncatalyzed process.
- Enzymes are proteins that catalyze biological reactions. Ribozymes are RNAs that catalyze biological reactions.

Water & Buffers

- Water is the most abundant component of every cell.
- The electronegativity of oxygen is greater than that of hydrogen, leading to unequal sharing of electrons between the two atoms. This is the cause of the formation of hydrogen bonds.
- Polar and ionic compounds (hydrophilic) dissolve readily in water. Non-polar compounds (hydrophobic) do not.
- Amphiphilic molecules have both polar and non-polar regions. Soaps are amphiphilic.

- Non-mixing of hydrophobic molecules and water rooted in the increase in entropy favored in the unmixed state.
- Amphiphilic substances can spontaneously form different shapes in water. These include micelles, liposomes, and lipid bilayer sheets.
- Phospholipids found in cellular membranes are amphiphilic
- Cellular membranes contain lipid bilayers
- Glycerophospholipids and sphingolipids spontaneously form lipid bilayers in water.
- The non-polar portions of globular proteins arrange themselves internally to the folded protein so as to avoid/exclude water. This too is an entropy driven process.
- Hydrogens in covalent bonds with unequally shared electrons are slightly positively charged and are called hydrogen bond "donors."
- Atoms with stronger electronegativities bonded to hydrogens are partly negatively charged and are called hydrogen bond "acceptors."
- Hydrogen bonds help hold together proteins and DNA.
- Hydrogen bonds are weaker than covalent bonds. Because of this, protein structures and DNA structures can be altered without the input of too much energy.
- Non-oxidative ionization of biomolecules involves loss or gain of protons. Since a proton has a charge of +1, gains of protons increase positive charge and loss of protons decrease positive charge.
- pH is a measure of proton concentration. Specifically, pH = -log[H^+]
- pOH is the corresponding measure of the hydroxide ion concentration

  -> pOH = -log[OH^-]
- pH + pOH = 14
- For the purposes of this book acids are molecules that can lose protons and salts are molecules that can gain protons. We shall use the term 'base' only to refer to strong bases, such as NaOH
- Strong acids, such as HCl completely dissociate in water.
- Strong bases, such as NaOH completely dissociate in water
- Weak acids only partly dissociate in pure water
- The amount of dissociation of a weak acid in a solution is a function of the pH of the solution.
- The pK_a is a measure of the strength of a weak acid. Weak acids with lower pK_a values are storger than those with higher pK_a values.
- The Henderson Hasselbalch equation gives the relationship between the pH, the pKa, and the amount of ionization of a weak acid.
- The Henderson Hasselbalch equation says

  $$pH = pKa + \log \{[A^-]/[HA]\}$$

where A^- is the salt formed by ionization of the weak acid and HA is the weak acid.

- A weak acid dissociates as follows

$$HA \rightleftarrows H^+ + A^-$$

- Within one pH unit of their pK_a values, weak acids resist changes of the pH of the solutions in which they are dissolved. We call this resistance buffering, making the weak acid/salt system a buffer.

- Buffers are strongest closest to the pK_a value of the weak acid/buffer system. Maximum buffering capacity occurs when $pH = pK_a$. From the Henderson Hasselbalch equation, this is also when

$$[Salt] = [Weak\ Acid]$$

- Buffers are important in living organisms because they help to maintain pH in a narrow range and allow proteins and DNA structures to be stable.

- Addition of a strong acid to a buffer will cause salt to be converted to weak acid. Each proton converts one salt molecule to one acid molecule

- Addition of a strong base to a buffer will cause weak acid to be converted to salt. Each hydroxide converts one weak acid molecule to one salt molecule

- When the capacity of a buffer is exceeded, it no longer acts like a buffer. This generally occurs at pH values more than 1 unit above or below the pKa value.

- A reasonable estimate of the charge of an ionizable group is as follows - if the pH is one or more units above the pKa value of the R-group, the proton is off. If the pH is one or more units below the pKa, the proton is on. It is only an estimate, though.

Biochemistry Pie (Part I)

To the tune of "*American Pie*"
Metabolic Melodies Website HERE

A long nine weeks ago
I can still remember
How the lectures sometimes made me smile
I pushed myself to study lots
So I could fill my head with thoughts
And then I'd find the effort all worthwhile

But mid-term one, it left me jaded
I worried as exams were graded
Sad news came from Kevin
The average - forty seven

It was so bad I went in shock
I couldn't stand to hear the talk
Of Henderson and Hasselbalch
And bi-o-che-mis-try

So why why biochemistry why
Does percent misrepresent that
My attention is high?
And all the students have a rallying cry
Singin' I will be a studious guy
I will be a studious guy

Did you draw an alanine?
And can you titrate a histidine?
If you know its p-K-a
Now do you believe you'll have it made
If you can pull a decent grade
And can recitation lead me to an 'A'?

Well we learned that protein structure is
A bunch of pleats and helixes
True beauty to behold
Man I dig how proteins fold!

There are seniors in pre-pharmacy
Learning all that chromatography
Gel filtration / HPLC
For bi-o-che-mis-try

I started Singin'
Why why biochemistry why
Must performance be enormous for
My grade to be high?
And all the students have a rallying cry
Singin' I will be a studious guy
I will be a studious guy

(*continued on next page*)

Recording by Tim Karplus
Lyrics by Kevin Ahern

Biochemistry Pie (Part II)

To the tune of "*American Pie*"
Metabolic Melodies Website HERE

Now for ten weeks we've been crammin' in
The fact that nuc-le-i have spin
But that's not all there is to see
There are six enzyme classes from E-C
A cat-a-lytic triad three
And a voice that whispers Delta G

Oh, with enzymes there are lots of facts
Like low Kms and high Vmax
Some zymogens break down
If trypsin is around
And while Kevin lectured Milam Hall
His camera captured movies small
Sometimes they had no sound at all
In bi-o-che-mis-try

We were singing
Why why biochemistry why
Should I lament my last percent
If my incentive was high?
And all the students have a rallying cry
Singin' I will be a studious guy
I will be a studious guy

R state, T state metabolic soul mates
Protein forms that we appreciate
ATCase binding siiii----iiiites
They grab a C-T-P upright
The enzyme gets itself uptight
With aspartate on the sidelines out of sight

Then the stage was set for ex-am two
And some of us were feeling blue
I almost lost my nerve
Whoa, 'til I moved up on the curve
'cause my memory to me revealed
The answers that had been concealed
As if the key had been unsealed
For bi-o-che-mis-try

I'm always Singin'
Why why biochemistry why
Must a student be so prudent
Just to qua-a-lify?
And all the students have a rallying cry
Singin' I will be a studious guy
I will be a studious guy

(*two stanzas skipped here*)

We all pulled down the MP_3s
And memorized the older keys
Then I just smiled and carried on
I went down to the class web site
To download ev-e-ry highlight
But the server said the pages were all gone

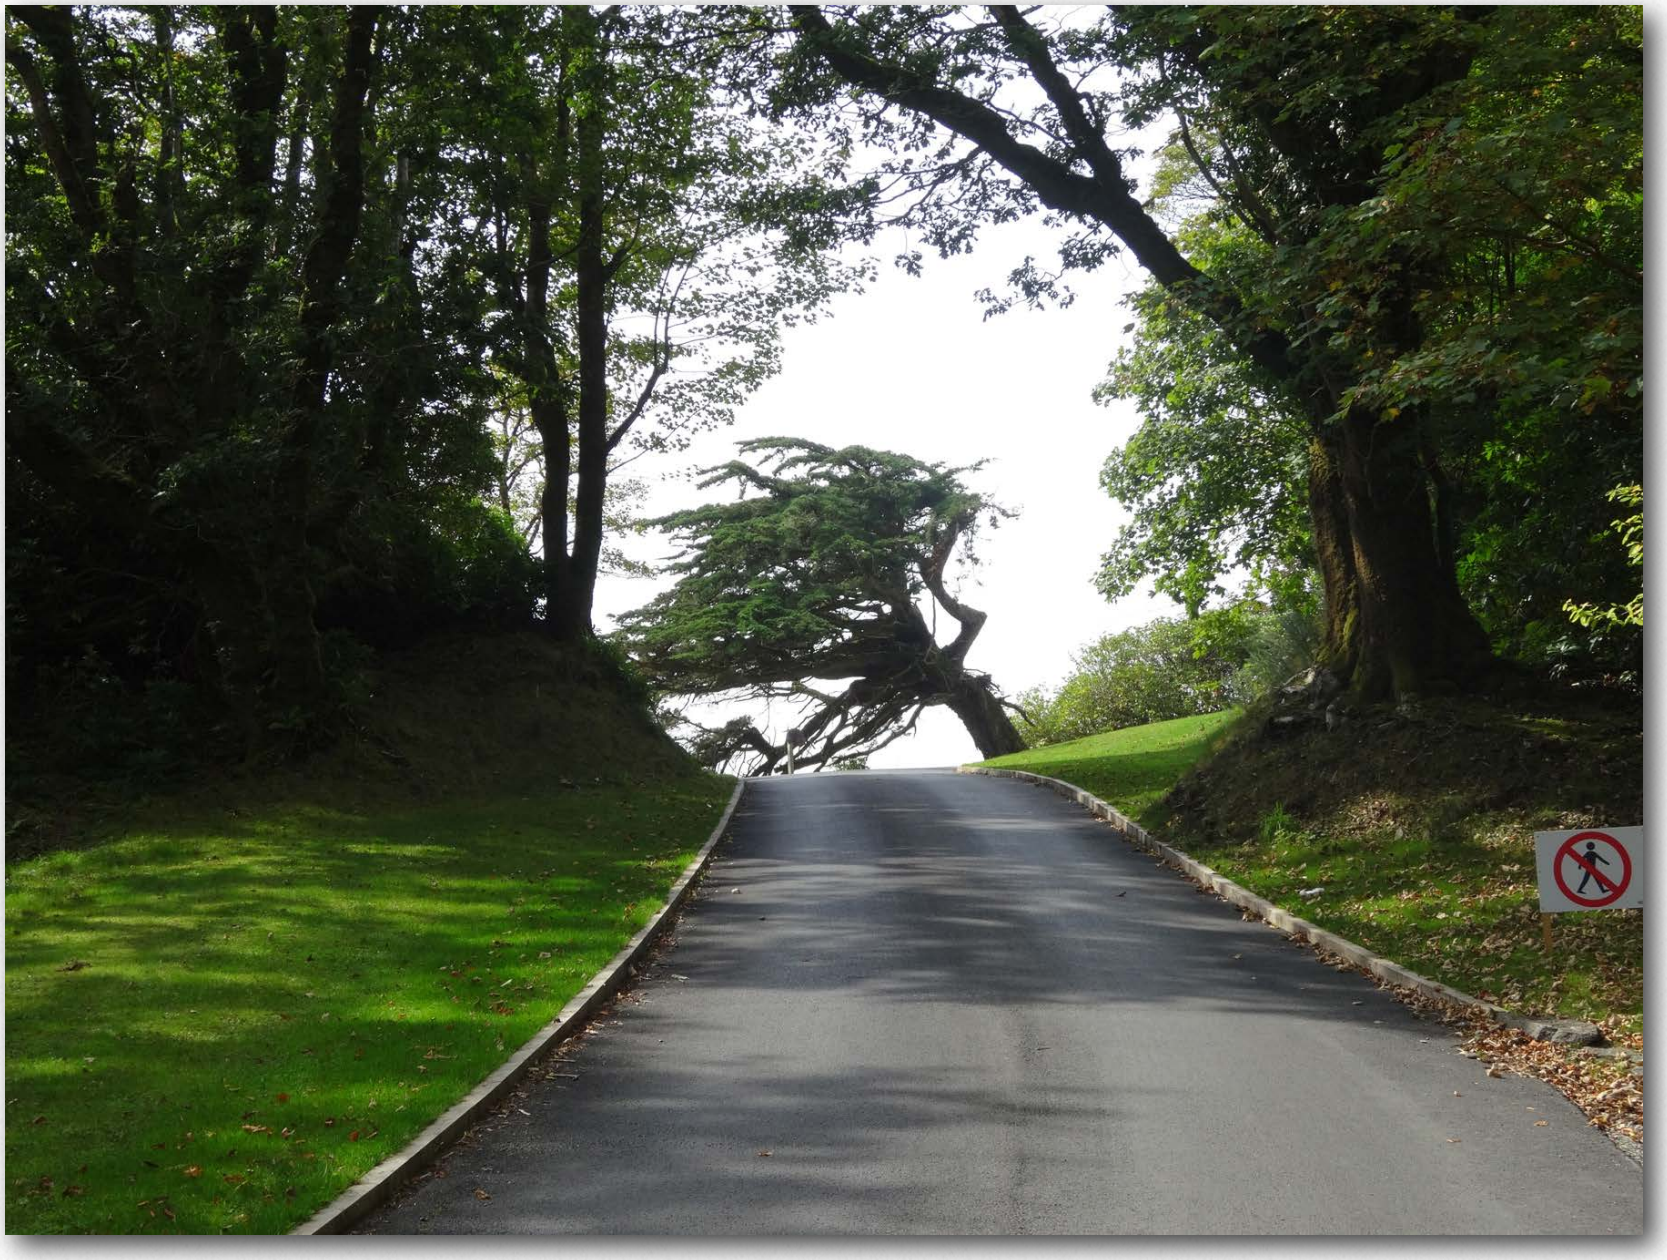
And in their rooms, the students stayed
The chemists crammed and the pre-meds prayed
There was no indecision
The end was in our vision
And the section that had made me fret
The questions for the problem set
I nailed them all without a sweat
In bi-o-che-mis-try

And I was Singin'
Bye bye biochemistry bye
You can debit all my credit
Cuz my grade is so high
And all the students have a rallying cry
Singin' there'll be a party tonight
There'll be a party tonight

Lyrics by Kevin Ahern

Entire recording is on previous page

Point by Point: Structure and Function



Amino Acids

- 20 amino acids comprise 99% of the proteins on this planet.
- Amino acids have the following general structure - a central α-carbon to which is attached the α-carboxyl, the α-amine, a hydrogen, and an R-group.
- 19 of the 20 amino acids have the α-carbon asymmetric, meaning they can exist in two different stereoisomers. With only very minor exceptions, all amino acids in proteins are in the L-configuration.
- The genetic code specifies the incorporation of the 20 amino acids into a protein during protein synthesis (translation). Specifications are via codons, which are three base sequences in tRNAs.
- Two amino acids, selenocysteine and pyrrolysine, are not encoded by the genetic code, but are put into proteins by unusual mechanisms in rare proteins involving stop codons during translation.
- Amino acids are divided into two general groups - essential (must be in the diet of the organisms) and non-essential (can be synthesized by the organism).

- Essential and non-essential amino acids vary by organisms. Humans have about 9 essential amino acids.

- Amino acids differ from each other by the composition of their R-groups.

- In this book, we categorize amino acids into six different categories based on the composition of their R-groups. They are non-polar (aliphatic R-group), carboxyl (carboxyl in R-group), amine (ionizable amino group in R-group), aromatic (contain benzene ring), hydroxyl (contain hydroxyl group), and other (contain carboxyamide, sulfhydryl, or other group).

- Alanine is one of simplest and most abundant amino acids in proteins. It is non-essential. A D-form of alanine is used to make the peptidoglycan layer of bacterial cell walls.

- Glycine is the simplest amino acid, having only a hydrogen as its R-group. It is the only amino acid to lack an asymmetric center (no stereoisomers) and is non-essential.

- Isoleucine is essential with a hydrophobic R-group.

- Leucine is the most abundant amino acid found in proteins and is also specified by the most codons (6). Its presence helps to stimulate the process of protein synthesis in muscle, however an overabundance of it is toxic.

- Methionine is one of two sulfur-containing amino acids. It is essential and is noteworthy in being the first amino acid put into all proteins. In bacteria, a modified form of it (formylated) is used only for the first amino acid in a protein.

- Proline is a non-essential only amino acid whose R-group covalently bonds to its α-amine group, creating a secondary amine. The ring leaves proline with less flexibility in a protein and often is the site of “bends” in a protein, as a result.

- Proline is often covalently modified in a protein after it is made by addition of a hydroxyl group. This happens in collagen and results in increased stability of the protein.

- Valine is an essential, non-polar amino acid. When it replaces glutamic acid in mutated formed of the globin gene in hemoglobin, the resulting hemoglobin aggregates in low oxygen conditions, giving rise to sickle cell disease.

- Aspartic acid is a non-essential amino acid readily made from oxaloacetate. Its side chain is acidic and it is negatively charged at physiological pH. Aspartate has the effect of stabilizing α-helices.

- Glutamic acid is also non-essential and chemically is very much like aspartic acid, being negatively charged at physiological pH. It is readily made from α-ketoglutarate.

- Arginine is an amino acid with an R-group that is amine-containing and positively charged at physiological pH.. It is borderline for being essential in humans. Premature infants cannot make it and may not be made in sufficient quantities in certain conditions.

- Histidine’s R-group contains an amine, but it can gain or lose a proton near physiological pH (pKa is about 6). Slight changes in physiological pH can sometimes change histidine’s charge.

- Lysine is an essential amino acid with an amine-containing R-group. It's pKa value is high, so like arginine, lysine's R-group is usually positively charged at physiological pH. Lysine is chemically modified in many ways after being incorporated into a protein.

- Phenylalanine has a non-polar aromatic R-group that is essential. Tyrosine is made from it. The genetic disease phenylketonuria arises from an inability to properly metabolize the amino acid. Phenylalanine is a component of Nutrasweet® (aspartame).

- Tryptophan is an essential amino acid containing a benzene ring in its indole R-group. It is a metabolic precursor of hormones such as serotonin and plant auxins.

- Tyrosine is a non-essential amino acid made from phenylalanine. It is both an aromatic amino acid and a hydroxyl-containing amino acid. Its hydroxyl group is a target for phosphorylation by tyrosine protein kinases in the process of signaling. Tyrosine is a precursor of neurotransmitters, such as dopamine and of hormones, such as epinephrine and thyroid hormones.

- Serine is a non-essential, hydroxyl-containing amino acid, making it a polar amino acid. It is a precursor of purines, pyrimidines, sphingolipids, folate, and of the amino acids glycine, cysteine, and tryptophan. Its hydroxyl group is also phosphorylated by cellular protein kinases.

- Threonine is a hydroxylated amino acid that is essential. Like serine and tyrosine, its hydroxyl group is a target for phosphorylation in proteins. It is also a target for O-glycosylation.

- Asparagine is a non-essential amino acid containing a carboxyamide in its R-group. Asparagine can be converted into acrylamide during the cooking of foods at high temperature. The amino acid is readily made from aspartic acid.

- Glutamine is another borderline essential amino acid. Normally it is not essential, but may be needed in the diet in some circumstances. Its carboxyamide R-group does not ionize at physiological pH, but is polar. It is made by amidation of glutamine. It is one of the few amino acids that cross the blood-brain barrier.

- Cysteine is the second amino acid with sulfur in it (methionine is the other) with the sulfur in the form of a sulfhydryl when in the reduced form. Oxidation of the sulfhydryl results in joining of two cysteines together to make cystine with a covalent disulfide bond. Cysteine is also found in glutathione.

- Selenocysteine is a component of selenoproteins and is found in all kingdoms of life, including 25 human proteins. Enzymes with it include glutathione peroxidases and thioredoxin reductases. It is incorporated into proteins by an unusual use of a stop codon.

- Pyrrolysine is a very rare amino acid found in archaeans making methane and in one methane-producing bacterium. It is a component of methane-producing enzymes and, like selenocysteine, is incorporated into proteins by an unusual use of a stop codon.

- Amino acids readily ionize at physiological pH values. In proteins, the only parts that ionize are the α-carboxyl and α-amine ends of the protein and ionizable R-groups in proteins. These include lysine, arginine, histidine, aspartic acid, glutamic acid, and cysteine.

- When amino acids are broken down into intermediates that can be made into glucose, they are called glucogenic.

- Amino acids that can be broken down into acetyl-CoA are called ketogenic. Some amino acids are both glucogenic and ketogenic.

- Covalent changes to amino acids in proteins after the protein is made are called post-translational modifications. Examples include phosphorylation (serine, threonine, and tyrosine), hydroxylation (proline and lysine), carbohydrates (asparagine, threonine, and serine), or addition to various amino acids of fatty acids, isoprenoid groups, acetyl groups, methyl groups, iodine, carboxyl groups, and sulfates.

Proteins I

- Proteins are the workhorses of cells. They are enzymes for catalysis, mediators of signaling, give structure to cells and control the proteome.

- There are four distinct levels of protein structure - primary (amino acid sequence), secondary (interactions between close amino acids that affect local protein shape), tertiary (interactions between amino acids not close in primary structure that affect folding), and quaternary (interactions between separate polypeptide subunits of a protein.

- Structure is essential for function. Proteins that lose structure lose their function.

- Proteins are flexible and very tiny changes in their structure can have large effects on their function. In hemoglobin, oxygen binding changes the protein's shape and affects its affinity for binding of other oxygens.

- The primary structure of a protein ultimately determines its shape and its properties. ‘

- Protein synthesis occurs in ribosomes and involves formation of peptide bonds between the α-carboxyl of one amino acid with the α-amine of the next one.

- The amino terminus of a protein is the end that has the free α-amino group. The carboxyl terminus is the end containing the free α-carboxyl group.

- Proteins are made starting at the amino end and ending at the carboxyl end.

- R-groups of consecutive amino acids in a protein are usually oriented on opposite sides of the polypeptide chain (*trans*). Positioning them on the same side (*cis*) often results in unfavorable steric interactions.

- Steric hindrance is an important factor driving folding of proteins.

- Common secondary structures include the **α**-helix and **β**-strands/sheets.

- α-helices have 3.6 amino acids per turn of the helix and are predominantly right-handed.

- Hydrogen bonds between carbonyl groups and amine groups four amino acids apart help to stabilize α-helices.

- The repeat of a helix is the number of amino acids in a chain before it begins to repeat its structure. This is 3.6 for an α-helix..

- The rise of a helix is the distance each step of the helix makes. For an α-helix, this is 0.15 nm per amino acid.

- The pitch of a helix is the distance between complete turns of the helix. For an α-helix, this is 0.54 nm.

- α-helices are stabilized by the presence of aspartate.

- β-strands are the equivalent of flattened helices. When β-strands are arranged together, they can form sheets, barrels, and other structures.

- Such arrangements are called supersecondary structures. These higher order structures are stabilized by hydrogen bonds.

- Chains in supersecondary structures can be parallel (same α-amino - α-carboxyl orientations) or anti-parallel (opposite α-amino - α-carboxyl orientations).

- Turns are a type of secondary structure that give rise to tertiary structure. They often connect different secondary structures, such as α-helices and β-strands.

- There are at least five types of turns - δ,γ,β,α,π - corresponding to turns spanning 1,2,3,4, or 5 amino acids, respectively.

- A 3_{10} helix is the fourth most abundant secondary structure in proteins - about 10% of all helices. It contains 10 amino acids in 3 right-handed turns. Hydrogen bonds form between amino acids that are three apart.

- **π**-helices are thought of as a special type of α-helix, as if an extra amino acid were placed in the middle. They are right-handed and have 22 amino acids in 5 turns of the helix. Most are only 7 amino acids long and occur in the middle of α-helices.

- The peptide bond has characteristics of a double bond and creates a planar structure. A polypeptide chain then can be thought of as a set of unrotatable planar structures separated by rotatable single bonds.

- Sequentially in the amino to carboxyl direction they are 1) a rotatable bond (**ψ**) between the α-carbon and α-carboxyl preceding the peptide bond, 2) an un-rotatable peptide bond (ω) between α-carboxyl and α-amine), and 3); a rotatable bond (**φ**) between the α-amine and α-carbon following the peptide bond. Note that in Figures 2.32 and 2.33 that the amino end is on the right and the carboxyl end is on the left.

- Ramachandran and colleagues performed theoretical calculations to determine the steric stability of the rotatable bonds on either side of the planar structures.

- Their results (shown in Ramachandran plots) identified three primary groups of stable rotatable angles and these correspond to the angles found in right handed α-helices, left handed α-helices, and β-strands.

- The amino acid sequence and secondary structure of thousands of proteins are known. By analyzing these sequences, it is possible to determine the frequency (likeli-

hood) of each of the amino acids occurring in any of the secondary structures. With this information, a computer can predict with about 80% accuracy where and what the regions of secondary structure are in a protein from its sequence of amino acids.

- Amino acids differ in their hydrophobicity/hydrophilicity. Hydropathy scores rate the relative hydrophobicity/hydrophilicity of each amino acid. High positive values indicate high hydrophobicity whereas high negative values correspond to high hydrophilicity.

- Proteins embedded in non-polar lipid bilayers have stretches of hydrophobic sequence (called transmembrane domains) that can be seen in a Kyte-Doolittle plot.

- Regions of proteins that have no regular, discernible structure are referred to as random coils. They may have fluid structures and exist in multiple stable forms. These may be metamorphic proteins or intrinsically disorder proteins and can be characterized by spectroscopic methods that include circular dichroism or nuclear magnetic resonance (NMR).

- Tertiary structure of proteins arises from the process known as folding and is determined ultimately by the amino acid sequence of the protein.

- Non-fibrous proteins are known as globular. Interactions between amino acids that are distant in primary sequence, but close in folded sequence stabilize tertiary structure. Chemical forces involved in the stabilization include hydrogen bonding, hydrophobic forces, ionic bonds, disulfide bonds, and metallic bonds.

- Breaking tertiary structure involves breaking the stabilizing forces. This can be accomplished by heat, pH change, detergents, urea, and mercaptoethanol. These treatments unfold proteins and destroy their function.

- Hydrogen bonds are weaker than covalent bonds. They are readily broken with boiling water or urea.

- Ionic interactions are important for structural stability and also in catalysis. pH can have a strong influence on ionization.

- Hydrophobic forces arise from interactions between hydrophobic side chains of amino acids that exclude water. They are commonly found in the interior of a protein and can readily be destroyed with detergent.

- Disulfide bonds are the only covalent bonds stabilizing tertiary structure. They form when two sulfhydryls are brought into close proximity in a folded protein. Breaking disulfide bonds requires a reducing agent, such as β-mercaptoethanol or dithiothreitol.

- van der Waals forces are forces of attraction and repulsion caused by correlations in the fluctuating polarizations of nearby particles.

- Post-translational modifications alter amino acids after a protein is made.

- There are two popular protein folding models. The first (diffusion collision model) involves a nucleation even followed by secondary structure formation. By contrast, the nucleation condensation model proposes that secondary and tertiary structures form together.

- Folding can begin before the synthesis of a protein is complete.

- A folding funnel energy landscape is hypothesized. This is an energy diagram with many local minima a folding protein can "fall into" and become trapped, thus explaining misfolding.

- Secondary structures can readily be predicted by computer from sequence. Tertiary structure prediction is much harder to predict. Leventhal's paradox presents the enormity of the problem from approach the prediction from a random basis.

- Problems arising from protein misfolding include Mad cow disease, Alzheimer's, Parkinson's, and Creutzfeld-Jacob disease.

- Misfolded proteins commonly form aggregates and become insoluble in water creating problems. They begin with a "seed" protein called prions and they act infectiously.

- Creutzfeld-Jacob diseases, Mad cow disease, and scrapie all have the same protein involved - it is a membrane protein called PrP. PrP^{c} is the properly folded form and PrP^{sc} is the folded form associated with disease. They each have the same amino acid sequence

- Amyloids are collections of misfolded protein aggregates. Examples include Alzheimer's disease (Amyloid β), Parkinson's disease (α-synuclein), Huntington's disease (huntingtin), rheumatoid arthritis (serum amyloid A), and fatal familial insomnia (PrP^{sc}).

- Huntingtin is the protein implicated in Huntington's disease. It must be mutated to misfold. Its mutation arises with formation of repeats of a glutamine coding sequence as a result of "slipping" of a repeated sequence causing additional copies of the repeat to be made during DNA replication.

- One class of proteins assist other proteins to fold properly. There are two classes of these proteins. Heat shock (Hsp) proteins use ATP hydrolysis to facilitate proper folding. They have a β-barrel structure that has affinity for hydrophobic amino acid side chains. Hsp70 binds to polypeptides as they are being synthesized on ribosomes. It largely protect proteins from aggregating with each other before they begin to properly fold. When proteins are damaged, Hsp70 binds to ubiquitinating factors to target them for destruction.

- The other class of proteins assisting folding is the chaperonins. The best studied are the GroEL/GroES complexes. They too provide a lidded chamber within which folding occurs. It may occur in a model like that of Hsp 70 or may involve a more active process of catalyzed folding.

- Proteasomes are cellular structures involved in degradation of damaged/misfolded proteins. Degradation is targeted on proteins flagged by being bound to ubiquitin. Proteasomes degrade targeted proteins into short peptides of 8 amino acids or fewer.

- Parkin is a protein involved in Parkinson's disease and is a component of ubiquitin ligase (involved in attachment of ubiquitin to proteins to be degraded).

- Intrinsically disordered proteins have more fluid structures. They are not misfolded, but may have multiple stable forms they switch between. In some cases, disor-

dered regions may become ordered upon binding to another protein.

- Metamorphic proteins have different stable structures that are in equilibrium with each other.

- A few proteins, such as ribonuclease, can properly refold after being denatured. Most, however, cannot properly refold after denaturation.

- Quaternary structure involves interactions between multiple polypeptides in a protein. Such interactions can give new properties, such as cooperativity and allosterism, in multi-subunit proteins that do not exist in similar proteins comprised of only a single subunit.

Proteins II

- Fibrous proteins have a strong structural component and mostly have primary and secondary structure - little tertiary structure.

- Fibrous proteins constitute hair, nails, hard substances like horns, and connective tissues. They include keratins, fibroin, elastin, and collagen.

- Keratins are found in hair, nails, beaks, scales, feathers, and claws. There are over 50 in the human genome. Keratins comprise the intermediate filaments of the cytoskeleton. α-keratins often have intertwined **α**-helices in coiled-coil structures. Disulfide bonds between chains add strength. Curling/uncurling hair involves breaking these bonds.

- β-keratins contain β-sheets.

- Fibroin is a component of silk and has a repeating amino acid sequence rich in glycine and alanine.

- Elastin has elastic properties and is rich in glycine and proline. Elastin is made by winding together chains of tropoelastin and then joining lysines within them in cross-linked desmosine structures.

- Collagen is the most abundant protein in mammals. It is found in tendons, skin, cornea, cartilage, bone, blood vessels and the gut.

- It contains three left-handed helical chains coiled together in a right-handed helix. On the inside of the helix, only glycines are found. In addition to glycine, collagen is also rich in proline and a modified form of it - hydroxyproline.

- Hydroxylation of proline is a post-translational modification that requires vitamin C. Deficiency of vitamin C leads to a weakened form of collagen, resulting in scurvy.

- Lamins are fibrous proteins in the cell nucleus. They help to regulate transcription and are similar to proteins in intermediate filaments. They are also involved in assembly and disassembly of the nuclear envelope relating to mitosis.

- Disassembly is mediated by phosphorylation by mitosis promoting factor. Dephosphorylation reverses the process, allowing for assembly.

- Tertiary structure includes structural domains (repeated structures in mamy proteins that are larger than secondary

structures. Structural domains are self-sustaining and can fold independently of the rest of the protein.

- One structural domain is a leucine zipper - a zipper-like structure found within and between proteins where leucines in the core of the zipper stabilize it by interacting with each other. Leucine zippers commonly interact with DNA and can be found in many transcription factors.

- Zinc fingers (often) use a coordinated zinc ion to stabilize a finger-like projection of the protein. They too can bind DNA and be found in transcription factors. Other molecules bound by zinc fingers include RNA, protein, and lipids.

- The src oncoprotein has a structural domain called SH_2 that binds to phosphorylated tyrosines in target proteins. The domain plays a role in signaling and is found in over 100 human proteins.

- The helix-turn-helix domain is commonly found in DNA binding proteins and contains two α-helices separated by a small number of amino acids. The helix parts of the domain interact with bases in the major groove of DNA.

- Pleckstrin homology domains bind to phosphorylated inositol residues (PIP_2 and PIP_3) in cell membranes. Proteins with this domain can also bind to G-proteins and protein kinase C. They play important roles in cellular signaling.

- The basement membrane is a glue that holds tissues together. It is a layered extracellular matrix of tissue comprised of protein fibers (type IV collagen) and glycosaminoglycans that separates the epithelium from other tissues.

- Structural globular proteins are globular proteins that are able to self-assemble into fiber-like structures.

- Actin is a structural globular protein comprising as much as 20% of the mass of muscles. Polymerization of actin leads to microfilaments (also called thin filaments)- a major component of the cytoskeleton. Thin filaments of actin are acted on by myosin in muscular contraction.

- Intermediate filaments are intermediate in size (average diameter = 10 nm) between that of the microfilaments (7 nm) and the microtubules (25 nm). They include the lamins in both nuclear and cytoplasmic forms. They are extremely flexible and can be stretched to several times their original length.

- There are six types of intermediate filaments and they vary considerably in the composition of proteins within them, ranging from one to four proteins. The lamins make up Type V proteins. Types I and II contain different keratins. Type III is the most complex with four proteins.

- Tubulins are monomeric units of microtubules.

- Microtubules provide rails for motor proteins to move on for transport of cargo inside of cells.

- Vimentin is the most widely distributed protein of the intermediate filaments, being found in fibroblasts, leukocytes, and the endothelial cells of blood vessels. It helps to position organelles in the cytoplasm, providing attachment to the nucleus, mitochondria, and the endoplasmic reticulum. Vimentin helps control the esterification of cholesterol.

- Mucins are proteins in epithelial tissue with numerous attached carbohydrates and are involved in lubrication, bone formation, binding of pathogens in the immune system, and mucosal secretions from mucus membranes.

- Vinculin is a protein in the cytoskeleton involved in focal adhesion structures found at the cell-cell and cell-matrix junctions. It interacts with integrin proteins as well as f-actin where it helps anchor actin microfilaments to the membrane.

- Syndecans are transmembrane proteins that facilitate G-protein coupled receptor's interaction with ligands. Syndecans typically have 3-5 heparan sulfate and chondroitin sulfate chains attached to them and cleavage of those chains at the site of a wound can help stimulate the healing process. Syndecans play a role in cell-cell adhesion. The syndecan 1 ectodomain can suppress growth of tumor cells without affecting normal epithelial cells.

- Defensins are small cationic proteins that act as ionophores to protect against infection by various bacteria, fungi, and viruses.

- Focal adhesions are structures with multiple proteins that link the cytoskeleton to the extracellular matrix. Over 100 proteins are involved. Since they are connected to the extracellular matrix, focal adhesions can communicate its status to cells containing them.

- Ankyrins are a family of membrane adaptor proteins that anchor integral membrane proteins to the spectrin-actin membrane cytoskeleton. Ankyrins are anchored to the plasma membrane by palmitoyl-CoA.

- Spectrin is a cytoskeletal protein that helps to maintain the structure and integrity of the plasma membrane. It gives red blood cells their shape and is found in the inner layer of the plasma membrane in a network of pentagonal and hexagonal shapes.

- Integrins are important transmembrane proteins for connecting cells together. They bind to collagen, fibronectin, laminin, and vitronectin and also play roles in communication, migration, viral attachments, and blood clotting. They are a bridge between the extracellular matrix and the cytoskeleton. The are important in focal adhesions.

- The binding response of integrins can be rapid - GPIbIIIa (on the surface of blood platelets) attaches to fibrin in a clot as it develops.

- Integrins can also help to recruit signaling molecules inside of the cell to activated tyrosine kinases to help them to communicate their signals.

- The class of integrin proteins is large, with 18 α- and 8 β-chains in mammals.

- Cadherins perform binding functions when bound to calcium and preferentially cluster with the same cadherins on other cells over different cadherins.

- Selectins are cell adhesion glycoproteins that bind to sugar molecules - a type of lectin. Their N-terminus binds calcium, which activates its lectin activity. Selectins are specific for endothelium (E), lymphocytes (L), or platelets (P). They help lymphocytes to bind to lymphoid organs in inflammation and have a role in metastasis. Selectins are involved in the inflammatory

processes of asthma, psoriasis, multiple scleroris, and rheumatoid arthritis.

- Laminins are extracellular matrix glycoproteins - major components of the basal lamina. They affect cell differentiation, migration, and adhesion. They are secreted into the extracellular matrix and are essential for tissue maintenance and survival. They are associated with fibronectin, entactin, and perlecan proteins in collagen and bind to integrin receptors in plasma membrane

- Vitronectin is a glycoprotein in blood serum (platelets), the extracellular matrix, and in bone that promotes cell adhesion and spreading. It binds to several protease inhibitors (serpins), integrin, and stabilizes plasminogen activator inhibitor. May play role in blood clotting and malignancy.

- Catenins interact with cadherin in cell adhesion at adherens junctions. They connect to actin fiber in the cytoskeleton and are important in contact inhibition of cells. Tumorigenesis may result from mutation in catenins.

- Glycophorins are heavily glycosylated proteins (sialic acid) on the surface of red blood cells that help them to avoid attaching to other cells. They help regulate mechanical properties and shape of the cells.

- Quaternary structure's multiple protein interactions allow for cooperative binding of substrates and allosterism to occur. Allosteric effectors that are also substrates are called homotropic, whereas those that are not substrates are called heterotropic.

- Cooperativity occurs when binding of one substrate by a multi-subunit protein favors the binding of more of the same substrate by the same protein (the term substrate here is used simply to indicate a molecule bound by any protein - not just an enzyme).

- In hemoglobin, for example, binding of the first oxygen increases the affinity of hemoglobin for binding subsequent oxygens. This happens because binding of the first oxygen in the lungs converts hemoglobin from the T-state (low affinity) to the R-state (high affinity).

- Rapidly respiring tissues have molecules they release that lower hemoglobin's affinity for oxygen and that convert it from the R to the T state. These include protons, 2,3, BPG, and carbon dioxide. Carbon dioxide is carried on amines by hemoglobin back to the lungs. Oxygen and carbon monoxide, by contrast, bind to the iron in the heme group.

- In contrast to myoglobin, which has strong affinity for oxygen, hemoglobin has varying affinity for oxygen as a function of oxygen concentration (low affinity in low oxygen, high affinity in high oxygen), thus allowing it to adapt to the boy's needs and availability of oxygen.

- As a consequence, myoglobin is better for storing oxygen and hemoglobin is better for transporting it.

- The Bohr effect describes how external molecules (protons, carbon dioxide, 2,3 BPG) decrease hemoglobin's affinity for oxygen and provide rapidly respiring tissues the oxygen that they need.

- 2,3 BPG (a byproduct of glycolysis) binds in the "donut" hole of hemoglobin, favoring the T-state and releasing oxygen. If the 2,3BPG concentration is high in the blood, it

may not get removed from hemoglobin before the returning to the lung, leaving hemoglobin in the T-state with a lower capacity for binding oxygen. Smokers have high 2,3 BPG concentrations in the blood and this is why smokers have a reduced oxygen carrying capacity.

- Smokers also have higher levels of carbon monoxide in their blood and this competes with oxygen for binding iron on the heme group, also reducing oxygen carrying capacity.

- Carbon dioxide moves from tissues to lungs in the blood by two mechanisms - 1) carried by hemoglobin and 2) dissolved as bicarbonate.

- Fetal hemoglobin is slightly different from adult hemoglobin, with two γ-chains replacing the β-chains of adult hemoglobin. The result is a hemoglobin that can bind oxygen cooperatively, but can't bind 2,3 BPG, resulting in a hemoglobin more frequently in the R-state. Fetal hemoglobin thus has a higher affinity for oxygen than adult hemoglobin so the fetus can take oxygen from the mother.

- Sickle cell disease arises from mutations in hemoglobin that cause aggregates to form under low oxygen conditions. This, in turn, causes blood cells containing the mutated hemoglobin to form sickle shapes, making it harder for them to pass through capillaries. The condition can be very painful under conditions of high exertion and may be fatal if too severe.

- People heterozygous for the sickle cell gene (one copy of the mutant and one unmutated) appear to have a selective advantage in being better able to survive malaria infections.

- Sickle cell anemia is treated with hydroxyurea, which induces expression of the fetal hemoglobin gene in adults to replace the defective mutant copy.

- Oxygen is needed more by plants than animals due to rapidly changing needs arising from muscular contraction.

- This is because oxygen is the terminal electron acceptor of electron transport, so when it and oxidative phosphorylation are running, ATP generation is much more efficient.

- Besides hemoglobin, two other oxygen binding proteins are of note - myoglobin (muscles of higher animals) and hemocyanin (molluscs and arthropods).

- Insects and unicellular organisms have other means of managing oxygen

- Myoglobin is the primary oxygen-storage protein found in animal muscle tissues. It has high affinity for oxygen and only releases it when the oxygen concentration is very low.

- Red meat gets its color from ferrous iron (Fe^{++}), which oxidizes to ferric iron (Fe^{+++}), causing browning when meat is cooked.

- Myoglobin has higher affinity for oxygen than hemoglobin.

- Mammals that dive deeply in the ocean, such as whales and seals, have muscles with particularly high abundance of myoglobin.

- Hemocyanin is a copper-containing protein that transports oxygen in the bodies of molluscs and arthropods.

- The oxygen in hemocyanin is held between two Cu^{+} ions, which are, in turn, held in place by six histidines.

- Most (but not all) oxygen binding to hemocyanin is non-cooperative. Horseshoe crabs and some arthropods bind oxygen cooperatively.

Proteins III

- Actin is a structural globular protein that exists in monomer and polymeric forms. Polymerization of actin leads to microfilaments - a major component of the cytoskeleton.

- Actin is essential for muscular contraction, cell signaling, and maintenance of cell junctions. α-actin is in the muscles, whereas the β and γ forms are components of the cytoskeleton.

- The monomeric unit of actin is called G-actin and the polymer is known as F-actin.

- Helical F-actin in muscles contains tropomyosin. In addition to tropomyosin, other proteins binding actin filaments include troponins I, T, and C.

- Actions in which actin plays a role include cell motility, cytokinesis, intracellular transport of vesicles and organelles, and it helps to establish cell shape.

- During polymerization of actin, its weak ATPase activity is stimulated to convert ATP to ADP.

- F-actin binds to structural proteins at adherens junctions, such as **α**-actinin, vinculin, catenins, and cadherins.

- The Arp 2/3 complex mimics an actin dimer and helps to initiate the process of actin polymerization. Thymosin at the end of actin filaments helps control growth of the filaments. The protein known as profilin acts to exchange ADP for ATP within actin monomers.

- Tubulins are monomeric units of microtubules. The α-tubulin and β-tubulin proteins polymerize to make microtubule structures in the cytoplasm of cells. Microtubules only grow in one direction. The end of growth is called the plus end and the other is referred to as the minus end.

- Microtubules are major components of the cytoskeleton. Stable microtubules contain tubulin units bound to GTP. Those bound to GDP are unstable and fall apart.

- Microtubules are found in the cytoplasm, the inner structure of cillia and flagella and provide rail-like structures for the movement of materials within cells. The proteins navigating these rails are dynein and kinesin, which operate in opposite directions. Centrosomes are focal points of connection of microtubules.

- Motor proteins act as their name suggests - the provide movement inside of cells. In their action, they carry cellular cargo from one location to another.

- Motor proteins navigating microtubules in cells include kinesin and dynein. Each uses hydrolysis of ATP as the fuel needed for the movement.

- Kinesin and dynein walk in opposite directions on a microtubule. Kinesin moves in the direction of synthesis of the microtubule (plus end movement, away from the cell center) whereas dynein exhibits minus end movement toward the cell center.
- Myosin proteins use ATP to enable movement along actin thin filaments. Myosin proteins form aggregated structures are called thick filaments.
- Myosin has a head, a tail, and a hinge/neck region. The head is where ATP is held and hydrolyzed.
- There are three types of muscle tissue - skeletal (striated), smooth, and cardiac.
- Muscles may be activated by the central nervous system or may contract involuntarily (smooth and cardiac only).
- Sarcomeres are the basic units of striated muscle and are comprised of thick (myosin) and thin (actin) filaments and a protein called titin.
- In muscular contraction, thick and thin filaments slide past each other fueled by myosin.
- A sarcomere is the region between the two Z-lines of striated muscle and encompasses the entire A band (See Figure 2.112). In muscular contraction, myosin heads move toward the center of the sarcomere.
- The center of the sarcomere's H-zone contains an M-line, which is attached to the cytoskeleton.
- The sarcolemma is the plasma membrane of muscle cells, with a lipid bilayer and a glycocalyx on the outside.
- Polysaccharides of the glycocalyx connect the sarcolemma with the basement membrane. Muscle fibers use the basement membrane as a scaffolding. Connections are also made by transmembrane proteins bound to the actin cytoskeleton.
- At the ends of muscle fibers, the sarcolemma is fused with a tendon fiber and the latter is adhered to bones.
- The sarcoplasmic reticulum is a muscle cell structure like the endoplasmic reticulum, serving as a calcium battery, releasing calcium to stimulate muscular contraction and absorbing it during relaxation.
- The sliding filament model is one attempt to explain muscular contraction.
- In it, a repeated set of "pulls" results in sliding of a thin actin filament over a thick myosin filament.
- The process starts with a signal from the central nervous system.
- At the end of the nerve, calcium channels open, allowing calcium to enter the neuron. This causes synaptic vesicles containing acetylcholine to fuse with the plasma membrane and be expelled into the synaptic cleft between the nerve and the muscle cell.
- Acetylcholine activates receptors on the muscle cell, allowing sodium and potassium ions to flow, depolarizing the muscle cell.
- The action potential, thus initiated spreads throughout the muscle cell.
- The sarcoplasmic reticulum responds by opening calcium channels, allowing calcium to escape.

- Calcium binds to troponin on actin filaments, causing it and the tropomyosin it is bound to to shift, allowing myosin binding sites on the tropomyosin to be exposed.
- Myosin's head binds to tropomyosin and the ATP it holds gets cleaved
- Release of ADP and P_i by the myosin head results in a bending of the hinge/neck area, pulling the actin filament over the myosin filament.
- The sarcomere thus shortens. If ATP is available, myosin binds it and continues the process.
- Tropomyosins are proteins that interact with actin filaments and regulate their ability to be used in movement. They form head to tail dimers on the α-helical groove of an actin filament. In this position they are able to control the interactions between myosin and actin and thus regulate contraction.
- Non-muscular tropomyosin helps to regulate cytoskeletal functions.
- Troponin I, C, and T form a complex and interact with tropomyosin on actin filaments. Troponin I prevents binding of myosin's head to actin, thus stopping contraction. Troponin C binds to calcium. Troponin T binds all three proteins to tropomyosin. Elevation of troponins in the blood occurs after a myocardial infarction and can remain high for up to two weeks.
- Actinin connects actin filaments to Z-lines of skeletal muscles.
- Titin is a muscle protein that is the molecular equivalent of a spring. It is the third most abundant protein in muscles and is the large protein with the largest exon known. Titin has both folded regions and unstructured domains. It serves to connect the M and Z lines to the muscle sarcomere.
- Muscle cells have an ATP battery in the form of creatine phosphate. When the oxygen concentration in a muscle cell is high, the reaction to form creatine phosphate moves in the direction of making ADP and creatine phosphate.
- ATP + Creatine <=> ADP + Creatine-P
- When the ATP concentration falls, the equation moves in the direction of making creatine and ATP, thus supplying needed ATP.

Nucleic Acids

- In the race to discover the structure of DNA, Watson and Crick combined observations of Erwin Chargaff with the data of Rosalind Franklin to determine the structure of B-DNA.
- At the core of DNA, bases are hydrogen bonded together - guanine (G) to cytosine (C) and thymine (T) to adenine (A). In RNA, uracil (U) replaces thymine (T).
- The interior of DNA is relatively hydrophobic and the exterior is hydrophilic.
- The DNA molecule is a polymer of nucleoside monophosphates with phosphodiester bonds between the phosphate on the 5' end of one deoxyribose and the 3' end of the next one.

- In the B-form, the DNA helix has a repeat of 10.5 base pairs per turn, with sugars and phosphate forming the covalent phosphodiester “backbone” of the molecule and the adenine, guanine, cytosine, and thymine bases oriented in the middle.
- B-DNA has a major and a minor groove in its structure.
- DNA strands of a double helix are anti-parallel - the 5’ end of one strand is paired to the 3’ end of the other strand.
- The building blocks of DNA and RNA are nucleotides.
- Nucleotides have a sugar (ribose in RNA, deoxyribose in DNA), at least one phosphate, and a nitrogenous base (U,T,A,G, or C). Nucleosides lack phosphate.
- Triphosphate ribonucleotides are important sources of cellular energy. ATP is most widely used for general purposes UTP is used to make glycogen. CTP is used to make glycerophospholipids, GTP is used to make proteins.
- ATP is mostly made in cells by oxidative phosphorylation or (in plants) photophosphorylation.
- Three forms of DNA predominate - A, B, and Z. A and B are right-handed. Z is left-handed.
- The A-form of DNA was discovered by Rosalind Franklin and is found in double-stranded RNA as well as DNA-RNA duplexes.
- ATP can be made from 2 ADPs by adenylate kinase -> 2ADP <=> ATP + AMP
- Nucleoside diphosphokinase (NDPK) allows interchange of all diphosphate and triphosphate nucleotides
- ATP + NDP <=> ADP + NTP
- Deoxyribonucleotides are made from nucleoside diphosphates by catalysis with ribonucleotide reductase.
- Kinases put phosphates onto molecules. Phosphatases remove phosphates from molecules.
- Superhelicity of DNA arises from tension in a duplex that alters the preferred ratio of 10.5 base pairs per turn. Tension is relieved by supercoiling in which the double strands cross over each other (Figure 2.110).
- Three terms are used to measure/describe winding of DNA strands - twists (T - number of turns of the DNA); writhes (W - number of superhelical turns where the double helix crosses over itself); and the linking number (L - number of twists and writhes).
- L = T + W
- Alteration of the superhelical density (number of writhes per base pair) is a factor in DNA replication and can affect transcription of genes.
- Topoisomerase enzymes can create or relieve DNA tension.
- Type 1 topoisomerases work by cutting one strand of a DNA helix. Type II topoisomerases work by cutting both strands of a double helix.

- Antibiotics targeting topoisomerases include fluoroquinolones and ciprofloxacin.
- RNAs come in several forms - ribosomal RNA (rRNA - makes peptide bonds); transfer RNA (tRNA - carries amino acids in protein synthesis); messenger RNA (mRNA - carries genetic message for making proteins), and several small RNAs with functions in control of gene expression and/or suppression of viruses. They include small interfering RNAs (siRNAs), small nuclear RNAs (snRNAs), and microRNAs (miRNAs). Each of these has short regions of duplex.
- In RNA, G-U base pairs are not unstable, allowing for more base-pairing possibilities. Single-stranded RNA therefore has many more ways to base-pair with itself than single-stranded DNA.
- RNAs like the rRNAs of ribosomes that catalyze reactions, are called ribozymes.
- RNA is less chemically stable than DNA.
- Cytosine can spontaneously deaminate to form uracil. Repair systems fix this in DNA.
- Denaturation of nucleic acids is accomplished by breaking the hydrogen bonds between the base pairs of the double helix. This is often accomplished with heat.
- When denatured, absorbance of light at 260 nm by single strands is greater than that of double strands, leading to the hyperchromic effect.
- Denaturation of strands is important for techniques like the polymerase chain reaction (PCR).
- The process of allowing strands to re-form a duplex is called annealing.
- Human DNA is a cell is over 7 feet long. It is wrapped in chromosomal coils (chromatin) by positively-charged proteins called histones.
- DNA is kept in the nucleus of eukaryotic cells and in a nucleoid of bacterial cells.
- Prokaryotes don't have histones, but do have nucleoid associated proteins that they wrap around.
- There are five main types of eukaryotic histones - H1, H2a, H2b, H3, and H4. Pairs of each of the last four are found as octamers in the core particle of the nucleosome - the fundamental repeating unit of chromatin. H1 binds to the DNA in the regions between core particles.
- Histones are positively charged and are rich in lysine and arginine.
- Tightly packed chromatin is called heterochromatin and is found in metaphase chromosomes of meiosis and mitosis.
- Chemical modification of lysine side chains in chromatin (acetylation, for example), changes the histones' charge and the tightness with which they are bound to the negatively charged DNA. This effectively loosens the grip of histones on DNA and is important in gene expression to allow transcription proteins to gain access to relevant DNA sequences.
- The Ames test allows one to determine the tendency of a compound to cause mutation.

- The Ames test works by using a biological assay to measure the frequency with which a specific mutation occurs in a plasmid. By comparing the mutation rate for bacteria treated with a compound compared to the mutation rate of bacteria not treated with the compound, the mutagenicity of the compound is determined.

Carbohydrates

- Carbohydrates are molecules that are literally hydrates of carbon. They are also known as sugars or saccharides and polymers of them are known as polysaccharides. Monosaccharides contain one sugar. Disaccharides contain two. Oligosaccharides contain several.
- Glucose is a monosaccharide, sucrose is a disaccharide, and glycogen is a polysaccharide.
- Sugars are names with the -ose suffix.
- Some sugars are modified, such as deoxyribose or glucose-6-phosphate.
- The most common monosaccharides include glucose, fructose, galactose, ribose, and mannose. All but fructose are sugars containing an aldehyde (aldoses). Fructose contains a ketone group (ketose).
- Glucose, fructose, galactose, and mannose all contain six carbons (hexoses). Ribose contains five carbons (pentose).
- Names can be combined. Fructose is a keto-hexose. Ribose is an aldo-pentose.
- Most sugars have multiple asymmetric centers.
- Sugars that are the same chemical type (aldoses, for example) with the same formula (hexoses, for example), but differ in only in arrangement of hydroxyls around asymmetric carbons are known as diastereomers.
- Diastereomers that differ only in configuration of one carbon are called epimers.
- Cyclization of linear sugar structures creates a new asymmetric center at the location of the carbonyl group of the linear sugar. This new asymmetric center is called the anomeric carbon.
- Diastereomers that differ only in the configuration of the anomeric carbon are called anomers. The location of the hydroxyl on the anomeric carbon determines whether it is in the α (hydroxyl down) or the β (hydroxyl up) configuration.
- Sugars that cyclize to form rings with 6 atoms are called pyranoses. Those that form rings of 5 atoms are called furanoses.
- A given form of a hexose sugar can exist in two different conformations known as the boat or the chair form (see Figure 2.127).
- Modifications to sugars can include oxidation, reduction, phosphorylation, and conversion of a hydroxyl to an amine or acetyl-amine. Alterations affecting the anomeric hydroxide create glycosides.
- A reducing sugar is a sugar that can easily be oxidized. Benedict's test determines if a sugar is a reducing sugar or not. In the test, cupric oxide (blue color) is reduced to cu-

prous oxide (orange color) if a reducing sugar is present.

- Aldoses and ketoses that can tautomerize to an aldose (such as fructose) are reducing sugars. Any sugar with a free, non-glycosidic anomeric hydroxyl group is a reducing sugar.
- Phosphorylation of sugars occurs in metabolism.
- Oxidation of a sugar creates modified sugars like glucuronic acid or galacturonic acid (oxidation of the sixth carbon in each case). The new carboxyl group can ionize easily.
- Glucuronic acid is a common constituent of glycosaminoglycans, proteoglycans, and glycoglycerolipids and is found in heparin, dermatan sulfate, chondroitin sulfate, hyaluronic acid, and keratan sulfate.
- Glucuronic acid is also a precursor of ascorbic acid (Vitamin C) in organisms that synthesize this compound.
- Reduction of sugars creates sugar alcohols, compounds widely used as thickeners of food or as artificial sweeteners.
- Common sugar alcohols (sugar progenitor in parentheses) include glycerol (glyceraldehyde), xylitol (xylose), sorbitol (glucose), galactitol (galactose), arabitol (arabinose), and ribitol (ribose).
- Most are inefficiently absorbed by the intestine.
- Artificial sweeteners are compounds that stimulate sweet receptors on the tongue.
- Disaccharides are comprised of two monosaccharides.
- The most common disaccharides include sucrose (glucose and fructose), lactose (galactose and glucose), and maltose (glucose and glucose.
- All of the common disaccharides contain at least one glycosidic bond.
- Oligosaccharides are comprised of a few (typically 3 to 9) sugar residues. Most are bound to other molecules/structures.
- Oligosaccharides in membrane glycoproteins play important roles in cellular identity/recognition - often a factor in transplanted organ rejection.
- Addition of sugar(s) to proteins is called glycosylation and the products are glycans.
- Immunoglobulin types (IgG, IgA, IgE, IgD, and IgM have distinct glycosylation patterns that confer unique functions by affecting their affinities for immune receptors.
- Blood types, arise from differential glycosylation of a blood cell membrane protein.
- Glycosylation can also play an important role in cell-cell adhesion - important in the immune system.
- Oligosaccharides that are attached to proteins may also determine their cellular destinations. I-cell disease, which arises from an oligosaccharide on a glycoprotein that lacks proper phosphorylation, results in the wrongful export of the protein from the cell instead of its intended destination in the lysosomes.

- There are five such classes - 1) N-linked (attachment to an asparagine or arginine side chain amine), 2) O-linked (attachment to the hydroxyl of serine, threonine, tyrosine, hydroxylysine, or to a lipid; 3) attachment to the phosphate of a phosphorylated amino acid, such as serine; 4) glypiations (use of a phosphatidylinositol to join proteins to lipids; or 5) c-linked (attachment to a carbon of a tryptophan side chain).

- Glycosylation may be required for proper protein folding or for stabilization.

- N-linked glycosylation is the most common type and occurs in the endoplasmic reticulum.

- The process starts on a dolichol pyrophosphate on the outside of the organelle where a core structure of seven sugars is assembled in a Y-shaped form. The structure then flips to bring the sugar structure to the inside of the endoplasmic reticulum (still attached to dolichol phosphate). Additional sugars may be added and then the oligosaccharide is attached to the target protein where additional modifications may occur.

- O-linked glycosylation is initiated primarily in the Golgi apparatus of eukaryotic cells, though a few such linkages start in the endoplasmic reticulum.

- Mucins are membrane or secreted glycoproteins that have many O-linked oligosaccharide chains and are present in most bodily secretions.

- In glypiation, a protein's carboxy terminus becomes linked to glycosylphosphatidylinositol to anchor it to a membrane. This is linked to mannose residues that are attached to GPI embedded in the membrane.

- C-linked glycosylation is the rarest and least understood protein glycosylation, occurring as a link between a mannose residue and a tryptophan side chain.

- Glycoproteins arise from glycosylation of a protein.

- Glycation refers to non-enzymatic reaction of a sugar with a protein or lipid. It is driven by the chemistry and concentration of monosaccharides.

- Exogenous glycation occurs outside of organisms and arises mostly from cooking of food (browning) where it contributes to the taste of cooked food.

- Endogenous glycation occurs inside of an organism. Most commonly it involves fructose, mannose, or glucose. It can be damaging to the endothelium or cartilage can arise from hydrogen peroxide reaction byproducts.

- Diabetes can be indicated by increased glycation of hemoglobin.

- Polysaccharides are polymers of monosaccharides. Most are homopolymers.

- Polysaccharides function in energy storage (animals), structural integrity of cells (plants, fungi, bacteria) and lubrication (joints, mucous).

- Amylose is a simple polysaccharide. It is a homopolymer of glucose units linked only with α-1,4 bonds. It is an energy storage form in plants.

- Amylopectin is related to amylose, having α-1,4 linked glucose units, but about every fifty residues, a new chain of glucoses (also linked α-1,4) branches off from carbon 6 from a glucose (the only 1,6 branch in the chain). Amylopectin is also an energy storage form in plants and a mixture of it with amylose is what we refer to as starch.

- Glycogen is an animal polysaccharide related to amylopectin. Its only difference is that the branches occur about every 8-10 residues instead of every 50 residues, meaning glycogen is more branched.

- In animals, glycogen is broken down starting at the ends, so more ends means more glucose can be released quickly.

- Cellulose is a structural polysaccharide found in plants and fungi, forming the cell wall. It is also a polymer of glucose, but the links between units are β-1,4. Cellulose cannot be digested by most animals because they lack the cellulase enzyme needed for that. Ruminants, however, contain a bacterium that has the enzyme and they can get glucose energy from plant cell walls.

- Hemicellulose is a class of molecules that encompasses several branched heteropolymers of (mostly) D-pentose sugars along with a few hexoses and L-sugars. Hemicelluloses are shorter than cellulose (500-3000 sugars versus 7000-15,000 sugars).

- Chitin is another structural polysaccharide, being comprised of N-acetylglucosamine units joined by β-1,4 linkages. It is like cellulose except for the acetyl-amine group replacing the hydroxyl on position 2.

- Pectins are structural polysaccharides rich in galacturonic acid that is present in most primary plant cell walls and abundant in non-woody parts of terrestrial plants.

- Pectins in the diet may reduce cholesterol due to its tendency to bind it and reduce absorption of cholesterol from food.

- Lectins are proteins that have high specificity of binding for certain sugars. They facilitate attached of bacteria and viruses to cellular targets. Some, such as ricin, are highly toxic.

- In the immune system, a mannan binding lectin (MBL) helps mediate the first defenses against microorganisms and may modulate inflammatory processes.

- Biofuels are fuels derived from biological sources. Most commonly, they are ethanol or methane and may be made by cellulase digestion of plant cellulose followed by fermentation or by native metabolism of methane producing organisms.

- Agar/agarose is a polysaccharide with laboratory applications. It is a polysaccharide polymer of D-galactose and 3,6-anhydro-L-galactopyranose extracted from seaweed. Agarose used to make laboratory gels for separation of DNAs. Agar, which is made by adding agaropectin to agarose, is used to make growth media for plating microorganisms or other cells.

- Glycosaminoglycans are polymers of unbranched repeating disaccharides. The repeating units of the disaccharide core of the molecules typically have an amino sugar (N-acetylglucosamine or N-acetylgalactosamine) and a uronic sugar (glucuronic acid or iduronic acid) or galactose.

- The presence of uronic acid residues and sulfates in glycosaminoglycans causes them to be polyanionic, so they can bind many cations.
- There are four groups - 1) those in connective tissues linked to collagen; 2) joint lubricants; 3) anti-clotting agents; and 4) mucus components.
- Chondroitin sulfate is a glycosaminoglycan found in cartilage and is given as a dietary supplement to reduce joint pain. It can be linked to proteins through serine residues to form proteoglycans, such as aggrecan, versican, brevican, and neurocan.
- Heparin helps prevent clotting of blood by inhibiting conversion of fibrinogen to fibrin. It is stored in the secretory granules of mast cells and released at the point of injury. The repeating disaccharide of 2-O-sulfated iduronic acid and 6-O-sulfated, N-sulfated glucosamine, occupies about 85% of the molecule and make heparin the molecule with the highest negative charge density known.
- Hyaluronic acid is a glycosaminoglycan in connective, epithelial, and nerve tissues that lacks sulfate and is formed in the plasma membrane instead of the Golgi apparatus. It has a molecular weight in the millions. Hyaluronic acid is important in joint lubrication (as a component of synovial fluid) and in the extracellular matrix, where it assists in cell proliferation and migration.
- Hyaluronic acid is also a major component of skin and has functions in tissue repair.
- Hyaluronic acid is abundant in the granulation tissue matrix that replaces a fibrin clot during the healing of wounds.
- Breakdown of hyaluronic acid is catalyzed by enzymes known as hyaluronidases. Humans have seven types of such enzymes, some of which act as tumor suppressors.
- Proteoglycans are made by linking glycosaminoglycans to proteins. Proteoglycans are made by glycosylation of target proteins in the Golgi apparatus.

Lipids

- Lipids are molecules that are significantly hydrophobic
- Many are important for energy storage or for functions in membranes
- Some, like fats are purely hydrophobic. Others, like glycerophospholipids and sphingolipids are amphipathic/ amphiphilic.
- Fatty acids are components of fats and they store a lot of energy.
- They can be saturated (no double bonds), unsaturated (at least one double bond), or polyunsaturated (more than one double bond).
- Double bonds in biologically produced fatty acids are almost exclusively in the *cis* configuration. Partial hydrogenation of vegetable oil produces *trans* fats containing fatty acids with *trans* double bonds.
- *Trans* fat increases LDL levels and lowers HDL levels.

- The Δ numbering system for fatty acids labels #1 as the carboxyl group whereas the ω numbering system calls the methyl group as #1.
- Animals lack the ability to make double bonds beyond position Δ-9, so those fatty acids are essential and must be in the diet.
- ω-3 and ω-6 fatty acids have important health considerations.
- Glycerophospholipids are components of the lipid bilayer of membranes.
- They are derived from phosphatidic acid, just as fats are.
- Glycerophospholipids often are esterified to ethanolamine, serine, choline, or inositol. These are phosphatidyl compounds.
- Phosphatidyl ethanolamine is found in all living cells and makes up 25% of the phosphatidyl compounds - up to 45% of brain tissue.
- Phosphatidyl serine is preferentially found on the inner leaflet of the plasma membrane. In apoptosis (programmed cell death), it appears on the outer leaflet and serves as a signal to macrophages to destroy the cell.
- Phosphatidly choline tends to be found more on the outer leaflet of the plasma membrane. It is positioned there by phosphatidylcholine transfer protein.
- Cardiolipin is an unusual glycerophospholipid containing two diacylglycerol backbones separated by a diphosphoglycerol. It occupies about 20% of the inner mitochondrial membrane and plays roles in facilitating electron transport through complexes III and IV.
- In apoptosis, cardiolipin gets oxidized and then moves to the outer mitochondrial membrane where it facilitates movement of cytochrome c to the cytoplasm.
- Diacylglycerol (DAG) is produced by hydrolysis of fat and hydrolysis of phosphatidylinositol-4,5-bisphosphate (PIP_2) by phospholipase c. It is a signaling molecule.
- Inositol is a component of many lipids. It contains six carbons and can contain 1-6 phosphates. It is a part of the signaling molecules known as PIP_2 and PIP_3.
- PIP_2 functions in the phospholipase c signaling cascade. In this signaling pathway, hydrolysis catalyzed by phospholipase c releases inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol.
- Phosphorylation of PIP_2 produces PIP_3, which helps recruit proteins in signaling cascades. Dephosphorylation of PIP_3 by phosphatase PTEN yields PIP_2.
- Plasmalogens are glycerophospholipids with a vinyl ether linkage at position 1 of glycerol, in contrast to other glycerophopsholipids, which have an ester linkage at this position. They are abundant in heart and nerve tissue (30% of total) and 70% of the ethanolamine lipids of the myelin sheath of nerve cells are plasmalogens.
- Lecithin is a generic term referring to many different lipids.
- Sphingolipids are synthesized from palmitic acid and serine. They are named for the amino alcohol known as sphin-

gosine, though they are not directly synthesized from it.

- Addition of a fatty acid to a simple sphingolipid creates a ceramide. If a phosphoethanolamine is added to the ceramide, sphingomyelin is made. It is an important component of the myelin sheath of nerve cells.

- If a simple sugar is added instead of phosphoethanolamine, a cerebroside is created and if a complex sugar is added, then a ganglioside is created.

- Sphingolipids are abundant in plasma membranes, but almost completely absent from mitochondrial and endoplasmic reticulum membranes.

- Fatty acids with 20 carbons, such as arachidonic acid, dihomo-γ-linolenic acid, and eicosapentaenoic acid are precursors of eicosanoids. Important ones include the prostaglandins, prostacyclins, thromboxanes, leukotrienes, lipoxins, and endocannabinoids.

- Prostaglandins are derived from arachidonic acid by action of cyclooxygenase enzymes (also called COX enzymes). The molecules have numerous, often conflicting physiological effects, such as constriction or dilation of vascular smooth muscle cells, induction of labor, regulation of inflammation, and action on the thermoregulatory center of the hypothalamus to induce fever, among others.

- Thromboxanes and prostacyclins are made from prostaglandins and the three are collectively known as prostanoids.

- Interesting prostaglandins include PGD_2, PGE_2, PGH_2, $PGF_{2\alpha}$, and PGI_2.

- Thromboxanes play roles in blood clotting. They are potent vasoconstrictors and facilitate platelet aggregation.

- Thromboxanes are synthesized from PGH_2 and can be reduced (blood thinning) by aspirin, which inhibits synthesis of prostaglandins from arachidonic acid.

- Prostacyclin is also known as PGI_2. It counters the effect of thromboxanes and is also made from PGH_2 by prostacyclin synthase.

- Leukotrienes are eicosanoids (from arachidonic acid) that are involved in regulating immune responses. Leukotrienes are found in numerous immune system cells. They can trigger contractions of the smooth muscles of bronchioles and may play a role in asthma and allergic responses.

- A fat is a triacylglycerol that is a solid at room temperature, whereas an oil is a triacylglycerol that is a liquid at room temperature. Increasing amounts of unsaturated fatty acids and shorter fatty acids lower the melting point of a fat.

- Adipocytes are cells specialized to store fats/oils.

- Lipases catalyze release of fatty acids from fats/oils by hydrolysis.

- Cholesterol provides membrane flexibility. It is made in many cells, but the most is made in the liver.

- The pathway responsible for cholesterol biosynthesis is known as the isoprenoid pathway. This path also leads to synthesis of other molecules, including fat soluble vitamins.

- Movement of lipids in the body is problematic due to their hydrophobic nature and the aqueous environment in which they must travel. This occurs in lipoprotein complexes made mostly in the liver and lymph system. They include chylomicrons (from small intestine), VLDLs, IDLs, LDLs, and HDLs. The last four are made in the liver.

- LDLs contain the highest concentration of cholesterol and they enter the cell via receptor-mediated endocytosis.

- Cholesterol is made into bile acids by the liver for excretion in the bile. Bile acids also help with emulsification of fats.

- Levels of *trans* fats in the diet correlate with incidence of coronary artery disease.

- Cholesterol is recycled through the digestive system. Plant equivalents of cholesterol called phytosterols compete with cholesterol in the recycling system and may lower body levels of cholesterol.

- LDLs are referred to as "bad" cholesterol because they are associated with atherosclerosis. HDLs are called good cholesterol because their levels correlate with removal of arterial debris (including cholesterol). They also help to reduce inflammation.

- Cholesterol acts an insulator for the transmission of signals in nerve tissue. It helps to manage fluidity of membranes over a wide range of temperatures and reduces the membrane's permeability. It also helps with the structure of lipid rafts in the membrane.

- Vitamin A is a fat soluble vitamin that comes in three forms - retinol (alcohol), retinal (aldehyde), and retinoic acid (acid).

- Retinol is the storage form. Retinal has a role in vision, and retinoic acid aids in stem cell differentiation through the retinoic acid receptor.

- Vitamin A is made from β-carotene. Vitamin A (retinal) is light sensitive with double bonds that isomerize (*cis-trans*) when exposed to light. Bound to a protein (rhodopsin), it initiates a nerve signal that results in detection of light by rod and cone cells in the eyes.

- Deficiency of vitamin A can result in blindness and excess vitamin A can result in death.

- Vitamin D is necessary for proper absorption of calcium and phosphorus from the diet. It behaves like a hormone and is made from cholesterol.

- Exposure of a vitamin D precursor to ultraviolet light is necessary for making an intermediate in the vitamin's synthesis.

- Vitamin D acts through a specific receptor.

- Vitamin E is a collection of stereoisomers of two compounds - tocopherols and tocotrienols that act as antioxidants.

- Vitamin E works via the glutathione peroxidase system to limit chain reactions involving lipid peroxidation in membranes. It also reduces levels of reactive oxygen species.

- After taking electrons from oxygen radicals, Vitamin E is recycled back to its original

form by a hydrogen donor - sometimes Vitamin C.

- Vitamin E can also can inhibit action of protein kinase C in smooth muscle and activate catalysis of protein phosphatase 2A to remove phosphates, stopping smooth muscle growth.

- Deficiency of vitamin E reduces the efficiency of nerve signals, can lead to low birth weights and premature deliveries.

- Excess vitamin E can reduce vitamin K levels, thus reducing the ability of the body to clot blood.

- Vitamin E may also protect by reducing harmful oxidation of LDLs - a step in atherosclerosis.

- Vitamin K also comes in multiple forms. It is used as a co-factor for enzymes that add carboxyl groups to glutamate side chains of proteins to increase their affinity for calcium. This is important in blood clotting. Proteins affected include blood proteins such as prothrombin (called Factor II), Factors VII, IX, and X, as well as proteins involved in bone metabolism - osteocalcin, also called bone Gla protein (BGP), matrix Gla protein (MGP), periostin and others.

- One strategy of blood thinning drugs (non-aspirin) is to interfere with vitamin K's role in carboxylating prothrombin. Warfarin is one such compound.

- Vitamin K is found abundantly in green, leafy vegetables. Vitamin K_1 is called phylloquinone, but has low bioavailability. Vitamin K_2 is produced by bacteria in the gut and is the primary source of the vitamin.

- Steroid hormones are all made from cholesterol and are grouped into five categories - mineralocorticoids (water/electrolyte balance), glucocorticoids (modulating immune system), progestagens (pregnancy maintenance), androgens (male sex hormones), and estrogens (female sex hormones).

- Cortisol is an important glucocorticoid with cardiovascular, metabolic, and immunologic functions.

- Progesterone is an important progestagen. It is produced primarily in the diestrus phase of the estrous cycle by the corpus luteum of mammalian ovaries.

- Androgens stimulate development and maintenance of male characteristics in vertebrates. Testosterone, dihydrotestosterone, and androstenedione are important androgens

- Estrogens are made from androgens. They play important roles in menstrual and estrous cycles by activating estrogen receptors inside of cells. These receptors, in turn, affect expression of many genes.

- Major estrogens and their primary times of importance include estrone (menopause), estradiol (reproductive years), and estriol (pregnancy).

- Estrogens are made from androgens by action of an enzyme known as aromatase. Inhibition of aromatase by specific aromatase inhibitors is used to stop estrogen production and is a strategy for stopping estrogen-responsive tumors.

- Cannabinoids are biochemicals that act on brain receptors to repress neurotransmitter release.

- Endocannabinoids are cannabinoids made in the body, whereas phytocannabinoids are made in plants, such as marijuana.

- Anandamide is an endocannabinoid neurotransmitter derived from arachidonic acid. It has roles in stimulating eating/appetite, as well as affecting motivation and pleasure. It may be responsible for "runner's high". It is found in chocolate.

- Lipoxins are eicosanoids that modulate immune responses and have anti-inflammatory effects - signaling the end of the inflammation response.

- Heme has a large heterocyclic aromatic ring known as a porphyrin ring with a ferrous (Fe^{++}) ion in the middle. It is a prosthetic group for proteins that include the globins (hemoglobin and myoglobin), cytochromes, catalase, and succinate dehydrogenase.

- Porphobilinogen is a pyrrole molecule involved in porphyrin metabolism. It is acted upon by the enzyme porphobilinogen deaminase. Deficiency of this enzyme can result in porphyria - accumulation of porphobilinogen in the cytoplasm of cells. It can cause temporary madness and may be the source of the vampire legend.

- Phosphorylated dolichols play central roles in the N-glycosylation of proteins in the endoplasmic reticulum. A membrane-embedded dolichol pyrophosphate is a point of attachment for oligosaccharides to be built for later transfer to target proteins. Sugars involved include glucose, mannose, and N-acetylglucosamine.

- Terpenes are non-polar molecules made from isoprene units (mostly by plants and some insects). They are common components of plant resins and help to protect against insects.

- The flavor of hops comes from terpenes.

- Dimethylallyl pyrophosphate and isopentenyl pyrophosphate are the two isoprenes used to make terpenes.

- Terpenes and terpenoids are classified according to how many isoprene units they contain. They are as follows - hemiterpenes (one unit), monoterpenes (two units), sesquiterpenes (three units), diterpenes (four units), sesterterpenes (five units), triterpenes (six units), sesquarterpenes (seven units), tetraterpenes (eight units), polyterpenes (many units).

- Common terpenes include terpineol (lilacs), limonene (citrus), myrcene (hops), linalool (lavender), and pinene (pine). Higher order terpenes include lycopene (tetraterpenes), carotenes (tetraterpenes), and natural rubber (polyterpenes).

- Caffeine is the world's most consumed psychoactive drug. It is closely related to adenine and guanine and this is responsible for many effects on the body. Caffeine blocks binding of adenosine to a receptor, preventing drowsiness.

- Caffeine crosses the blood-brain barrier and stimulates release of neurotransmitters. It inhibits phosphodiesterase and causes cAMP levels to rise, thus stimulating breakdown of glycogen and an increase in blood glucose. It inhibits TNF-α and leukotriene synthesis, which results in reduction of inflammation and innate immunity.

- Lipoprotein complexes are combinations of apolipoproteins and lipids bound to them that solubilize fats and other non-polar molecules, such as cholesterol, allowing them to move in the bloodstream.

- From highest density to lowest they are high density lipoproteins (HDLs), Low Density Lipoproteins (LDLs), Intermediate Density Lipoproteins (IDLs), Very Low Density Lipoproteins (VLDLs) and the chylomicrons. The particles are synthesized in the liver and small intestines.

- The apolipoproteins ApoC-II and ApoC-III are found in all of the complexes and respectively activate or inactivate lipoprotein lipase.

- ApoE helps to predict the likelihood of the occurrence of Alzheimer's disease in a patient.

- ApoB-48 and ApoB-100 are coded by the same gene, but a unique mRNA sequence editing event occurs that converts one into the other. This is a deamination of the cytosine base in nucleotide #2153. It changes C to a U and changes the codon it is in from CAA (codes for glutamine) to UAA (stop codon). The enzyme for the deamination is only present in small intestine. Thus ApoB-100 is made for chylomicrons and ApoB-48 is made for VLDLs by the liver.

- Three relevant pathways for moving lipids in the body are 1) the exogenous pathway; 2) the endogenous pathway, and 3) the reverse transport pathway.

- Dietary lipids take the exogenous pathway. These get emulsified by bile acids, pass through intestines, get packaged in chylomicrons, pass through the lymph system and enter the bloodstream.

- In the bloodstream, lipoprotein lipase breaks down the fats causing the chylomicrons to shrink and become what are known as chylomicron remnants. These are absorbed by the liver to end the exogenous pathway.

- The endogenous pathway begins with packaging of lipids into VLDLs which enter the bloodstream and travels to muscles/tissues where lipoprotein lipase cleaves fatty acids from fats. These get oxidized in muscle cells or rebuilt into fats in adipocytes. VLDLs shrink to IDLs and LDLs. Cholesterol is unaltered in this process so the cholesterol concentration increases with each shrinkage of the complexes.

- The LDLs are comprised primarily of lipids and ApoB-100. This latter protein is bound by cellular receptors for binding and internalization by the process of receptor-mediated endocytosis. LDLs not internalized by cells return to the liver where they are bound by a liver LDL receptor and internalized. The more LDLs making it back to the liver, the fewer VLDLs will be released by the liver. This ends the endogenous pathway.

- HDLs play important roles in the last lipid movement pathway - the reverse transport pathway. HDLs are synthesized in liver and small intestine with little or no lipid. They scavenge cholesterol from remnants of lipoprotein complexes (sometimes damaged) in the blood. The cholesterol causes the HDL to swell and it returns with its load to the liver where it is internalized. This ends the reverse transport pathway.

- The role of liver LDL receptors in managing LDL and cholesterol levels is critical. Non-functioning receptors leads to a condi-

tion known as familial hypercholesterolemia - dangerously high LDL levels due to the fact that the liver gets no LDLs returned to it, so it continues to release large quantities of VLDLs.

- Because of the fact that high LDL levels correlate with increased incidence of atherosclerosis, LDLs are know as bad cholesterol, whereas HDLs are known as “good” cholesterol, since it has the effect of reducing cholesterol and damaged LDLs from the blood stream.

- Foam cells arise when macrophages take up damaged LDLs. Damage may commonly arise from oxidation by reactive oxygen species arising from smoking. Foam cells are the beginnings of formation of atherosclerotic plaques.

- The lipoprotein ApoE comes in four different forms - E1, E2, E3, and E4. People homozygous for the E4 allele are 15 times more likely to contract Alzheimers disease. The cause of the association is not known.

Anthem for BB 350

To the tune of "*She'll Be Comin' 'Round the Mountain*"
Metabolic Melodies Website HERE

Oh the students taking BB 350 - 350
Have an awful lot of things that we must know - 350
With acetic acid buffer
Kevin Ahern makes us suffer
The exams could not be tougher 3-5-0 – 350

There's amino acid side chains to recall - 350
And the things it takes to make cholesterol - 350
Anabolic catabolic
Kevin Ahern's diabolic
I'm becoming alcoholic 3-5-0 -350

There must be a way to jam into my head - 350
All the metabolic enzyme names I dread - 350
Can you help me learn the spaces
Where the endonucleases
Cut the DNA in places 3-5-0 -350

I must find a way to make a better grade
Or my GPA will truly get waylaid
I shall overcome frustration
To achieve my aspiration
On the last examination 3-5-0, 350

Here's the plan I made to help me to succeed
Fill the notecard with the knowledge I will need
I've put all of Ahern's quotes
Along with what each one denotes
Onto a massive stack of notes for 3-5-0, 350

So there's just one teensy problem I must fix
It requires some very skillful penman tricks
Squeezing info I must store
Onto the card he gave before
Will mean a font the size of zero point one four

Oh the students taking BB 350 - 350
Have an awful lot of things that we must know - 350
With acetic acid buffer
Kevin Ahern makes us suffer
The exams could not be tougher 3-5-0 – 350

Point by Point: Membranes

Basic Concepts

- Cell membranes contain cholesterol, proteins, glycolipids, glycerophospholipids, and sphingolipids.
- Lipid bilayers form spontaneously when glycerophospholipids, and sphingolipids are mixed in an aqueous solution.
- Water, CO_2, CO, and O_2 move efficiently across the lipid bilayer. Other molecules don't move so readily and require proteins/energy to assist their movement.
- Cells need energy, export of wastes, and osmotic balance. They create chemical/ion gradients for energy purposes.
- When energy is required to move a substance across a membrane, the process is called active transport.
- Facilitated diffusion is driven by the process of diffusion and occurs through specific cellular channels made of protein.
- Surrounding cells are plasma membranes and (in some cases) cell walls.
- Bacteria, fungi, and plants all have cell walls in addition to plasma membranes.

Animal cells only have a plasma membrane.

- All plasma membranes contain amphiphilic substances, such as glycerophospholipids and sphingolipids.

- Glycerophospholipids are based on glycerol. They have two fatty acids esterified to it and the third position has a phosphate (making phosphatidic acid) to which something else is often esterified - serine, ethanolamine, choline, or inositol (making a phosphatidyl compound, such as phosphatidylserine).

- Cells tend to have more negative charges on the exterior half of the lipid bilayer (outer leaflet) and more positive charges on the interior half (inner leaflet).

- Sphingolipids are named for sphingosine, which they resemble. Attachment of a phosphoethanolamine or phosphocholine creates a sphingomyelin.

- Most sphingolipids, however, lack a phosphorylated molecule and instead have a simple sugar (cerebrosides) or a complex set of them (gangliosides).

- Glycerophospholipids and sphingolipids each have components in which one end is polar and the other is non-polar (amphiphilic).

- The components arrange themselves in aqueous solutions in a bilayer with the non-polar portions aligning in the middle of the bilayer and the polar portions projecting out on either side interacting with water.

- Plasma membranes have biases in the constituents of the inner and outer layers of the bilayer. Some, like phosphatidylcholine and sphingomyelin are predominantly found in the outer leaflet of the bilayer and others like phosphatidylserine and phosphatidylethanolamine predominate in the inner leaflet.

- Such specific arrangements are important in apoptosis (programmed cell death). Movement of biased lipids from one leaflet to another occurs during this process and may be a signal.

- Molecules with sugars attached almost always have the sugars arranged on the outside of the cell.

- Cellular organelles in eukaryotes also have biases of composition of their membrane lipids. Cardiolipin, for example, isn't commonly found in the plasma membrane or that of the endoplasmic reticulum, but is common in other organelle membranes.

- Lipids typically move freely within the layer in which they are found (called lateral diffusion), but rarely "flip" from one side to the other (transverse diffusion) without the assistance of an enzyme.

- Enzymes catalyzing transverse diffusion of membrane lipids include flippases (move from outer leaflet to inner leaflet); flippases (move from inner leaflet to outer leaflet), and scramblases (move both directions).

- Cholesterol and proteins are other important components of the lipid bilayer.

- Cholesterol is also a metabolic precursor of bile acids, and steroid hormones.

- Cholesterol influences membrane fluidity.

- Membrane fluidity is also influenced by the fatty acids within it - long and more saturated fatty acids favor higher T_m values. The T_m is the midpoint of the transition between more fluid and more solid characteristics of the lipid bilayer.

- Cholesterol does not change the T_m. Rather, it widens the range of that transition temperature.

- Cholesterol is found abundantly in membrane structures called lipid rafts. These are membrane sub-structures that are more organized that the surrounding material and often contain lipids with more saturated fatty acids and up to 5 times the amount of cholesterol. They are also rich in sphingolipids, which appears to help cholesterol to fit better into the structures.

- Prenylated proteins, such as Ras, may be excluded from lipid rafts.

- Lipid rafts may provide concentrating platforms after individual protein receptors bind to ligands in signaling and protect them from being altered (dephosporylation, for example).

- The lipid bilayer is an effective barrier to the movement of most molecules.

- Membrane proteins play roles, in some cases, with transport of molecules across the bilayer. Proteins occupy (typically) about 30-75% of the weight of a lipid bilayer.

- An integral membrane protein completely spans from one side of the bilayer to the other and often projects out from both sides. These transmembrane proteins can be 1) docking sites to the extracellular matrix; 2) as receptors of chemical signals; or 3) facilitators of the transport of molecules in or out of the cell.

- Peripheral membrane proteins interact with part of the bilayer, but do not project through it.

- Associated membrane proteins do not have hydrophobic regions and do not embed in any part of the lipid bilayer, but are found near them as a result of interaction with other proteins or molecules in the bilayer.

- Anchored membrane proteins are not embedded in the layer, but instead are attached to a non-polar molecule that is embedded in the membrane.

- Integral and anchored membrane proteins are categorized into six different types. Type I has one portion of the protein traversing the lipid bilayer. The protein's amino terminus is on the outside and the carboxy terminus is on the inside. Type II membrane proteins have this reversed. Type IIIs have a single chain that crosses the membrane multiple times to form a channel. Type IVs have multiple chains that cross multiple times. Type Vs do not cross the membrane but are anchored to something in the membrane. Type VIs have a part that crosses and they are anchored.

- Glycoproteins embedded in membranes play important roles in cellular identification. Blood types differ from each other in the structure of the carbohydrate chains projecting out from the surface of the glycoprotein in their membranes.

- The permeability of water across a lipid bilayer and the impermeability of materials inside the cell create osmotic pressure

- Osmotic pressure is a measure of the tendency of a solution to take in water by the process of osmosis.
- The osmotic pressure of a solution is the pressure difference needed to halt the flow of solvent across a semipermeable membrane.
- $P_{osmotic}$ = MR*T where M is the molarity of the dissolved molecules, R* is the gas constant expressed in (L atm)/(K mol), and T is the temperature.
- A hypotonic situation occurs if the concentration of solutes is greater inside the cell than outside. Water will tend to move into the cell, causing the cell to swell.
- It is hypertonic if the solute concentration is greater outside the cell than inside of it. Then water will exit the cell and the cell with shrink.
- When the concentrations of solutes inside and outside of the cell is equal, this is called an isotonic solution - no change will occur.
- If the osmotic pressure is greater than the forces holding together a cellular membrane, the cell will rupture. Cell walls resist rupturing due to osmotic stresses.

Membrane Transport

- Cells must internalize nutrients from their environment.
- A protein involved in moving only one molecule across a membrane is called a uniport.
- Proteins that move two molecules in the same direction across a membrane are called symports.
- If two molecules are moved in opposite directions across the bilayer, the protein is called an antiport.
- Proteins involved in moving ions are called ionophores.
- Electrogenic transport involves movements that result in a net change of charge.
- Electroneutral transport involves movements that result in no net change of charge.
- If simple diffusion is the driving force, the process is called facilitated diffusion and if the process requires other energy input, the process is active transport.
- Channels largely provide openings with some specificity and molecules pass through them at close to the rate of diffusion. Examples include sodium and potassium channels.
- Transporters have high specificity and transfer rates that are orders of magnitude slower than channels. An example is the Na+/K+ ATPase.
- At the end of the process of facilitated diffusion, molecular concentrations on either side of a lipid bilayer will be equal if nothing else is done.
- The ion channels are membrane proteins forming pores in cell membranes to regulate movement of selected ions across a membrane.
- Ion channels help to establish the resting membrane potential and to affect action

potentials and other electrical signals. They are important in nerve transmission.

- Ion channels are controlled by mechanisms that include voltage, ligands, light, temperature, and mechanical deformation.
- Ligand-gated ion channels (LGICs) are transmembrane proteins which open to selectively allow ions such as Na^+, K^+, Ca^{++}, or Cl^- to pass through the membrane in response to the binding of a ligand messenger.
- Sodium ion channels in the tongue for sugar receptors open in response to binding of sucrose, initiating a nerve signal.
- Calcium gates in the eye are open by default, but stimulation by light causes them to close, triggering a series of events that result in a signal being sent the brain about the perception of light.
- Voltage gated channels are essential for transmission of nerve signals.
- Ion channels selectively allow ions to pass based on 1) size and 2) energy of dehydration/hydration.
- Sodium channels exclude potassium ions on the basis of size, but potassium channels exclude sodium ions based on unoptimal orientation of the sphere of water around sodium ions. The potassium channel is perfectly set up for the hydration shell around potassium ions, thus making dehydration of potassium on entering the channel optimal and energetically favorable when exiting the channel, but for sodium ions, the energy of rehydration is insufficient to make dehydration of the sodium ions energetically favorable. As a result potassium ions selectively pass through a channel even though they are bigger than sodium ions.
- Ionic balance is important for cells. If the ionic balance of a cell is sufficiently disturbed by an uncontrolled ionophore, a cell may die.
- Gramicidin is an antibiotic peptide made by a soil bacterium. It is an ion channel that gets inserted in to a target cell and kills it by allowing sodium to leak in.
- Transporter proteins are slower than ion channels. They use conformational changes to move ions.
- An active transport system moves at least one molecule against a concentration gradient.
- The energy source for active transport is frequently, but not necessarily ATP. The sodium-glucose transporter, for example, uses a sodium concentration gradient to move glucose into the cell.
- The Na+/K+ ATPase is an electrogenic antiport that moves three sodium ions out of the cell and two potassium ions in the cell with every cycle of action. Each movement is against a concentration gradient. ATP is the energy source. The pump is important for balancing osmotic pressure.
- The cycle goes as follows - 1) binding of three Na^+ in the cytoplasm; 2) phosphorylation of aspartate on the pump by ATP hydrolysis; 3) conformational change of pump releases Na^+ to outside; 4) two K^+ ions bind from outside; 5) dephosphorylation of pump inverts pump pushing K^+ in.
- The Na+/K+ ATPase is a P-type ATPase.

- ATPases are put into five categories. Some work in reverse and make ATP instead of breaking it down.

1. F-type - mitochondrial, chloroplasts, bacterial membrane. A proton gradient is energy source for making ATP. Complex V of mitochondria is an F-type ATPase.

2. V-type - Uses ATP to pump protons into vacuoles and lysosomes

3. A-type - found in archaeans. Similar to F-type ATPases in function.

4. P-type - bacteria, fungi, eukaryotic membranes, and organelles. Use ATP and phosphorylated aspartate to move ions across membranes

5. E-type - found on cell surfaces. Hydrolyze extracellular nucleoside triphosphates.

- The Na+/glucose transporter is an electrogenic symporter that moves glucose into intestinal cells. The sodium ion gradient is the energy source. Referred to as a secondary active transport system.

- Calcium pumps in the plasma membrane and organelle membranes pump calcium and keep cytoplasmic concentration of it low. ATP or a sodium gradient is typically the energy source.

- Opening of calcium channels allows calcium to quickly flow into the cytoplasm to facilitate muscular contraction and/or signaling.

- The sodium/calcium pump relies on a sodium gradient for energy to move calcium out of a cell. It is an electrogenic antiport.

- When heart cells are treated with digitalis (blocks Na+/K+ ATPase), the sodium gradient is significantly reduced. As a consequence, less sodium gets pumped out of the heart cells. Since calcium stimulates muscular contraction, the heart cells are stimulated to be harder due to the higher concentration of calcium on digitalis treatment. Digitalis is used to treat congestive heart failure.

- ABC transporters are a class of transport proteins that move lipids, sterols, and drugs across membranes.

- Some ABC transport proteins can provide resistance to antibiotics in bacteria as well as resistance to chemotherapy in higher cells by exporting drugs used to treat both of these types of cells.

- There are 3 groups of ABC transporters - 1) importers; 2) exporters; and 3) non-transporters that function in DNA repair and translation.

- All ABC transporters have two membrane domains and two cytoplasmic domains and they flip between opening to cytoplasm and the extracellular space in response to ATP hydrolysis.

- The protein implicated in cystic fibrosis (CFTR) is an ABC transporter.

- It normally moves chloride and thiocyanate ions across epithelial tissue membranes exerts its effect mostly in the lungs.

- Manifestations of the disease arising from lack of CFTR function include breathing difficulty and overproduction of mucus in the lungs.

- Lactose permease facilitates the movement of the sugar lactose across the lipid bilayer of the cell membrane.
- Glucose Transport Proteins (GLUTs) are uniport, type III integral membrane proteins that facilitate transport of glucose into cells.
- The one in red blood cells is known as GLUT 1 and has 12 membrane-spanning hydrophobic helices.
- GLUT 4 is regulated by insulin and is found primarily in adipose and striated muscle tissue.
- Insulin acts to stimulate uptake of glucose by cells by favoring movement of various GLUT proteins (including GLUT 4) from intracellular vesicles to the cell membrane.
- Once inside the cell, phosphorylation of glucose by hexokinase prevents it from exiting via GLUTs.

Other Considerations

- Another means of getting material into cells is by endocytosis. This method tends to move particles, some of which are larger than could be transferred via a transporter protein.
- Materials entering this way include LDLs, iron packaged in transferrin, vitamins, hormones, proteins, and some viruses.
- Receptor mediated endocytosis uses a specific cell receptor called clathrin that binds to particles with a binding site for it.
- Cellular structures lined with clathrin are called coated pits.
- ApoB-100 of LDLs binds to clathrin and is internalized and gets targeted to the early endosome for sorting and processing of contents.
- In signaling, internalization of bound receptors may result in a response in the nucleus. It can also serve to reduce the number of receptors on the surface and thus reduce the amount of signaling.
- Other types of endocytosis include 1) caveolae-based endocytosis; 2) macropinocytosis; and 3) phagocytosis.
- Caveolae-based endocytosis uses a an integral membrane protein receptor called caveolin that creates cave-like structures in a plasma membrane.
- Caveolins appear to be involved in cellular migration.
- Caveolins inhibit cancer-related growth factor signaling pathways, but can also lead to metastasis.
- Macropinocytosis literally involves a cell invaginating and “taking a gulp” of the extracellular fluid, creating a tiny vesicle. This internalized vesicle will fuse with endosomes and lysosomes. The process is non-specific for what is internalized.
- In phagocytosis, relatively large particles are internalized.
- Cells of the immune system use this to internalize debris, apoptotic cells, and microbes.
- It uses specific cell surface receptors and the internalize structure is called a phagosome. The phagosome merges with lysosome to create a phagolysosome which

gets exposed to toxic materials to kill any contents.

- Non-phagocytic internalizations target incoming material to endosomes. They provide a sorting function and can receive materials from the *trans*-Golgi network. Materials can be delivered to lysosomes or targeted to the Golgi apparatus. There are three forms of endosomes - early, late, and recycling.

- Exocytosis is used to expel materials that won't easily pass through the plasma membrane. Within the cytosol, this internalized vesicle will fuse with endosomes and lysosomes. A a result of the fusion, contents in the membrane of the vesicles become part of the plasma membrane.

- Membrane fusion is important for both endocytosis and exocytosis and occurs when two distinct lipid bilayers merge their hydrophobic cores, producing one interconnected structure.

- Processes involving membrane fusion include fertilization of an egg by a sperm, separation of membranes in cell division, transport of waste products, neurotransmitter release, fusion of artificial liposomes to cells, and entry of pathogens.

- Fusion of vesicles in exocytosis is mediated by proteins known as SNAREs (Soluble NSF Attachment Protein REceptor).

- SNARE proteins that facilitate fusion of vesicles to release neurotransmitters can be targeted and proteolytically cleaved by neurotoxins in botulism and tetanus.

- v-SNAREs are found in the membranes of transport vesicles during the budding process, whereas t-SNARES can be found in the membranes of targeted compartments.

- Fusion in neurotransmission results in release of intracellular calcium due to activation of voltage-dependent calcium channels in the targeted cell. Calcium further helps to stimulate the fusion.

- During the fusion process, v- and t-SNAREs "zipper" themselves together to bring the membrane vesicle and the target membrane closer together. Zippering also causes flattening and lateral tension of the curved membrane surfaces, favoring hemifusion of the outer layers of each membrane. Continued tension results in subsequent fusion of the inner membranes as well, yielding opening of the contents of the vesicle chamber to its target.

- Shuttles are another way to move materials across membranes.

- Electrons from NADH are shuttled across the mitochondrial inner membrane using the glycerol-phosphate shuttle or the malate-aspartate shuttle.

- In the glycerol-phosphate shuttle, electrons from NADH are donated to DHAP to create glycerol-3-phosphate, which gets moved across the inner mitochondrial membrane by a transport protein.

- Inside the mitochondrial matrix, glycerol-3-phosphate donates electrons to FAD to make $FADH_2$ and DHAP. FADH2 does not pump as many electrons in the electron transport system as NADH, so the system is not 100% efficient.

- In the malate-aspartate shuttle, inefficiency is not a problem - starting with

NADH and ending with it. In this shuttle, NADH donates electrons to oxaloacetate to create malate, which gets moved across the inner mitochondrial membrane in exchange for α-ketoglutarate. In the mitochondrial matrix, malate donates electrons to NAD^+ to create NADH and oxaloacetate. The rest of the cycle involves regenerating the original starting contents about in the inter membrane space. Oxaloacetate gets an amine from glutamate and is converted to aspartate, which is moved to the intermembrane space in exchange for another glutamate. Aspartate in the cytoplasm donates an amine to α-ketoglutarate to create glutamate and regenerate oxaloacetate. Glutamate gets transported to the matrix in exchange for aspartate (same as above). In the matrix, glutamate is the source of the amino for making aspartate, creating α-ketoglutarate. α-ketoglutarate is transported to the intermembrane space in exchange for malate (above).

- Molecules can also be shuttled across membranes. An example is the acetyl-CoA shuttle across the mitochondrial membranes. In it, acetyl-CoA is joined to oxaloacetate to by citrate synthase to create citrate and a free CoASH. The citrate is transported to the cytoplasm where the reverse reaction occurs (catalyzed by citrate lyase), yielding oxaloacetate and acetyl-CoA. Oxaloacetate can make it back to the mitochondrial matrix by several means, completing the cycle.

- Cell junctions are found in three main categories - 1) gap junctions; 2) adherens junctions; and 3) tight junctions.

- In gap junctions two connexons (one on each cell) join and link the cytoplasms of each cell together. Similar structures in plants are called plasmodesmata.

- Adherens junctions are complexes on the cytoplasmic side of cell membranes that are linked to each other or the extracellular matrix. Proteins in adherens junctions include α-catenin, β-catenin, γ-catenin, cadherins, plakoglobin, actin filaments, vinculin, and α-actinin.

- Adherens junctions may help to maintain the actin contractile ring which forms in cytokinesis.

- Tight junctions seal cells together and restrict the flow of ions in the spaces between them. They restrict the movement of materials through tissues by requiring them to pass through cells instead of around them.

- Membrane proteins attached to glycosylphosphatidylinositol (also known as a GPI anchor) are referred to as being glypiated.

- Liposomes are artificial extracellular vesicles created by spontaneous formation of lipid bilayers of glycerophospholipids and/or sphingolipids in aqueous solution. Through membrane fusion, the contents of liposome vesicles can be delivered to a cell's cytoplasm.

- Amino acids in integral membrane proteins must have hydrophobic R-groups in the region(s) of the protein crossing the lipid bilayer. From analysis of the hydropathy index of a protein sequence, a computer can readily identify potential membrane-crossing regions of a protein. Assisting that analysis is the fact that tryptophan or tyrosine is commonly positioned

at the non-polar/polar interface of the bi-layer.

- Cell walls are found in plants, fungi, and bacteria. They provide at least some protection against bursting from osmotic pressure.

- Gram positive bacteria have the simplest ones - on the outside, there is a peptidoglycan layer, followed by a periplasmic space, a plasma membrane and then the cytoplasm.

- Gram negative bacteria have a more complicated structure with an outer lipopolysaccharide layer, a periplasmic space, the peptidoglycan cell wall, a second periplasmic space, a plasma membrane and then the cytoplasm.

- Herbaceous plants have a rigid outer cell wall primarily composed of cellulose, hemicellulose, and pectin and an inner plasma membrane. Woody plants add lignin between the cellulosic wall and the plasma membrane of herbaceous plants.

The *E. coli* Song

To the tune of "*Rudolph the Red-Nosed Reindeer*"

Metabolic Melodies Website HERE

E. coli's very simple
That's the way the story goes
But if you worked around it
You would probably hold your nose

Most of the other cell types
Have a mitochondrion
They use to make triphosphates
By phos-phor-y-la-she-un

When there is no oxygen
Coli's got it made
Glucose breakdown products all
Wind up making ethanol

Then all the cells around it
Shout *E. coli's* name with glee
"You make us feel light-headed"
"When you act fermentally"

Point by Point: Catalysis

Basic Principles

- Enzymes are protein catalysts that speed reactions enormously.
- Catalysts lower the magnitude of the energy barrier for a reaction without changing the overall energy. The energy barrier they help to overcome is the activation energy.
- At equilibrium, the concentration of products and reactants will not change over time.
- At equilibrium, the concentration of products and reactants will not be equal unless the value of $\Delta G^{\circ\prime}$ is zero.
- All reactions move in the direction of equilibrium.
- Enzymatic reactions have substrates (reactants) and products.
- The part of an enzyme where catalysis occurs is called the active site.
- In metabolic pathways, the product of one reaction is the substrate of the next reaction.

- Activation energy is the amount of energy that must be put into a reaction in order for it to begin.
- Non-catalyzed (non-enzymatic) reactions have higher activation energies than catalyzed (enzymatic) reactions.
- The overall ΔG for a reaction does not change when a reaction is catalyzed compared to an uncatalyzed reaction.
- The extent of a reaction proceeding forward is a function of the size of the energy difference between the product and reactant states. The lower the energy of the products compared to those of the reactants, the greater percentage of products that will be present at equilibrium.
- All reactions are theoretically reversible.
- When a product, such as CO_2 is volatile, it can make reversibility less likely.
- Removal of products tends to "pull" reactions forward. Addition of reactants "pushes" reactions forward.
- Enzymes differ from chemical catalysts (such as platinum) in being flexible. Flexibility allows movement and movement facilitates alteration of electronic environments necessary for catalysis. Koshland's induced fit model reflects this flexibility. It states that not only do enzymes change substrates, but substrates also transiently change enzymes. At the end of a reaction, though, an enzyme goes back to its original state.
- The Fischer lock and key model contrasts with Koshland's model in saying only that an enzyme fits its substrate like a lock fits a key. It makes no note of the flexibility of an enzyme.
- Two distinct structural states are described for enzymes. The T-state is the "tight" state and in this state, the enzyme will bind less substrate and be much less able to catalyze reactions. The R-state (R=relaxed) is a state where the enzyme is better able to bind substrate and is much more active.
- Reactions can be a) one substrate/one product; b) one substrate/multiple products; c) multiple substrates/one product; or d) multiple substrates/multiple products.
- For multiple substrate reactions, there are two ways in which substrate can sequentially bind - ordered or random. In ordered binding, one substrate must bind first or the other one will not bind. In random binding, it doesn't matter which one binds first.
- Ordered binding is consistent with the Koshland model because binding of the first substrate is likely needed to cause the enzyme to change shape in order to allow binding of the second one.
- Lactate dehydrogenase exhibits ordered binding and creatine kinase exhibits random binding.
- A third mechanism for handling multiple substrate reactions is that of double displacement (or ping-pong) reactions. In this case, the enzyme exists in two states. The first state is necessary for the reaction of the second state to occur. Transaminases exhibit ping-pong kinetics with the enzyme ferrying oxygen or an amine between two different molecules.

- Enzymatic reactions proceed as E + S ⇄ ES -> E + P. The ES state is actually more complicated and could be written as E + S ⇄ ES -> ES* -> EP -> E + P

- To study an enzymatic reaction, two parameters are considered - velocity and affinity of the enzyme for substrate. Reactions are started with substrate and enzyme only (no products). Velocity is measured by concentration of product over time.

- To measure velocity most accurately, Michaelis-Menten kinetics conditions are employed. The involves

- 1) measuring initial velocities (V_0) before product has a chance to accumulate (which would favor the reverse reaction and reduce the apparent velocity). Mathematically, V_0 = [Product]/time of reaction

- 2) using substrate in great excess to enzyme

- 3) reaction conditions corresponding to steady state

- In steady conditions, [E] and [ES] are not changing much over the time of the reaction.

- In pre-steady state conditions, [E] is rapidly decreasing and [ES] is rapidly increasing. Changing [ES] means reaction velocity will vary over the time of measurement.

- Enzymatic reactions get to equilibrium faster than non-enzymatic reactions, but equilibrium is nonetheless the same.

- For an enzyme obeying Michaelis-Menten kinetics (some don't), a plot of V0 vs [S] will result in a hyperbola. The top end of the hyperbola will approach a maximum value of V_0 called V_{max} (maximum velocity). At this point, the enzyme is saturated with substrate.

- To determine the affinity of an enzyme for a substrate, a quantity called K_m is calculated. Km corresponds the substrate concentration that gets an enzymatic reaction to $V_{max}/2$. The higher the value of K_m for an enzyme, the lower its affinity for its substrate. On the other hand, the lower the K_m value, the higher the affinity the enzyme has for its substrate.

- The velocity of a reaction, v, can be determined as follows:

- $$v = \frac{V_{max}[S]}{K_m + [S]}$$

- V_{max} is limiting for describing reaction velocities, since it depends on the quantity of enzyme used in a reaction. If one doubles the amount of enzyme, one will double V_{max}.

- Consequently, for comparing rates of reaction, the quantity K_{cat} is used. K_{cat} (also called turnover number) is calculated by dividing V_{max} by the concentration of enzyme used in a reaction. The numerical value obtained has units of inverse time (for example, seconds^{-1}) and corresponds to the number of molecules of product made per molecule of enzyme per second.

- As noted above, not all enzymes obey Michaelis-Menten kinetics. Examples include multi-subunit enzymes that change in such a way upon binding the first substrate molecule that binding of further substrate molecules by the same enzyme is affected (positively or negatively).

- Perfect enzymes are enzymes for which the ratio K_{cat}/K_m approaches a theoretical maximum. For these enzymes, the only thing limiting them in catalysis is the rate with which the substrate can diffuse to the active site of the enzyme.

- Not all enzymes have evolved to perfection because too much speed can be hard to control. One of the reasons perfection has evolved is to reduce the time an unstable intermediate is present, thus preventing it from having too much time to wreak havoc. Triose phosphate iosomerase is an example, catalyzing a reaction rapidly to prevent escape and accumulation of the toxic intermediate known as methyl glyoxal.

- To measure the "tightness" of binding of a ligand by a protein, the dissociation constant is calculated. Dissociation of a ligand-protein complex is given by the following equation:

- LP <=> L + P

- The corresponding dissociation constant (K_d) is

$K_d = [L][P]/[LP]$

where [L], [P], and [LP] are the molar concentrations of the protein, ligand and the complex when they are joined together.

Where multiple molecules bond together, such as

JxKy <=> xJ + yK

(complex JxKy is breaking down down into x subunits of J and y subunits of K)

the dissociation constant is then defined as

$K_d = [J]^x[K]^y/[JxKy]$

- Another way of analyzing enzyme kinetic data is to plot velocity/substrate data by the Lineweaver-Burk method. In these plots, the inverse of V_0 is plotted against the inverse of the [S].

- These so-called double reciprocal plots ($1/V_0$ vs $1/[S]$) give straight lines for enzymes following Michaelis Menten kinetics. The line of these plots, when extrapolated to the X-axis, give the value of $1/V_{max}$ as Y-intercept and the value of $-1/K_m$ as the X-intercept.

- The term molecularity refers to the number of molecules that must come together in order for a reaction to take place. Unimolecular reactions are when there is only one reactant molecule.

- For a bimolecular reaction where A + B <=> C, the reaction depends on the concentration of both A and B and its rate will be related to the product of the concentration of A and of B.

- Coenzymes are molecules that help enzymes to perform catalysis. These include both inorganic ions and organic molecules. If the latter is covalently or tightly bound to the enzyme, it is referred to as a prosthetic group.

- Enzymes lacking their co-factors are called apoenzymes.

- Not all biological catalysts are proteins. Ribozymes are catalytic RNA molecules. The most prominent of these are the 23S rRNA of prokaryotes and the 28S rRNA of eukaryotes. Each of these functions in the ribosome to catalyze the formation of peptide bonds in protein synthesis.

Control of Enzyme Activity

- The inhibition of specific enzymes by drugs can be medically useful.
- There are four types of inhibition that are of interest - competitive, non-competitive, uncompetitive, and suicide inhibition.
- Only suicide inhibition is not reversible.
- Competitive inhibition occurs when the inhibitor resembles the natural substrate of an enzyme and competes with it for binding at the active site.
- An example is methotrexate that resembles the folate normally acted on by the enzyme dihydrofolate reductase (DHFR).
- When methotrexate binds to DHFR, the enzyme is inhibited and won't function.
- However, since methotrexate and folate compete for binding to DHFR, the more one increases the amount of folate, the less methotrexate will be able to bind, meaning that the amount of inhibition will decrease. At infinite amounts of folate, the inhibition of methotrexate disappears. Thus, methotrexate has no effect on the V_{max} of the DHFR reaction though it can affect velocities at lower concentrations.
- On the other hand, at lower concentrations, methotrexate does have effects and thus causes an increase in the amount of substrate necessary to reach $V_{max}/2$. Since this is known as the K_m for an enzyme, it means that in competitive inhibition, K_m increases.
- On a Lineweaver-Burk plot, the line of the competitively inhibited reaction crosses the line of the uninhibited reaction at the Y-intercept - 1/Vmax. This makes sense, since the V_{max} of the uninhibited and the inhibited reaction is the same.
- In a study of competitive inhibition, the percentage of inhibited enzyme varies considerably over the range of [S] used. At low [S], the inhibition is highest and at very high [S], the percent of enzyme inhibited is negligible.
- Non-competitive inhibition occurs when an inhibitor acts by binding and inhibiting an enzyme at a site apart from the active site. In this case, the non-competitive inhibitor molecule will not resemble the substrate and will not compete with it for binding to the active site.
- In this case, the amount of inhibition of the enzyme is fixed by the amount of inhibitor used. This percentage will not change no matter how much substrate is added because the substrate cannot compete with the inhibitor. As noted above, V_{max} depends on the amount of enzyme. If you knock out a fixed percentage of an enzyme, you will reduce V_{max} accordingly.
- Thus, for non-competitive inhibition, V_{max} decreases.
- K_m for a non-competitive inhibition does not change, however. This is because the inhibited enzyme does not enter the picture. One can only measure K_m for uninhibited enzymes. This never changes. As a conse-

quence, K_m remains the same in non-competitive inhibition.

- Uncompetitive inhibition occurs when the inhibitor only binds and inhibits the ES complex, forming an ES-I complex. It cannot release product. ES (and ES-I) complex forms primarily under high substrate conditions. In fact, as the substrate concentration gets higher, more ES-I complex will form. This has the effect of reducing V_{max}.

- It may seem unintuitive, but K_m actually decreases. This is because ES-I reduces the concentration of ES. Reduced ES results in formation of more ES by Le Chatelier's principle. Thus, the enzyme appears to gain affinity for substrate since more ES is forming. Higher affinity for substrate translates to lower K_m.

- Suicide inhibition occurs when the inhibitor makes a covalent attachment to the active site of an enzyme, stopping all activity permanently. For this to occur, the suicide inhibitor must resemble the substrate. Thus suicide inhibition is somewhat like competitive inhibition, except that the binding of the inhibitor is permanent in suicide inhibition, but reversible in competitive inhibition.

- Penicillin is a suicide inhibitor. It binds to the enzyme known as D-D transpeptidase, which is responsible for making the bacterial peptidoglycan cell wall.

- Enzymes are controlled by 1) allosterism; 2) covalent modification; 3) access to substrate; and 4) control of enzyme synthesis/breakdown.

- Allosterism occurs when a molecule binding to an enzyme affects the enzyme's activity. This requires a multi-subunit enzyme, typically.

- Homotropic effectors are substrates for the enzyme.

- Heterotropic effectors are non-substrates.

- Homotropic effectors convert the hyperbola of a V_0 vs. [S] plot to a sigmoidal shape due to the conversion of the enzyme from the T-state to the R-state on binding the effector.

- Homotropic effectors have the same effect on enzymes as oxygen does on the cooperative binding property of hemoglobin.

- Allosteric effectors can act positively (favor R-state - increasing enzyme activity) or negatively (favors T-state - decreasing enzyme activity).

- One interesting use of allosteric control helps to regulate metabolic pathways. This is feedback inhibition, which occurs when the end product of a metabolic pathway allosterically inhibits an early enzyme in the same pathway.

- An example of feedback inhibition is cholesterol's inhibition of HMG-CoA reductase. Cholesterol is the end product of a long pathway and HMG-CoA reductase is an early enzyme in the pathway. By acting on an early enzyme, the entire pathway is stopped, along with many energy-requiring reactions so materials are not wasted.

- ATCase is another allosterically regulated enzyme. It has three effectors - ATP, CTP, and aspartate.

- ATCase is comprised of 12 subunits - 6 regulatory subunits and 6 catalytic subunits.

ATP (activates) and CTP (inhibits) bind to the regulatory subunits. They are heterotropic effectors.

- Aspartate (activates) is a substrate, so it binds to catalytic subunits. It is a homotropic effector.

- There are three models to explain how allosteric regulation occurs - 1) sequential; 2) MWC (concerted); and 3) morpheein.

- The sequential model of allosterism says that changing the configuration of one subunit of an enzyme (say T-state to R-state) causes the others to change in the same way. The sequential model is associated with cause and effect.

- The concerted model proposes that the entire multisubunit enzyme complex changes from T-state to R-state (and vice versa) independently of changes to any one unit. It also proposes that binding of an allosteric effector locks the enzyme in that state. Binding of inhibitors will tend to favor the T-state and binding of activators will favor the R-state.

- The morpheein model is the newest of the three and is similar to the concerted model. It proposes that the multi-subunit complex breaks down to individual units which each can flip T- and R-states. but that only subunits in the same state can reassociate into a larger complex (all in the same state). Again, activators will favor R-state and inhibitors will favor T-state.

- Enzymes are known exhibiting each of the models and most enzymes probably employ a hybrid of the models described here.

- A second means of controlling enzymes is covalent control. In this mechanism, covalent modifications are made to enzymes to activate or inhibit them. One category of activation is that of zymogens.

- Zymogens are inactive forms of enzymes (commonly proteases) that are synthesized in a state that requires a peptide bond to be cleaved for them to become active. Cleaving the bond may, for example, provide access to the active site.

- Zymogen control is employed for digestive proteases (trypsin, chymotrypsin, carboxypeptidase, elastase, etc) and proteases involved in blood clotting (fibrin, thrombin, etc).

- Nomenclature for zymogens involves (in many, but not all cases) addition of the suffix -ogen to the enzyme name to designate the inactive form of the enzyme and removal of the suffix to indicate the active form. Thus, trypsinogen is inactive and trypsin is active.

- Zymogens are commonly activated in cascades. This has the effect of activating a large number of enzymes very quickly as each enzyme in the cascade activates a large number of other enzymes that each continue the process. For a process like blood clotting, this is very important to occur quickly.

- Another common covalent modification is that of phosphorylation/dephosphorylation. In this system (commonly used in signaling pathways), addition of a phosphate to an enzyme either activates or inactivates it, depending on the enzyme. Phosphates are added by kinases and removed by phosphatases. ATP is typically the source of the phosphate added.

- Another covalent modification is that of reduction/oxidation. It is found in enzymes of photosynthetic plants. In it, when the NADPH concentration is high from light energy, the concentration of reduced ferredoxin increases. Ferredoxin can then reduce thioredoxin, which can further reduce disulfide bonds in the enzyme. Four enzymes of the Calvin cycle can be reduced and thus be activated by this method.

- A third means of controlling enzymes is access to substrate/substrate level control. Hexokinase is an example. it is largely regulated by availability of its substrate, glucose. When glucose concentration is low, the product of the enzyme's catalysis, glucose-6-phosphate, inhibits the enzyme's function.

- The last means of controlling enzymes is via control of their synthesis by regulation of gene expression.

Enzymes - Mechanism

- Chymotrypsin is a serine protease - a class of enzymes with several members.

- Some examples of serine proteases include trypsin, chymotrypsin, elastase, subtilisin, and signal peptidase I.

- Proteases catalyze the cleavage of peptide bonds.

- Serine proteases use a serine in their active site as part of the catalytic process.

- Serine is one of three amino acids in the protein that play critical roles in the catalysis. The three amino acids make up what is called the catalytic triad and they are serine, histidine, and aspartic acid.

- Activation of serine in the catalytic process creates a nucleophile called an alkoxide ion which attacks the peptide bond, causing it to be broken.

- Specificity of serine proteases is determined by a part of the enzyme called the S1 pocket. The S1 pocket has a geometry and/or chemical composition that allows only certain amino acid side chains to fit in it. Since the S1 pocket is adjacent to the active site, the amino acid that fits into the S1 pocket is the one where the peptide bond is broken.

- Trypsin has an aspartate (negatively charged) side chain at the bottom of its S1 pocket, favoring binding of positively charged amino acids, such as lysine or arginine.

- Chymotrypsin has a broad, non-polar S1 pocket favoring amino acids like phenylalanine and others.

- The process of catalysis of a serine protease begins with binding of a suitable amino acid in the S1 pocket. This induces a slight structural change in the enzyme (Koshland's induced fit model) causing the side chains of the catalytic triad to move closer to each other.

- The result of this is that the electron-rich imidazole ring pulls a proton from the hydroxyl side-chain of serine, creating a negatively charged alkoxide ion.

- The alkoxide ion makes a nucleophilic attack on the carbonyl carbon of the peptide bond involving the amino acid of the substrate protein bound in the S1 pocket.

This breaks the peptide bond after stabilization of the structure by another region in the active site known as the oxyanion hole.

- With the peptide bond broken, one piece of the protein is loosened and exits the active site. The other part of the protein is linked to the serine side chain via the carbonyl carbon. At this point, the fast phase of catalysis has completed.
- In the next phase of catalysis, the covalently bound peptide must be released from the serine side chain and the enzyme must be returned to its original state.
- This begins with entry of a molecule of water into the active site.
- Histidine abstracts a proton from the water, leaving a nucleophilic hydroxyl group. It attacks the carbon bound to the serine and releases it (again, after stabilization by the oxyanion hole).
- The proton on histidine returns to serine's oxygen, recreating the hydroxyl group and the process is complete.
- Serine proteases are in two broad categories - 1) chymotrypsin-like and 2) subtilisin-like. They both use the same mechanism, but are not related to each other by sequence and have evolved independently by convergent evolution.
- Cysteine proteases are related to serine proteases in mechanism of action, but instead have an active site with histidine and cysteine. In their catalytic mechanism, histidine removes a proton from cysteine's side chain to create a reactive, negatively charged sulfur ion that performs the same functions as serine's reactive, negatively charged oxygen.
- Some examples of cysteine proteases include papain, caspases, hedgehog protein, calpain, and cathepsin K.
- Caspases (Cysteine-ASPartic ProteASEs) are a family of cysteine proteases that function in apoptosis, necrosis, inflammation, and the immune system. They are known as the executioner enzymes and are synthesized in a zymogen form.
- Caspases come in two forms. Initiator caspases, when activated, activate the effector caspases. The effector caspases cleave other proteins in the cell beginning the process of cellular suicide.
- Metalloproteases use catalytic mechanisms for breaking peptide bonds involving a metal - usually zinc. In their catalytic mechanism, the bound metal abstracts a proton from water to create a nucleophilic hydroxyl group that attacks the peptide bond and causes it to fall apart, much like the second phase of serine protease action.
- Some carboxypeptidases are metalloproteases.
- Aspartyl proteases use aspartic acid in their catalytic mechanism. Like metalloproteases, they activate a water by abstracting a proton.
- Threonine proteases have a different mechanism of action than serine proteases. Like the serine proteases, they activate a hydroxyl to act as a nucleophile and attack the carbonyl carbon of a peptide bond. They are different in how the hydroxyl's proton is removed. Serine proteases use a catalytic triad, but threonine's own α-amine group is what removes the proton. To have a free α-amine group, threo-

nine must be at the N-terminus of the enzyme. Threonine proteases are found in proteasomes.

- Protease inhibitors stop the catalytic action of proteases. Mechanisms of their action include suicide inhibition, transition state inhibition, denaturation, and chelation. Metalloproteases, for example are sensitive to chelating agents like EDTA that remove their metal ion.

- A broad category of proteinaceous protease inhibitors is the serpins. These proteins inhibit serine proteases by altering their active sites. Serpins like antithrombin help to regulate the blood clotting process.

- Non-serpin serine protease inhibitors are competitive inhibitors of the active site.

- α-1-anti-trypsin (A1AT) functions in the lungs to inhibit the elastase protease. Reactive oxygen species produced by smoking can oxidize a critical methionine residue of A1AT, rendering it unable to inhibit elastase. Uninhibited, elastase can attack lung tissue and cause emphysema.

- Protease inhibitors are used as anti-viral agents to prohibit maturation of viral proteins - commonly viral coat proteins.

- Protease inhibitors are part of drug "cocktails" used to inhibit the spread of HIV in the body and are also used to treat other viral infections, including hepatitis C.

Blood Clotting

- Blood clotting is a process in which liquid blood is converted into a gelatinous substance which hardens.

- Steps in the process include 1) activation (wounding); 2) a cellular response (aggregation of blood platelets) and 3) a molecular response (polymerization of fibrin to create a meshwork that hardens).

- An injury to the epithelial lining of a blood vessel begins the process of clotting almost instantly.

- In the cellular response, blood platelets are activated in an initial response by exposure to collagen beneath the damaged epithelium and form a plug. Platelets do this by binding to collagen through their glycoprotein VI. In the process, platelets' integrins get activated and then bind tightly to the extracellular matrix to anchor them to the site of the wound.

- The von Willebrand factor assists by forming additional links between the platelets' glycoproteins Ib/IX/V and the collagen.

- In the amplification phase of the cellular response, platelets release factor 4, a cytokine stimulating inflammation and moderating action of the heparin anticoagulant. They also release thromboxane, a molecule that increases stickiness of platelets.

- A Gq-linked protein receptor cascade is also activated in the platelets, releasing calcium into their cytoplasms and the surrounding area. It plays a role in the molecular response.

- In the molecular response, a mesh or web comprised of polymers of the protein fibrin

is created. Two catalytic pathways called intrinsic (also known as the contact activation pathway) and extrinsic (also known as the tissue factor pathway) converge to create this. Both pathways contain a cascading series of zymogen activation of serine proteases. Cascades such as these allow for rapid activation of inactive enzymes, allowing the clot to form rapidly.

- The tissue factor pathway has an initial phase (a thrombin burst where thrombin is quickly activated) and an amplification phase where a chain reaction rapidly amplifies the amount of active thrombin

- Thrombin is a serine protease that catalyzes activation of fibrinogen to form fibrin for the clot).

- The initiation phase of the extrinsic (tissue factor) pathway begins with activation of FVII to form FVIIa as a result of the blood vessel damage. A complex of factors then act to convert a tiny amount of prothrombin (zymogen) to the active thrombin. The factors include TF, FVIIa, FIXa, and calcium from the cellular response. This is the end of the initiation phase and the product is a small amount of thrombin.

- In the amplification phase, factors of both the extrinsic and intrinsic pathways interact and the pathways converge. The aim is to make a sufficient amount of thrombin to catalyze formation of enough fibrin to make a clot.

- The small amount of thrombin made in the initiation phase is critical. It activates several factors which, in turn, help to make more thrombin. Thus, thrombin helps to stimulate production of more thrombin. Inactive factors activated by thrombin include FV, FXI, and FVIII and the products are FVa, FXIa, and FVIIIa. FIXa also helps to stimulate production of more active copies of itself.

- FIXa plus FVIIIa stimulate production of a considerable amount of FXa. FVa joins FXa and calcium to make a much larger amount of thrombin.

- Besides activation of fibrinogen to make fibrin and helping to increase production of more copies itself, thrombin also activates an enzyme known as transglutaminase (FXIIIa) that helps to harden the clot. This occurs via formation of a covalent bond between adjacent glutamine and lysine side chains in the fibrin polymers.

- Hemophilia is a hereditary (X-linked) genetic disorder affecting the blood clotting process in afflicted individuals. It is treated by exogenous provision of missing clotting factors

- A deficiency of FVIII leads to Hemophilia A and deficiency of FIX produces Hemophilia B.

- Lack of the von Willebrand factor gives rise to von Willebrand's disease, a genetically linked disease much like hemophilia.

- The von Willebrand factor binds to several things essential to the clotting process.

- First, it anchors platelets near the site of the wound in the cellular response.

- Second, it binds to the anticoagulant heparin to moderate its action.

- Third, it binds to the collagen exposed by the wound.

- Fourth, it binds to FVIII in the molecular response, playing a protective role for it. In the absence of the von Willbrand factor, FVIII is destroyed.
- Fifth, it binds to the platelets' integrin proteins.
- Vitamin K is a pro-clotting factor, serving as a coenzyme to help catalyze addition of an additional carboxyl group to the side chains of glutamic acid in several clotting enzymes.
- The additional carboxyl group allows the enzyme to bind to calcium and this is critical to the clotting process.
- Blocking action of vitamin K results in reduced clotting abilities and is referred to as blood thinning.
- In the process of the reaction above, vitamin K is oxidized and must be recycled (reduced) by vitamin K epoxide reductase in order to function. The compound known as warfarin (coumadin) interferes with vitamin K epoxide reductase and can be used to reduce blood levels of active vitamin K, thus "thinning" the blood.
- Warfarin is commonly given to patients prone to clotting to reduce their likelihood of stroke. It is very critical that the proper amount be given. Too much can result in hemorrhaging.
- Vitamin K can be obtained (inefficiently) from consumption of plants and more abundantly from action of gut bacteria.
- Plasmin is a serine protease (zymogen = plasminogen) that breaks down fibrin polymers and dissolves blood clots in the healing process.
- It can also activate collagenases (break down collagen) and this too may play a role in healing.
- Plasmin can be activated by several proteins, including tissue plasminogen activator (tPA), (using fibrin as a co-factor), urokinase plasminogen activator (using urokinase plasminogen activator receptor as a co-factor), kallikrein (plasma serine protease with many forms and blood functions), and FXIa and FXIIa of the blood clotting pathway.
- Conversion of plasminogen to plasmin can be inhibited by plasminogen activator inhibitor (inactivated tPA and urokinase plasminogen activator).
- Active plasmin can be inhibited by α2-antiplasmin and α2-macroglobulin. Thrombin also can play a role in plasmin inhibition.
- Fibronectin is a large glycoprotein found in the extracellular matrix that binds to integral cellular proteins called integrins and to extracellular proteins, including collagen, fibrin, and heparan sulfate. It is important in the healing process and in blood clot formation.
- In the repair of the wound, the damaged area is acted on by fibroblasts and macrophages, which degrade blood clot matrix proteins and replace them with a new matrix like the undamaged, surrounding tissue.
- Fibroblasts release proteases that cleave the fibronectin from the plasma, causing wound contraction. Then, fibroblasts release cellular fibronectin and integrate it with the matrix.

- Fibronectin is also essential for embryogenesis.

- Platelet Activating Factor (PAF) is a host defense chemical produced in greater quantities in inflammatory cells upon proper stimulation. It acts like a hormone and can transmit signals between cells to trigger and amplify inflammatory and clotting cascades.

- Unregulated PAF can cause severe inflammation resulting in sepsis and injury. Inflammation in allergic reactions arises partly as a result of PAF and is an important player in bronchoconstriction in asthma. In fact, at a concentration of only 10 picomolar, PAF can cause life threatening asthmatic inflammation of the airways.

The Way They Work

To the tune of "*The Way We Were*"

Metabolic Melodies Website HERE

Enzymes
Might powerhouse peptides
Cause reactions to go faster
In the cells' insides

Tiny substrates
Bring about an induced fit
Enzyme structure is affect-ed
By what binds to it

Can it be that it's just simple zen?
How the enzymes activate
If they bind effector, will they go
To an R-State, T-State?

Folding
Gives the mechanistic might
To three-D arrangement
Of the active site

(Additional stanza)
Enzymes
Have a bias they can't hide
Hydrophobic side chains are
Mostly found inside

So it's the structure
For celebrating
Whenever there's debating
The way they work
The way they work

Lyrics by Kevin Ahern

Point by Point: Energy

Energy Basics

- Maintaining and creating order in cells takes the input of energy.
- Oxidation is the main form of non-photosynthetic energy in organisms.
- Carbon is the most commonly oxidized biological material.
- Energy released during the oxidative steps is “captured” in ATP.
- The more reduced a carbon atom is, the more energy can be realized from its oxidation.
- Fat is used as the primary energy storage form in animals because it is more reduced than carbohydrates and can store more energy.
- Biochemical processes that break things down from larger to smaller are catabolic processes. Catabolic processes are oxidative in nature and energy releasing.
- Energy from biological oxidation is largely captured (ultimately) as ATP.

- Uncaptured energy of metabolism is released as heat.
- Synthesizing large molecules from smaller ones is referred to as anabolism.
- Anabolic processes are reductive in nature and require energy input.
- Anabolic process counter entropy (larger things made from smaller pieces and energy required). To do this requires input of energy. Plants use energy from the sun to accomplish this.
- Cells use energy coupling to make reactions favorable that would otherwise be energetically unfavorable. A good example is phosphorylation of a sugar. By itself, this process is not energetically favorable, with the equilibrium far to the left. However, if the phosphorylation is coupled to hydrolysis of ATP, the reaction is energetically favorable. This is because the energy released by the hydrolysis is used by the enzyme catalyzing the reaction to put the phosphate onto the sugar.
- Cells that derive the metabolic energy directly from the sun are autotrophic. Those that get it from organic material in their food are heterotrophic.
- Besides using energy to counter entropy, cells also need metabolic energy for muscular contraction, synthesis of molecules, neurotransmission, signaling, thermoregulation, and subcellular movements.
- ATP is the most common energy 'currency' of the cell, but other triphosphates are also used. GTP is the energy source for protein synthesis. CTP is used to make glycerophospholipids, and UTP is used to make glycogen and other polysaccharides.
- ATP can be converted to other triphosphates by action of the enzyme NDPK.
- ATP is made by three distinct types of phosphorylation – oxidative phosphorylation (in mitochondria), photophosphorylation (in chloroplasts of plants), and substrate level phosphorylation (in enzymatically catalyzed reactions).
- Gibbs free energy is the amount of useful work obtainable in a constant temperature/ constant pressure system.
- Mathematically, the Gibbs free energy, G is measured by

$$G=H-TS$$

- where H is the enthalpy, T is the temperature in Kelvin, and S is the entropy.
- Gibbs free energy is not easy to measure directly, but the change in Gibbs free energy that occurs in a reaction is. For that reason, we typically measure the change in Gibbs free energy, ΔG.

$$\Delta G = \Delta H - T\Delta S$$

- ΔG also tells us the direction of a reaction. There are three cases:
- $\Delta G < 0$ - the reaction proceeds as written
- $\Delta G = 0$ - the reaction is at equilibrium
- $\Delta G > 0$ - the reaction runs in reverse
- For a reaction $aA \rightleftarrows bB$

where 'a' and 'b' are integers and A and B are molecules) at pH 7, ΔG can be determined by the following equation,

- $\Delta G = \Delta G^{\circ\prime} + RT\ln([B]^b/[A]^a)$
- For multiple substrate reactions, such as

$$aA + cC \rightleftarrows bB + dD$$

- $\Delta G = \Delta G^{\circ\prime} + RT\ln\{([B]^b[D]^d)/([A]^a[C]^c)\}$
- The **ΔG°'** term is the change in Standard Gibbs Free energy, which is the change in energy that occurs when all of the products and reactants are at standard conditions and the pH is 7.0. It is a constant for a given reaction.
- If we collect all of the terms of the numerator together and call them {Products} and all of the terms of the denominator together and call them {Reactants}, then

$$\Delta G = \Delta G^{\circ\prime} + RT\ln(\{Products\}/\{Reactants\})$$

- A negative $\Delta G^{\circ\prime}$ indicates an energetically favorable reaction, whereas a positive $\Delta G^{\circ\prime}$ corresponds to an unfavorable one. This is not absolute. The actual direction of a reaction is given ONLY by the value.
- Le Chatelier's Principle states that a system responds to stress by acting to alleviate the stress.
- If the amount of products increases, the ln term becomes more positive and **ΔG** becomes more positive, moving the reaction backward. Conversely, if the amount of reactants increases, then the ln term becomes more negative and and ΔG becomes more negative, moving the reaction forward. Thus, the system responds to the stress by acting to relieve it.
- From $\Delta G = \Delta H - T\Delta S$, an increase in entropy will make ΔG more negative, favoring reactions that increase entropy. The hydrophobic effect, described in protein folding, is favorable, for example, because the exclusion of water arising from interacting hydrophobic amino acids internal to a protein actually increases the entropy of the process.
- Whenever there is a difference in concentration of molecules across a membrane, there is said to be a concentration gradient across it.
- A difference in concentration of ions across a membrane creates an ionic (or electrical) gradient. When both are present, then we refer to it as an electrochemical gradient.
- Such gradients function like batteries and contain potential energy.
- For two solutions of uncharged material separated by a lipid bilayer (say inside a cell versus outside a cell, where C_1 is the concentration inside and C_2 is the concentration outside), The Gibbs free energy associated with moving material in the direction of C_2 is given by

$$\Delta G = RT\ln[C_2/C_1]$$

- To move material in the direction of C_1, the result would be

$$\Delta G = RT\ln[C_1/C_2]$$

- The last two equations assume the molecules have no charge. If they have charge, this must be taken into account with another term -> $ZF\Delta\psi$.
- Here, Z refers to the charge of the transported species (+1 for a potassium or -1 for a chloride, for example), F is the Faraday con-

stant (96,485 Coulombs/mol), and $\Delta\psi$ is the electrical potential difference (voltage difference) across the membrane. This term accounting for the charge is added to the first equation (movement in the direction of C_2) to yield

$$\Delta G = RT\ln[C_2/C_1] + ZF\Delta\psi$$

- For a situation of movement of potassium ions from outside to inside where $C_2 > C_1$, the signs of the terms would be as follows:

$$RT\ln[C_2/C_1] = \text{positive, since } C_2 > C_1$$

- $ZF\Delta\psi$ = positive, since Z is positive (K = +1) and the $\Delta\psi$ term is positive, since positive ions are moving against a positive charge gradient ($C_2 > C_1$). Thus, the ΔG term will be positive and movement in the direction of C_2 would not be favored.

- Gain and loss of electrons has an electrical component and Gibbs free energy component as well. Reduction potential measures the tendency of a chemical to be reduced by electrons.

- Reduction potential is commonly measured in volts, or millivolts.

- If two chemicals are mixed in an aqueous solution, the chemical with the greater (more positive) reduction potential will tend to take electrons away, thus being reduced, from the one with the lower reduction potential, which becomes oxidized.

- The standard of reference for measurement is the half-reaction

$$H^+ + e^- \rightarrow 1/2H2$$

- The electrode where this reaction occurs (referred to as a half-cell) is given the value of E° (Standard Reduction Potential) of 0.00 volts.

- The hydrogen electrode is connected via an external circuit to another half cell containing a mixture of the reduced and oxidized species of another molecule (for example, Fe^{++} and Fe^{+++}) at 1M each and standard conditions of temperature (25°C) and pressure (1 atmosphere).

- Electrons can either flow into the reference cell if hydrogen's reduction potential is greater than that of the ions being measured) or away from the reference cell if the reverse is true.

- Voltages for electron flow away from the reference cell are positive and voltages of flow into the reference cell are negative.

- Under standard conditions, electrons will move from compounds with lower voltages to compounds with higher (more positive) voltages.

- Actual direction of electron movement depends on concentration, just as ΔG varied with concentration.

- Thus, we can define the overall reduction potential for a system as follows

$$E = E^\circ + (RT/nF)*\ln\left(\frac{[\text{reduced molecule}]}{[\text{oxidized molecule}]}\right)$$

where E° is the standard reduction potential measured above (under standard conditions), F is the Faraday constant (96,480 J/(Volts*moles), R is the gas constant (8.315 J/(moles*K), n is the number of moles of electrons being transferred, and T is the absolute temperature in Kelvin.

- Like the Gibbs free energy, consideration is given for measuring values at conditions found in cells. This means doing measurements at pH = 7, which differs from having all species at 1M, so an alternative E°' is used in place of E° for the same reason ΔG°' is used in biological systems instead of ΔG°.

- The relationship between ΔG and reduction potential then is as follows:

$$\Delta G_{red} = -nF\Delta E$$

where ΔG_{red} is the ΔG for the reduction potential difference. Similarly, we can write

$$\Delta G_{red}{}^{\circ\prime} = -nF\Delta E^{\circ\prime}$$

- Thus in considering the overall ΔG for a chemical reaction involving electrochemical changes

$$\Delta G_{total} = \Delta G_{chemical} + \Delta G_{red}$$

- Cells mostly store energy arising from oxidation in the form of triphosphate nucleotides - most commonly ATP.

- In a given day, an average human being makes and breaks down more than its body weight in triphosphates.

- Energy in ATP is released by hydrolysis of a phosphate from the molecule.

- The three triphosphates starting with the one closest to the sugar are referred to as α, β, and γ.

- Hydrolysis between the β, and γ phosphate of ATP produces ADP and P_i

- Hydrolysis between the α, and β phosphate produces AMP and pyrophosphate (PP_i).

- All of the diphosphate nucleotides can be interchanged with triphosphate nucleotides by nucleoside diphosphate kinase (NDPK). The reaction proceeds as

$$XTP + YDP \rightleftarrows XDP + YTP$$

where X = adenosine, cytidine, uridine, thymidine, or guanosine and Y can be any of these as well.

- Cells have another way of making ATP when ADP concentrations are high. Adenylate kinase catalyzes the following reaction:

$$2\ ADP \rightleftarrows ATP + AMP$$

- The AMP produced in this reaction is an indicator to the cell that energy levels are low and it activates phosphofructokinase of glycolysis to catalyze glucose breakdown to get more energy.

- In enegy coupling, energetically favorable reactions that release energy, such as hydrolysis of ATP are coupled enzymatically to energetically unfavorable reactions in order to make the latter favorable.

- Another mechanism for moving a reaction forward is by removal of a product. An example is the orotate reaction:

$$Orotate + PRPP \ <=> \ OMP + PP_i$$

- The PP_i (pyrophosphate) product can be further broken down by pyrophosphorylase as follows

$$PP_i + H_2O <=> 2P_i$$

- Thus, the concentration of a product decreases and this helps to "pull" the reaction forward.

- From an energy perspective, removal of product (pulling a reaction) and/or increasing the concentration of reactant (pushing a reaction) decreases **Δ**G because these have the effect of making the fraction in the term below smaller and its Ln value more negative, thus reducing ΔG

$$\Delta G = \Delta G^{\circ\prime} + RT\ln(\{Products\}/\{Reactants\})$$

Electron Transport and Oxidative Phosphorylation

- The vast majority of ATP synthesis in eukaryotes occurs in the mitochondria in a process called oxidative phosphorylation.

- Oxidative phosphorylation is preceded in the mitochondria by another process known as electron transport.

- NADH and $FADH_2$ donate their electrons to the electron transport system and become NAD^+ and FAD, respectively.

- Peter Mitchell proposed the chemiosmotic hypothesis to explain oxidative phosphorylation.

- Mitchell proposed that mitochondrial ATP synthesis results from an electrochemical gradient across its inner membrane that arises ultimately from the energy of reduced electron carriers, NADH and $FADH_2$

- Mitchell said further that electron carriers transfer electrons to an electron transport system (ETS) in the inner mitochondrial membrane and movement of the electrons causes protons to be pumped out of the mitochondrial matrix across the inner mitochondrial membrane, creating a proton gradient. Flow of the electrons back into the matrix through a transmembrane ATP synthase is the driving force for synthesis of ATP from ADP and P_i.

- Tight coupling of electron transport and oxidative phosphorylation exists when the two processes are interdependent - stopping of one stops the other. This is the basis of metabolic control.

- Uncoupling of electron transport occurs when the integrity of the inner mitochondrial membrane is compromized, allowing protons to re-enter the matrix without passing through the ATP synthase. When this occurs, the proton gradient is destroyed and no ATP is made.

- In the electron transport system, electrons flow through the system via complexes and shuttles. The order of movement for electrons from NADH is NADH -> Complex I -> CoQ -> Complex III -> Cytochrome c -> Complex IV. The order of movement for electrons from $FADH_2$ is $FADH_2$ -> Complex II -> CoQ -> Complex III -> Cytochrome c -> Complex IV.

- Electrons enter the system in pairs and travel in pairs until CoQ, which passes them off singly to Complex III. CoQ is called a traffic cop for electrons.

- Movement of electrons through complexes I, III, and IV cause protons to be pumped from the mitochondrial matrix to the intermembrane space, creating the pro-

ton gradient (higher proton concentration outside the mitochondrion than in the matrix).

- Complex III is a docking station for CoQ and cytochrome C. It is the site of the Q cycle.
- Cytochrome c ferries electrons to Complex IV one at a time - Complex IV requires 4 electrons to reduce O2 to 2 H_2O molecules.
- O_2 is the terminal electron acceptor of electron transport.
- Pumping protons out of the mitochondrion creates a proton gradient - electrochemical potential energy that is later used to make ATP.
- Complex I contains 44 individual polypeptide chains, numerous iron-sulfur centers and a molecule of flavin mononucleotide (FMN)
- In the process of electron transport through it, four protons are pumped across the inner membrane into the intermembrane space and electrons move from NADH to coenzyme Q, converting it from ubiquinone to ubiquinol.
- Complex I moves electrons through seven primary iron sulfur centers within it.
- The Complex I inhibitor rotenone stops electron movement by binding to the site where CoQ would bind.
- Other complex I inhibitors include ADP-ribose, which binds to the NADH site, and piericidin A, a rotenone analog.
- Electron movement through complex I is reversible and can result in production of reactive oxygen species.
- Complex II is a membrane bound enzyme of the citric acid cycle (succinate dehydrogenase). It also transfers electrons to CoQ.
- The oxidized form of CoQ is known as ubiquinone and the fully reduced form (gain of two electrons) is ubiquinol. An intermediate form (gain of one electron) is known as either ubisemiquinone or just semiquinone. The three forms of CoQ allow it to function as a traffic cop - accepting up to two electrons and passing them off one at a time.
- Inhibitors of complex II include carboxin, malonate, malate, and oxaloacetate. The last two are thought to function as inhibitors of the production of reactive oxygen species.
- Complex III contains 11 subunits, a 2-iron ferredoxin, cytochromes b and c_1 and belongs to the family of oxidoreductase enzymes.
- Complex III accepts electrons from coenzyme Q in electron transport and passes them off to cytochrome c in the Q cycle.
- Movement of electrons through the complex can be inhibited by antimycin A, myxothiazol, and stigmatellin.
- In the Q-cycle, electrons are passed from ubiquinol (QH_2) to cytochrome c using Complex III as a docking station.
- The process starts with a ubiquinol ($CoQH_2$), a ubiquinone (CoQ), and a cyto-

chrome c (lacking an electron) docking at Complex III.

- The two electrons from $CoQH_2$ split - one to cytochrome c (which exits with the electron) and one to CoQ (creating CoQ.- - also called CoQH or ubisemiquinone).
- The $CoQH_2$ that donated electrons becomes CoQ (ubiquinone) and is replaced by another $CoQH_2$.
- The two electrons from the new $CoQH_2$ split as the last ones did - one to cytochrome c (which exits with the electron) and one to CoQH (creating $CoQH_2$). Both CoQ ($CoQH_2$ that lost its electrons) and $CoQH_2$ exit and the process is complete.
- In the overall process, two protons are consumed from the matrix and four protons are pumped into the intermembrane space.
- Cytochrome c is a small protein, conserved from unicellular species to animals, that is loosely associated with the inner mitochondrial membrane.
- It uses a heme to carry a single electron from Complex III to Complex IV.
- Mitochondrial damage in higher organisms results in release of cytochrome c that stimulates assembly of the apoptosome and programmed cell death.
- Complex IV (cytochrome c oxidase) is a 14 subunit integral membrane protein that accepts one electron each from four cytochrome c proteins. It adds them to molecular oxygen (O_2) with four protons from the mitochondrial matrix to make two molecules of water. It is inhibited by cyanide, carbon monoxide, azide, and hydrogen sulfide.
- Four protons from the matrix are also pumped into the intermembrane space.
- The complex contains two molecules of heme, two cytochromes (a and a_3), and two copper centers (called CuA ad CuB).
- Complexes I, III, and IV appear to form a supercomplex, which has been dubbed the respirasome.
- Oxidative phosphorylation uses the energy of the proton gradient to make ATP.
- Things that destroy the proton gradient destroy the mitochondrion's ability to make ATP.
- The protein complex harvesting energy from the proton gradient to make ATP from ADP is an enzyme most commonly called complex V or ATP synthase.
- Protons moving through it (from the intermembrane space back into the matrix) will only provide energy to make ATP if their concentration is greater in the intermembrane space than in the matrix.
- During periods of rest, the rate of ATP synthesis exceeds the rate of ATP usage. Then ADP concentrations fall everywhere.
- Reducing ADP concentration in the matrix reduces oxidative phosphorylation and this, in turn, reduces electron transport because protons are not moving in through the ATP synthase. As a consequence, the proton gradient grows steeply, while electron transport is still running, but it quickly stops growing, since it because it becomes too difficult for the complexes to continue

pumping protons. As a consequence, electron transport slows or stops and oxygen consumption decreases (breathing slows).

- When the electron transport system stops, the concentration of NADH and $FADH_2$ increases, since they can't put their electrons into the electron transport system. This means that the citric acid cycle will slow or stop, since it requires NAD^+.

- The scenario described above is a good example of respiratory control. It moves the other way when exercise begins. First, ATP gets used by muscles, so the ADP concentration increases. This allows ATP synthase to function and protons re-enter the mitochondrial matrix. As the proton gradient falls, electron transport starts up because it can once again pump protons, since the gradient isn't too steep.

- When electron transport starts, oxygen usage increases (heavier breathing) and NADH and $FADH_2$ get converted to NAD^+ and FAD. As NAD^+ and FAD concentrations increase, the citric acid cycle starts and you start breaking down acetyl-CoA. Thus, if you exercise, you can lose weight, by oxidizing material and if you don't exercise, you can't burn off as much material

- These controls work only when there is tight coupling (intact mitochondrial inner membrane).

- If one does not have the proper amount of exercise, reduced carriers remain high in concentration for long periods of time. This favors anabolic pathways (since NADH and NADPH are needed for many biosynthesis reactions) particularly fatty acid synthesis, are favored, so we get fatter.

- ATP made in oxidative phosphorylation is released in the mitochondrial matrix, but is needed in the rest of the cell. To get it out, an ADP-ATP translocase (antiport) in the inner membrane of the mitochondrion is used for the transfer. Phosphate is moved into the mitochondrial matrix by a proton-phosphate translocase symport.

- Movement of protons through the ATP Synthase c-ring causes it and the γ-ε stalk attached to it to spin. It is this action that is necessary for making ATP.

- The γ-ε stalk projects into the F1 head and its rotation affects the α and β units, which are a set of three dimers. The β subunits slightly change configuration as the γ-ε stalk rotates, moving from configurations called loose (L) to tight (T) to open (O). The L form binds and holds ADP and P_i. The T form squeezes them together to make ATP and the O form opens to release the ATP.

- Inhibiting electron transport and/or oxidative phosphorylation with exogenous chemicals is dangerous and can be fatal.

- ATP synthase can be physically stopped with an inhibitor known as oligomycin A. Oxidative phosphorylation can be also stopped by destroying the proton gradient. This can be accomplished with an uncoupling agent, such as 2,4 dinitrophenol (2,4 DNP), which pokes holes in the mitochondrial inner membrane, allowing an alternate way for protons to enter the matrix from the intermembrane space that does not involve ATP synthase.

- When an uncoupling agent is used, oxidative phosphorylation stops because there is no proton gradient, but electron transport, on the other hand operates rap-

idly, since no gradient accumulates to stop it. Thus oxygen consumption goes up and heat is generated, due to the increased metabolic activity. This can be very dangerous, as cells can run out of ATP.

- Some cells actually use a biological uncoupling agent known as thermogenin to generate heat. This occurs in brown fat cells. Thermogenin allows protons to flow back into the matrix. As a result, metabolism increases and heat is generated. This differs from treatment with 2,4 DNP in that it is tightly controlled and can be reversed.

- Another way some cells generate heat is by taking a shortcut through the electron transport system. This occurs in fungi, plants, and protozoa and involves a protein known as alternative oxidase. It short-circuits the electron transport system by accepting electrons from CoQ and passing them directly to oxygen, bypassing the rest of the electron transport system.

- As a result, each pair of electrons entering the system pumps much fewer protons (bypassing complexes III and IV) and fewer ATPs are made per pair of electrons. That requires increased oxidation of foodstuffs to generate ATP and increased oxidation results in generation of heat.

- Alternative oxidase is only activated by cold temperatures.

- Reactive oxygen species (ROS) are byproducts of electron transport and other cellular enzymes. Some ROS include peroxides, hydroxyl radical, superoxide, peroxynitrite, and others that are very chemically reactive.

- Some ROS, such as peroxide and nitric oxide function in signaling, but increases in reactive oxygen species in times of stress can cause significant damage in the cell. Some cells use enzymes like NADPH oxidase to generate superoxides to kill bacteria.

- Phagocytes of the immune system engulf foreign cells and then use ROS to kill them.

- Damaged tissues of zebrafish have increased levels of H_2O_2 and this is thought to signal white blood cells to converge on the site.

- Cell organelles called peroxisomes can generate ROS as a byproduct of oxidation of long chain fatty acids.

- The free radical theory of aging states that organisms age due to the accumulation of damage from free radicals in their cells.

- In yeast and *Drosophila*, there is evidence that reducing oxidative damage can increase lifespan.

- Bcl-2 proteins on the surface of mitochondria monitor damage and if they detect it, will activate proteins called Bax to stimulate the release of cytochrome c from the mitochondrial inner membrane, stimulating apoptosis (programmed cell death).

- Superoxide can be produced when movement of electrons into and out of the chain don't match well. Then CoQ can donate an electron to O_2 to form O_2^- (superoxide). Superoxide can react with many things, including DNA where it can cause damage leading to mutation.

- Countering the effects of ROS are enzymes, such as catalase, superoxide dismutase, and anti-oxidants, such as glutathione and vitamins C and E.

- Catalase catalyzes the breakdown of hydrogen peroxide into water and oxygen.
- Catalase converts up to 40,000,000 molecules of hydrogen peroxide to water and oxygen per enzyme per second. It is abundantly found in peroxisomes.
- There is evidence that reduced levels of catalase with aging may allow higher levels of H_2O_2 that are responsible for bleaching that produces gray hair.
- Superoxide dismutase (SOD) is found, like catalase, in virtually all organisms living in an oxygen environment.
- Like catalase, superoxide dismutase has a very high K_{cat} value and has the highest K_{cat}/K_m known for any known enzyme.
- It operates by ping-pong (double displacement) mechanism, shuffling between reactions 1 and 2 below
- 1. $O_2^- + \text{Enzyme-Cu}^{++}$ $O_2 + \text{Enzyme-Cu}^{+}$
- 2. $O_2^- + \text{Enzyme-Cu}^{+} + 2\ H^+$ $H_2O_2 + \text{Enzyme-Cu++}$
- As can be seen, superoxide uses a copper ion in its catalytic mechanism.
- The hydrogen peroxide produced in the second reaction is easily handled by catalase.
- Superoxide can react with nitrous oxide (NO) to form very toxic peroxynitrite ions.
- In humans, superoxide dismutase is associated with the genetically-linked form of Amyotrophic Lateral Sclerosis (ALS) and over-expression of the gene is linked to neural disorders associated with Down syndrome.
- Mixed function oxidases use molecular oxygen for two different purposes in one reaction.
- Monooygenases are one type of mixed function oxidase that catalyze reactions like the one shown below

$AH + BH_2 + O_2 <=> AOH + B + H_2O$

- Cytochrome P450 enzymes (called CYPs) are family of heme-containing mixed function oxidase enzymes. The type of reaction catalyzed by them is shown below

$RH + O_2 + NADPH + H^+ <=> ROH + H_2O + NADP^+$

- There are six different classes of P_{450} enzymes based on how they get electrons

1. Bacterial P_{450} - electrons from ferredoxin reductase and ferredoxin

- 2. Mitochondrial P_{450} - electrons from adrenodoxin reductase and adrenodoxin
- 3. CYB5R/cyb5 - electrons come from cytochrome b_5
- 4. FMN/Fd - use a fused FMN reductase
- 5. Microsomal P_{450} - NADPH electrons come via cytochrome P_{450} reductase or from cytochrome b_5 and cytochrome b5 reductase
- 6. P_{450} - only systems - do not require external reducing power

- CYP enzymes perform important functions in synthesis of steroids (cholesterol, estrogen, testosterone, Vitamin D, e.g.), breakdown of endogenous compounds (bilirubin), and in detoxification of toxic compounds including pharmaceutical drugs.

- Cytochromes are heme-containing proteins that play major roles in the process of electron transport in the mitochondrion and in photosynthesis in the chloroplast.

- An atom of iron at the center of the heme group flips between the ferrous (Fe^{++}) and ferric (Fe^{+++}) states as a result of the movement of electrons through it.

- Cytochrome c is a soluble protein loosely associated with the mitochondrion. Cytochromes a and a_3 are found in Complex IV. Complex III has cytochromes b and c_1 and the plastoquinol-plastocyanin reductase of the chloroplast contains cytochromes b6 and f. Cytochrome P_{450} enzymes (absorb light at 450 nm when heme is reduced) contain cytochromes as well.

- Iron-sulfur proteins have many configurations and functions. In the electron transport system, they function in the redox reactions involved in the movement of electrons (complexes I and II).

- Aconitase uses an iron sulfur center in catalysis.

- Ferredoxins are iron-sulfur containing proteins performing electron transfer. Some function in photosynthesis in chloroplasts.

- Some ferredoxins provide electrons to enzymes (glutamate synthase, nitrate reductase, and sulfite reductase) and others serve as electron carriers between reductase flavoproteins and bacterial dioxygenase systems.

- Ferritin is a globular protein complex with 24 subunits and is the primary intracellular iron-storage protein in eukaryotes and prokaryotes. It keeps iron in a soluble non-toxic form and keeps the concentration of free iron from going to high or falling too low.

- Monoamine oxidases (MAOs) catalyze the oxidative deamination of monoamines, such as serotonin, epinephrine, and dopamine. Removal of the amine with oxygen results in the production of an aldehyde and ammonia.

- MAO-A and MAO-B inactivate monoaminergic neurotransmitters such as dopamine, tyramine, and tryptamine.

- MAO-A is the primary enzyme for metabolizing melatonin, serotonin, norepinephrine, and epinephrine, while MAO-B is the primary enzyme for phenethylamine and benzylamine.

- MAOs have been linked to numerous psychological problems, including depression, attention deficit disorder (ADD), migraines, schizophrenia, and substance abuse.

- Excess levels of catecholamines, such as epinephrine, norepinephrine, and dopamine, can result in dangerous hypertension events.

- The DNA Damage Theory of Aging says that accumulated oxidative damage to DNA alters its ability to perform its function properly, so this can induce changes in gene expression associated with aging.

- Mouse cells are thought to cell experience 40,000 to 150,000 damage events per day. Slowly replicating cells, such as in the lens of the eye or brain, may be more susceptible to this damage.

- DNA repair systems, of course, protect against damage to DNA, but over time, unrepairable damage may accumulate.

- Oxidation of guanine by reactive oxygen species can produce 8-oxo-guanine which is capable of forming a stable base pairing interaction with adenine, potentially giving rise to a mutation when DNA replication proceeds.

- 8-oxoguanine can be repaired if recognized in time by a DNA glycosylase,

- Polycyclic aromatic hydrocarbons from cigarette smoke, diesel exhaust, or overcooked meat can covalently bind to DNA and, if unrepaired, lead to mutation.

- Diseases affecting DNA repair can lead to premature aging.

- Individuals with Werner syndrome, for whom the life expectancy is 47 years, are missing two enzymes in base excision repair.

- People suffering from Cockayne syndrome have a life expectancy of 13 years due to mutations affecting transcription-coupled nucleotide excision repair.

- Life expectancies of 13 species of mammalian organisms correlates with the level of expression of the PARP DNA repair-inducing protein.

- Antioxidants have the chemical property of protecting against oxidative damage by being readily oxidized themselves and may protect against ROS.

- Cellular antioxidant defenses include vitamins C, A, and E, glutathione, and enzymes that destroy ROS such as superoxide dismutase, catalase, and peroxidases.

- Oxidation by ROS is mutagenic and has been linked to atherosclerosis.

- However, no reduction in mortality rates as a result of supplementation with these materials has been found, so the protective effects of antioxidants on ROS in human health remain poorly understood.

- Glutathione is a tripeptide comprised of glutamate, cytsteine, and glycine that protects cells against damage caused by reactive oxygen species and heavy metals. It is important for

• Neutralization of free radicals and reactive oxygen species.

- Maintenance of exogenous antioxidants such as vitamins C and E in their reduced forms.

- Regulation of the nitric oxide cycle

- The thiol group of glutathione's cysteine is a reducing agent that reduces disulfide bonds to sulfhydryls in cytoplasmic proteins and results in it forming a disulfide bond with the sulfur of the cysteine of another glutathione.

- Glutathione is made by two enzymes rather than being synthesized in ribosomes.

- In healthy cells, 90% of glutathione is in the GSH state. Higher levels of GSSG corre-

spond to cells that are oxidatively stressed. Mice lacking glutathione die in infancy.

- Resveratrol is a phenolic stilbenoid compound produced in the skin of plants. It may improve the functioning of mitochondria by acting as an antioxidant and by causing concentration of another antioxidant, glutathione, to increase.

- Resveratrol induces expression of manganese superoxide dismutase and inhibits several phosphodiesterases. This increases cAMP concentrations which result in increases in oxidation of fatty acids, mitochondria formation, gluconeogenesis, and glycogen breakdown.

- Resveratrol has been claimed to be the cause of the French paradox in which drinking of red wine is supposed to give protection for the cardiovascular system. Research data in support of it, though, is lacking.

- Resveratrol is known to activate sirtuin proteins, which play roles in gene inactivation.

Photophosphorylation

- Photophosphorylation is the third general mechanism for synthesizing ATP (substrate level phosphorylation and oxidative phosphorylation are the others). It is a mechanism of photosynthesis, a process which occurs only in plants and some microbes.

- Photophosphorylation is similar to oxidative phosphorylation in relying on a proton gradient for making ATP, having a proton gradient being made by an electron transport system, and using an ATP synthase enzyme very similar to the one in mitochondria.

- Photophosphorylation (PP) differs from oxidative phosphorylation (OP) in several respects.

- The source of electrons in PP is H_2O (releasing oxygen), but in OP, it is $NADH/FADH_2$ (releasing NAD^+ and FAD).

- The terminal electron acceptor in PP is $NADP^+$, producing NADPH, but is O_2 for OP, producing water.

- The driving force for movement of electrons in PP is sunlight, but is oxidation for OP.

- The proton gradient is reversed for OP and PP. Protons move out of an organelle structure (thylakoid of the chloroplast) to make ATP for PP, but move into an organelle (mitochondria) for the same purpose in OP.

- Photophosphorylation is only part of the process of photosynthesis - referred to as the “light reactions or light cycle.” The other part of photosynthesis involves “fixing” of carbon dioxide from the atmosphere into organic compounds that can be used to make glucose or other carbohydrates. These reactions are known as the “dark reactions or dark cycle,” though they do not occur in the dark - it simply means light is not directly required for them to take place. The dark reactions are also known as the Calvin cycle.

- The light cycle of photosynthesis starts with energy capture from light by proteins containing chlorophyll pigments called reaction centers. Plants have these in chloroplasts, bacteria have them in the plasma membrane.

- The light reactions of photosynthesis occur inside chloroplasts in specialized structures called thylakoids. In the membranes of the thylakoids are contained the electron transporting system and the ATP synthase.

- Light energy is used to excite electrons (which ultimately come from water), thus beginning a series of electron transporting steps and releasing O_2 from the oxidized water.

- There are two photosystems for harvesting light in the membranes of the thylakoid. Chlorophyll is the most common pigment used for this purpose in plants, but carotenes and xanthophylls are also used.

- The thylakoid membrane does its magic using four major protein complexes - photosystem II (PS II), cytochrome b6f complex (Cb6f), photosystem I (PS I), and ATP synthase.

- The process of photosynthesis begins in PS II with the absorption of a photon of light at a reaction center, which excites an electron to a high energy. This electron must be replaced as it will pass through the electron transport system.

- The electron replacing the excited electron ultimately comes from water, but first is replaced by one from the oxygen evolving complex with four manganese centers (the source of the initial replacement electrons). After four electrons have been replaced, the oxygen evolving complex extracts four electrons from two water molecules, liberating oxygen and dumping four protons into the thylakoid space.

- The excited electron transfers to pheophytin and then to protein bound plastoquinones (in order - PQA to PQ). PQ waits and accepts two electrons and two protons to become PQH2.

- When PQH_2 donates the electrons to the next acceptor (Cytochrome b6f, - Cb6f), it pumps the protons into the thylakoid space. Thus, the proton gradient is growing a a result of the splitting of water and the movement of electrons. Cb6f passes off one electron at a time to plastocyanin. At this point the electron is ready to replace an excited electron in photosystem I (PS I). Also in the thylakoid membrane at this time, ATP synthase makes ATP from the proton gradient.

- Absorption of light by photosystem I begins a similar process to what occurred in PS II. Loss of an electron by absorption of light creates a positive charge in PS I and it is neutralized by the electron from PS II in plastocyanin. Meanwhile, the excited electron moves through an iron-sulfur protein, then to ferredoxin, then to the last protein in the system known as Ferredoxin:$NADP^+$ oxidoreductase, which gives the electron and a proton to the terminal electron acceptor, $NADP^+$, creating NADPH. At this point, the light cycle is complete - water has been oxidized, ATP has been created, and NADPH has been produced.

- Plants also have an alternate route electrons can take. It is known as cyclic photophosphorylation. It primarily involves PS I. in it, excited electrons of PS I are not passed to the route leading to $NADP^+$. Instead, they pass off to the proton-pumping Cb6f complex. The electrons take the route they would have taken from PS II through Cb6f

to plastocyanin, pumping protons along the way. In this method, no NADPH is made, but a proton gradient is made, thus allowing continued synthesis of ATP.

- The ability of plants to switch between non-cyclic and cyclic photosystems allows them to make the proper ratio of ATP and NADPH they need for assimilation of carbon dioxide in the dark cycle of photosynthesis.

Student Nightmares

To the tune of "*Norwegian Wood*"

Metabolic Melodies Website HERE

I answered 3 'b'.
But then I thought. It might be 'c'
Or was the false true?
I can't undo. It makes me blue

It asked me to list all the enzymes that regulate fat
As I wrote them down I discovered I didn't know Jack

I ought to give thanks,
Scoring some points, filling in blanks
I squirmed in my seat
Feeling the heat, shuffling my feet

Professor then told me there wasn't a chance I would pass
So I started crying and fell through a big pane of glass

I suffered no harm,
'Cuz I awoke, to my alarm
Oh nothing compares
To deadly scares, of student nightmares

Lyrics by Kevin Ahern

Point by Point: Metabolism

Sugar Metabolism

- Glycolysis is the breakdown of sugars.
- It is a catabolic process where the oxidation of sugars begins and it occurs in the cytoplasm of cells.
- The end product of glycolysis is pyruvate.
- The reversal is the synthesis of glucose and that is called gluconeogenesis. It is reductive.
- Complete oxidation of glucose yields carbon dioxide.
- Glucose is the most abundant hexose in nature.
- Fructose is also readily metabolized in glycolysis by being converted to fructose-6-phosphate (F6P).
- Galactose can also be readily oxidized in glycolysis.
- Products of glycolysis include 2 ATP, 2 NADH, and 2 pyruvates per glucose molecule.
- Pyruvate is further oxidized to acetyl-CoA and oxidized in the citric acid cycle if oxygen is available.

- Pathways with a few common intermediates to glycolysis include the Calvin cycle and the pentose phosphate pathway (PPP). These include glucose-6-phosphate (PPP, glycogen metabolism), Fructose-6-phosphate (Calvin Cycle, PPP), Glyceraldehyde-3-phosphate (Calvin Cycle, PPP), dihydroxyacetone phosphate (PPP, glycerol metabolism, Calvin Cycle), 3-phosphoglycerate (Calvin Cycle, PPP), phosphoenolpyruvate (C_4 plant metabolism, Calvin Cycle), and pyruvate (fermentation, acetyl-CoA genesis, amino acid metabolism).

- Glycerol from fat is the only part of used in glycolysis. It must first be converted to DHAP.

- The first reaction of glycolysis is catalyzed by hexokinase and it converts glucose to G6P, using energy from ATP.

- Hexokinase is one of three regulated enzymes of glycolysis and it is inhibited by G6P.

- Hexokinase can catalyze reactions on several six carbon sugars, including fructose, mannose, and galactose.

- Phosphorylation of glucose keeps it from escaping out of the cell.

- G6P can be used in the pentose phosphate pathway and can be converted to glucose-1-P for glycogen synthesis.

- Glucokinase is an enzyme related to hexokinase and it is found in the liver. It has a much higher K_m for glucose than hexokinase, allowing liver cells to more easily export glucose without converting it to G6P.

- In the second reaction of glycolysis, G6P is converted to F6P by phosphoglucoisomerase - a readily reversible reaction.

- In reaction 3, F6P is phosphorylated to F1,6BP in a reaction catalyzed by phosphofructokinase (PFK-1) with energy provided by ATP.

- PFK-1 is an important regulatory enzyme for glycolysis - several allosteric effectors. The reaction it catalyzes is essentially irreversible.

- A variant enzyme to PFK-1 in plants and bacteria uses pyrophosphate as the energy/phosphate source and that reaction is readily reversible.

- In reaction 4, F1,6BP is split into glyceraldehyde-3-phosphate (GLYAL-3-P) and dihydroxyacetone phosphate (DHAP) in a reaction catalyzed by aldolase.

- The reaction has a large positive $\Delta G°'$ value. Cells decrease the concentration of products to help drive the reaction forward.

- Reaction 5 involves conversion of DHAP to GLYAL3P in a reaction catalyzed by the "perfect" enzyme known as triose phosphate isomerase.

- Enzymes in this category have very high ratios of K_{cat}/K_m that approach a theoretical maximum limited only by the diffusion of substrate into the active site of the enzyme.

- They do this to avoid accumulation of a toxic intermediate.

- In the 6th reaction, the only oxidation of glycolysis occurs - catalyzed by GLYAL-

3P dehydrogenase. In it, GLYAL-3P is converted to 1,3 BPG. NADH is also formed.

- The need for NAD^+ is this reaction is the reason cells go through fermentation (which produces NAD^+).
- The seventh reaction is the first substrate-level phosphorylation of glycolysis in which 1,3BPG donates a phosphate to ADP to form ATP and 3-phosphoglycerate (3-PG).
- The enzyme is phosphoglycerate kinase.
- Oxidative phosphorylation (predominant producer of ATP) and photophosphorylation (plants) are two other ways cells make ATP.
- Reaction 8 is a phosphoglycerate mutase catalyzed reaction in which 3-PG is converted to 2-PG. An intermediate in the process is 2,3BPG which is stable and can be released by the enzyme. 2,3BPG binds to hemoglobin and favors oxygen release, which helps rapidly metabolizing cells.
- 2,3BPG can also be made by the enzyme bisphophoglycerate mutase by action on 1,3BPG.
- In reaction 9, water is released from 2-PG in a reaction catalyzed by enolase to form phosphoenolpyruvate (PEP) - a high energy intermediate.
- In the last reaction of glycolysis (#10), the “big bang” occurs - PEP is converted to pyruvate, ATP is made, and there is still a lot of energy left over, which can be released as heat.
- This reaction is the second substrate level phosphorylation in glycolysis and is catalyzed by pyruvate kinase.
- Galactose is produced in cells by breakdown of lactose, catalyzed by lactase.
- To use galactose in glycolysis, it must be converted to galactose-1-phosphate by galactokinase.
- Galactose-1-phosphate swaps with glucose-6-phosphate from UDP-glucose to make UDP-galactose, which is made into UDP-glucose by an epimerase. The G6P on the UDP in the first reaction was originally a galactose-1-phosphate, so each turn of the cycle results in binding of a galactose-1-P and release of a glucose-6P, effectively converting galactose into a glycolysis intermediate.
- Deficiency of galactose conversion enzymes results in accumulation of galactose, which is converted to galactitol. Galactitol in the human eye lens causes it to absorb water and may favor formation of cataracts.
- Fructose can be phosphorylated to F6P by hexokinase or it can enter glycolysis by being converted to F1P by fructokinase. F1P can be broken down by fructose-1-phosphate aldolase to yield DHAP and glyceraldehyde.
- Phosphorylation of glyceraldehyde by triose kinase yields GLYAL3P.
- This alternative pathway for entry of fructose bypasses the PFK-1 reaction and has been proposed as an explanation for fat production in people who consume high fructose corn syrup, since bypassing PFK-1 favors production of excess pyruvate, which

is converted to acetyl-CoA, a precursor of fatty acids.

- Mannose enters glycolysis by 1) phosphorylation by hexokinase to make mannose-6-phosphate followed by its conversion to fructose-6-phosphate, catalyzed by phosphomannoisomerase.

- Glycerol is important for synthesis of fats, glycerophospholipids, and other membrane lipids. Most commonly it is made into glycerol-3-phosphate which can easily be made into DHAP and vice-versa (catalyzed by glycerol-3-phosphate dehydrogenase).

- Thanks to glycolysis, DHAP (for making glycerol-3-phosphate) can be produced by several sugars - glucose, galactose, fructose, and mannose.

- Thanks to gluconeogenesis, DHAP (for making glycerol-3-phosphate) can be produced from pyruvate, lactate, alanine, oxaloacetate, and aspartic acid.

- Animals can't use acetyl-CoA from fatty acid oxidation to make glucose in net amounts, but plants and bacteria can, since they have the glyoxylate cycle (which animals lack).

- Both glycolysis and gluconeogenesis, however, can use glycerol from fat metabolism, as noted.

- Pyruvate has three pathways, depending on the cell and the conditions it is in. It can be made into acetyl-CoA in most cells when oxygen is abundant. In animal cells, it is converted to lactate in low oxygen conditions (fermentation) and in bacteria and yeast, it is made into ethanol under the same conditions.

- The reason for the different paths depending on oxygen is because NAD^+ is needed to keep reaction 6 of glycoslysis going. In the absence of oxygen, the electron transport system (producer of NAD^+) is not operating very much. Formation of lactate from pyruvate produces NAD^+ as does conversion of pyruvate to ethanol.

- Pyruvate is readily interconverted with alanine by transamination.

- Pyruvate metabolism enzymes include include pyruvate dehydrogenase (makes acetyl-CoA), lactate dehydrogenase (makes lactate), transaminases (make alanine), pyruvate carboxylase (makes oxaloacetate), and pyruvate decarboxylase (a part of pyruvate dehydrogenase that makes acetaldehyde in bacteria and yeast).

- Gluconeogenesis occurs mostly in liver and kidney.

- Seven gluconeogenesis reactions are reversals of glycolysis reactions. Four gluconeogenesis reactions replace three essentially irreversible reactions of glycolysis.

- The four enzymes unique to gluconeogenesis are pyruvate carboxylase and PEP carboxykinase - PEPCK (catalyze reactions that bypass pyruvate kinase), F1,6BPase (bypasses PFK-1) and G6Pase (bypasses hexokinase).

- Pyruvate carboxylase and G6Pase are found in the mitochondria and endoplasmic reticulum, respectively. All of the other enzymes are found in the cytoplasm.

- Biotin (vitamin B_7) is a coenzyme used in carboxylation reactions, such as by pyruvate carboxylase.

- Biotin is readily produced by gut bacteria.
- All of the enzymes of glycolysis and nine of the eleven enzymes of gluconeogenesis are all in the cytoplasm.
- Cells avoid having anabolic and catabolic pathways occurring simultaneously, lest they produce a futile cycle.
- One method of control is called reciprocal regulation. In reciprocal regulation, things that activate catabolic pathways inactivate anabolic pathways and vice-versa. Methods can include allosteric effectors with opposite effects or covalent modifications (dephosphorylation/phosphorylation) with opposite effects.
- For example, PFK-1 is activated by F2,6BP, but F1,6BPase is inactivated by the same molecule.
- In glycogen metabolism enzymes, phosphorylation of phosphorylase kinase and glycogen phosphorylase (catabolic enzymes) has the effect of making them more active, whereas phosphorylation of glycogen synthase (anabolic enzyme) makes it less active. Dephosphorylation reverses these effects.
- Reciprocal regulation is very efficient.
- PEPCK is controlled largely at the level of synthesis, which can be controlled by hormones.
- Sequestering in an organelle is another means of regulation and is what occurs to pyruvate carboxylase - in mitochondria.
- Three regulated enzymes of glycolysis - hexokinase, PFK-1, and pyruvate kinase.
- Pyruvate kinase must be regulated to avoid creating a futile cycle when gluconeogenesis is occurring
- It takes energy from two triphosphates (ATP and GTP) to reverse the pyruvate kinase reaction.
- Feedforward activation occurs when a metabolite in a pathway activates an enzyme catalyzing a reaction ahead of it in the same pathway. F1,6BP feedforward activates pyruvate kinase to remove products so the aldolase reaction becomes favorable.
- Removing products is known as pulling a reaction.
- Increasing reactants is known as pushing a reaction.
- F2,6BP activates PFK-1 and inhibits F1,6BPase. PFK-1 is also allosterically activated by AMP, whereas F1,6BPase is inhibited. On the other hand, citrate inhibits PFK-1, but activates F1,6BPase.
- PFK-1 is also inhibited by ATP and is exquisitely sensitive to proton concentration.
- PFK-1 inhibition by ATP is due to a second ATP binding site (allosteric site separate from active site).
- F2,6BP is made from F6P by PFK-2.
- The liver is the major organ in the body for the synthesis of glucose. Muscles are major users of glucose to make the ATP they need for contraction.

- When muscles are exercising, they use oxygen faster than the blood can deliver it, causing them to go anaerobic. This causes pyruvate to be converted to lactate (to make NAD^+ for glycolysis), which is dumped into the blood. It travels to the liver where there is plenty of oxygen and is converted to pyruvate and then back to glucose, which is dumped into the blood for the muscles. This is the Cori cycle.

- The glucose-alanine cycle is a sort of parallel cycle to the Cori cycle for amines. Instead of reduction to make lactate, pyruvate is transaminated in tissues to make alanine, which travels in the blood to the liver where the amine is removed to make urea and the pyruvate is converted back to glucose.

- Glucose in high concentrations is hazardous to cells, so it is converted into polysaccharides to reduce problems and store it. This can be amylose, amylopectin (both in plants), or glycogen in animals. Cellulose is a structural polysaccharide of glucose in plants.

- Glucose (as G1P) is released from glycogen's α-1,4 bond by action of glycogen phosphorylase, which uses phosphate to clip off a glucose.

- Free glucose is released from α-1,6 bonds by action of debranching enzyme, which performs a hydrolysis reaction.

- In glycogen synthesis, G1P is converted to UDP-glucose by UDP-glucose pyrophosphorylase, using energy from UTP to make the activated intermediate.

- Glycogen synthase uses UDP-glucose to add glucose to a growing glycogen chain.

- Branching enzyme catalyzes formation of α-1,6 branches.

- Glycogen metabolism is regulated allosterically and covalently.

- Phosphorylation of glycogen phosphorylase b (GPb) creates glycogen phosphorylase a (GPa), which is considered more active.

- GPa converts from the R-state to the T-state in the presence of glucose.

- GPb converts to the R-state in the presence of AMP and to the T-state in the presence of ATP or G6P.

- Epinephrine or glucagon can activate a signaling cascade to favor phosphorylation of GPb to make GPa.

- The sequence of signaling steps are 1) hormone binding; 2) activation of a G-protein; 3) activation of adenylate cyclase to make cAMP; 4) activation of protein kinase A to phosphorylate phosphorylase kinase, activating it; 5) phosphorylation of GPb to make GPa.

- Phosphorylase kinase can be activated both by phosphorylation and by calcium.

- Phosphorylation of GPb to make GPa favors glycogen breakdown. Phosphorylation of glycogen synthase by protein kinase A inhibits glycogen synthesis (converts glycogen synthase A to glycogen synthase B).

- The G protein in the signaling cascade is activated by the hormone receptor by binding GTP. The G protein is active with GTP and over time slowly dephosphorylates GTP to make GDP, which inactivates itself.

- Phosphodiesterases break down cAMP to AMP, thus turning off that signal.
- Caffeine inhibits phosphodiesterases.
- Phosphoprotein phosphatase (PP-1) is activated by insulin binding to cell surface receptors. It catalyzes removal of phosphates from all of the phosphorylated enzymes mentioned above.
- It is regulated by an inhibitor called PI-1. PI-1 acts to inhibit when phosphorylated and this can be catalyzed by protein kinase A.
- Phosphoprotein phosphatase is carried in an inactive form by GPa in the R-state. When GPa binds glucose, it flips to the T-state, releasing PP-1 in an active state.
- Phosphoglucomutase interconverts G1P and G6P.
- Glycogen synthesis is catalyzed by glycogen synthase and starts with a protein called glycogenin.
- Phosphorylation/dephosphorylation reciprocally regulates glycogen's catabolism (phosphorylation activates) and anabolism (dephosphorylation activates).
- Glucagon/epinephrine binding favors phosphorylation. Insulin binding favors dephosphorylation.
- Cellulose formation is catalyzed by cellulose synthase. GDP-glucose or UDP-glucose can serve as substrates.
- The pentose phosphate pathway (PPP) is an multipurpose pathway involving sugars. It can produce NADPH from oxidation, ribose-5-phosphate for nucleotide synthesis and intermediates for use in other pathways.
- PPP doesn't really have a beginning, but one "starting point" is oxidation of G6P to form phosphoglucono-δ-lactone, catalyzed by G6P dehydrogenase.
- NADPH is important for anabolic pathways.
- The only decarboxylation (and last oxidation) occurs when 6-Phosphogluconate is converted to ribulose-5-phosphate (Ru5P), NADPH, and carbon dioxide. The reaction is catalyzed by 6-phosphogluconate dehydrogenase
- Ru5P interconverts with ribose-5-phosphate (R5P), catalyzed by Ru5P isomerase.
- Ru5P also interconverts with xylulose-5-P (Xu-5-P), catalyzed by Ru-5-P epimerase.
- Xu-5-P and erythrose-4-P combine (rearrange) to form GLYAL3P and F6P in a reaction catalyzed by transketolase (enzyme also in Calvin cycle).
- Thiamine pyrophosphate (TPP) is a coenzyme for transketolase. Its thiazole ring allows it to donate a proton and act as an acid, forming a carbanion.
- The carbanion is a nucleophile that attacks the carbonyl carbon of the substrate and covalently links to it, allowing it to carry the carbonyl group to the other substrate. A similar reaction occurs with sedohelptulose-7P (S-7-P) and GLYAL3P to interchange with R5P and Xu-5-P.

- The PPP allows glycolysis intermediates, such as GLYAL3P and F6P to be made into R5P for nucleotide synthesis. Thus PPP can make R5P for nucleotide metabolism even if its oxidative steps are blocked.
- Translaldolase catalyzes interconversion of GLYAL3P and S-7-P to E-4-P and F6P.
- Thiamine is vitamin B_1
- Thiamine pyrophosphate (TPP) is an enzyme cofactor found in all living systems derived from thiamine by action of the enzyme thiamine diphosphokinase.
- TPP is required for the oxidative decarboxylation of pyruvate to form acetyl-CoA and similar reactions.
- TPP is also required for oxidative decarboxylation of α-keto acids like **α**-ketoglutarate and branched-chain α-keto acids arising from metabolism of valine, isoleucine, and leucine. It is also used by transketolase.
- In the pyruvate dehydrogenase complex, TPP carries the activated acetaldehyde molecule to its attachment (and subsequent oxidation) to lipoamide.
- The Calvin cycle (dark cycle) is a metabolic pathway occurring exclusively in the chloroplasts of higher photosynthetic organisms.
- In the Calvin cycle, carbon dioxide is taken from the atmosphere and built into glycolysis intermediates that can ultimately be built into sugars.
- Reactions occur in regions of the chloroplast known as the stroma, the fluid areas outside of the thylakoid membranes.
- There are three phases to the Calvin cycle - assimilation of CO_2, reduction, and regeneration of starting materials.
- To synthesize a glucose from CO_2 requires electrons from 12 molecules of NADPH (and 18 ATPs).
- Ribulose-1,5-bisphosphate (Ru1,5BP) is the molecule that accepts the CO_2 in a reaction catalyzed by ribulose-1,5-bisphosphate carboylase (RUBISCO) - the most abundant enzyme on Earth.
- Reduction reactions in the Calvin cycle require electrons from NADPH.
- The resynthesis phase has multiple steps, but only utilizes two enzymes unique to plants - sedoheptulose-1,7 bisphosphatase and phosphoribulokinase. RUBISCO is the third (and only other) enzyme of the pathway unique to plants.
- In the resynthesis phase, Ru1,5BP is regenerated. GLYAL3P is converted to DHAP by triose phosphate isomerase. Some DHAPs are converted (via gluconeogenesis) to F6P (one phosphate is lost for each F6P).
- Two carbons from F6P are given to GLYAL3P to create E-4P and Xu-5P (reversal of PPP reaction). E-4P combines with DHAP to form sedoheptulose-1,7 bisphosphate (S1,7BP). The phosphate at position #1 is cleaved by sedoheptulose-1,7 bisphosphatase to yield S-7-P.
- Transketolase (another PPP enzyme) catalyzes transfer to two carbons from S-7-P to GLYAL3P to yield Xu-5P and R5P.
- Phosphopentose isomerase catalyzes conversion of R5P to Ru5P and phos-

phopentose epimerase similarly converts Xu-5P to Ru5P. Finally, phosphoribulokinase transfers a phosphate to Ru5P (from ATP) to yield Ru1,5BP.

- Ribulose-1,5-bisphosphate carboxylase (RUBISCO) catalyzes the addition of carbon dioxide to ribulose-1,5-bisphosphate (Ru1,5BP) to create two molecules of 3-phosphoglycerate.

- Oxygen competes with CO_2 for binding to RUBISCO. When that happens, an alternative metabolic pathway called photorespiration occurs. It involves production of 3-PG (like the CO_2 pathway) and one molecule of phosphoglycolate. The latter is converted to glyoxylate and then transaminated to form glycine. A complicated set of reactions convert glycine to serine. Serine can ultimately be converted into 3-PG, but there are significant energy costs, making the oxygen pathway less efficient than the carbon dioxide pathway.

- C4 plants differ from other plants (called C3 plants) in how they get the carbon dioxide to operate the Calvin cycle. C3 plants get it directly from the atmosphere. C4 plant assimilate it first onto PEP to make oxaloacetate, which is converted to malate and donates it to Ru1,5BP (Calvin cycle) in the bundle sheath cells of plants. This helps C4 plants to conserve oxygen and avoid photorespiration involving oxygen.

- Bacterial cell walls contain a layer of protection known as the peptidoglycan layer. The multi-step process for its synthesis begins with a modified sugar (glucosamine-6-P) and after converting it to UDP-N-acetylmuramic acid, a pentapeptide sequence of L-Ala-D-Glu-L-Lys-D-Ala-D-Ala is attached and it is linked to another pentapeptide of the same sequence. These D- amino acids are rare examples of such stereoisomers in living cells.

- Additions and rearrangements to the growing chain yields N-acetylmuramic acid-N-acetylglucosamine-decapeptide, which is added to the growing peptidoglycan chain in a reaction catalyzed by an enzyme known as DD-transpeptidase. This enzyme is the target of penicillin.

- Metabolons are cellular complexes containing multiple enzymes of a metabolic pathway that are arranged so that the product of one enzymatic reaction is passed directly to the enzyme that catalyzes the next reaction in the metabolic pathway.

- Metabolic pathways thought to use metabolons include glycolysis, the citric acid cycle, nucleotide metabolism, glycogen synthesis, steroid synthesis, DNA synthesis, RNA synthesis, the urea cycle, and the process of electron transport.

- Hypoxia occurs when the body or a region of it has an insufficient oxygen supply.

- The body's response to hypoxia is to produce Hypoxia-Inducible Factors (HIFs) - transcription factors that induce expression of genes to help cells adapt to hypoxic conditions. Many of the genes are, in fact, enzymes of glycolysis and GLUTs (glucose transport proteins).

- The hypoxia response allows cells to 1) import more glucose and 2) metabolize it when it arrives. This is important, since anaerobic glucose metabolism is only 1/15 as efficient as aerobic glucose metabolism.

- Cytoglobin facilitates transfer of oxygen from arteries to the brain.

- HIFs are regulated by oxidation. When oxygen is high, prolyl hydroxylase hydroxylates prolines in them to target them to the proteasome for destruction.

Citric Acid Cycle / Related Pathways

- The primary catabolic pathway in the body is the citric acid cycle - occurs completely in the mitochondrion.
- It is a common pathway for metabolism of the cells' major building blocks - sugars, fatty acids, and amino acids.
- The molecule "feeding" the citric acid cycle is acetyl-CoA and it can be obtained from pyruvate (from glycolysis), from fatty acid β-oxidation, from ketone bodies, and from amino acid metabolism.
- Molecules from other pathways feeding into the citric acid cycle for catabolism make the citric acid cycle 'cataplerotic'.
- Anabolically, acetyl-CoA is also very important for providing building blocks for synthesis of fatty acids, ketone bodies, amino acids and cholesterol.
- Some citric acid cycle intermediates are also important in amino acid metabolism, heme synthesis, electron shuttling, and shuttling of acetyl-CoA across the mitochondrial inner membrane.
- Anaplerotic means 'to fill up and it describes the pathway's ability to provide intermediates for use in other pathways.
- The pyruvate dehydrogenase enzyme complex has multiple copies of three subunits (E_1, E_2, and E_3) that catalyze the decarboxylation of pyruvate to form acetyl-CoA.
- The reaction mechanism requires use of five coenzymes - thiamine pyrophosphate (TPP), lipoamide, coenzyme A, NAD^+/NADH, and FAD/$FADH_2$.
- E_1 is the decarboxylase. E_2 is dihydrolipoamide acetyltransferase and E_3 is called dihydrolipoyl dehydrogenase.
- The steps, sequentially occurring on E_1, E_2, and E_3, are 1) decarboxylation of pyruvate; 2) oxidation of the decarboxylated product; and 3) transfer of electrons to ultimately form NADH.
- The process begins with formation of a nucleophilic carbanion on the TPP that attacks the electrophilic ketone carbon on the pyruvate, releasing carbon dioxide in a non-oxidative decarboxylation.
- The remaining two carbon piece is known as an activated acetaldehyde (or hydroxyethyl unit) attached to TPP.
- Next, acetylation occurs as the 2-carbon hydroxyethyl unit is transferred to lipoamide on E_2. This is an oxidation of the hydroxyethyl (to form an acetyl group) and a reduction for the lipoamide to which the unit is transferred.
- Lipoamide is a lipoic acid covalently attached to a lysine of E_2.
- Prokaryotes have the option to release the acetyl group as acetaldehyde (and form ethanol in fermentation when oxygen is limiting), but animals cannot.

- In animals and prokaryotes with abundant oxygen, the acetyl group is then transferred from lipoamide to coenzyme A in E_2 to form acetyl-CoA, which is released.
- The lipoamide is left with sulfhydryl groups and these must be converted back to disulfides to complete the cycle.
- Lipoamide transfers electrons to FAD in E_3, forming $FADH_2$ and a disulfide bond on lipoamide. $FADH_2$ transfers electrons to NAD^+, forming NADH, which is released.
- Pyruvate deyhdrogenase is regulated both allosterically and by covalent modification - phosphorylation / dephosphorylation.
- ATP, acetyl-CoA, NADH, and fatty acids (indicators of high energy) inhibit the enzyme.
- AMP, coenzyme A, NAD^+, and calcium stimulate it.
- Phosphorylation by pyruvate dehydrogenase kinase (PDK) inhibits the enzyme. PDK is itself inhibited by pyruvate.
- Dephosphorylation by pyruvate dehydrogenase phosphatase (PDP) activates it.
- Low concentrations of NADH and acetyl-CoA are necessary for PDP to dephosphorylate the enzyme and remain on it. When those concentrations rise, PDP dissociates and PDK gains access to a serine for phosphorylation.
- Insulin and calcium can also activate the PDP.
- In the citric acid cycle, acetyl-CoA combines with oxaloacetate (OAA) to form citrate (catalyzed by citrate synthase).
- The $\Delta G°'$ is fairly negative and helps to "pull" the reaction preceding it in the cycle catalyzed by malate dehydrogenase.
- In the next reaction, citrate is isomerized to isocitrate by action of the enzyme called aconitase.
- Isocitrate is a branch point for the glyoxylate cycle, which occurs in plants and bacteria.
- Oxidative decarboxylation of isocitrate by isocitrate dehydrogenase produces NADH and **α**-ketoglutarate.
- **α**-ketoglutarate is a branch point for synthesis of glutamate (by transamination).
- Decarboxylation of α-ketoglutarate yields succinyl-CoA and is catalyzed by **α**-ketoglutarate dehydrogenase, an enzyme similar to pyruvate dehydrogenase - employs the same five coenzymes.
- Succinyl-CoA is a branch point for the synthesis of heme.
- Succinyl-CoA is converted to succinate in a substrate level phosphorylation reaction catalyzed by succinyl-CoA synthetase. Cleavage of the thioester Co-A bond provide the energy for the formation of GTP.
- Succinate is also produced by metabolism of odd-chain fatty acids.
- Oxidation of succinate to fumarate is catalyzed by succinate dehydrogenase and produces $FADH_2$.

- Fumarate is also a byproduct of nucleotide metabolism and the urea cycle.
- Succinate dehydrogenase is embedded in the inner membrane of the mitochondrion and transfers electrons to coenzyme Q of the electron transport system.
- In the next reaction, fumarate gains a water to become malate (catalyzed by fumarase).
- Malate is an important shuttle molecule in the malate-aspartate shuttle for moving electrons across the mitochondrial inner membrane in ferrying carbon dioxide from mesophyll cells to bundle sheath cells in C_4 plants.
- Conversion of malate to oxaloacetate by malate dehydrogenase is a rare biological oxidation that has a $\Delta G°'$ with a positive value (29.7 kJ/mol). As noted above, it is pulled by the citrate synthase reaction.
- Oxaloacetate intersects pathways for amino acid metabolism (readily converted to aspartic acid), transamination (nitrogen movement) and gluconeogenesis.
- Reversal of the citric acid cycle provides a mechanism for assimilating CO_2 in bacteria (Arnon-Buchanan cycle).
- ATP and NADH will tend to inhibit the cycle and NAD^+, AMP, and ADP will tend to activate the cycle.
- Citrate synthase is inhibited by NADH, ATP, and succinyl-CoA.
- Isocitrate dehydrogenase is inhibited by ATP, activated by ADP and NAD^+.
- α-ketoglutarate dehydrogenase is inhibited by NADH and succinyl-CoA and activated by AMP.
- The citric acid cycle is an important source of molecules needed by cells (anaplerotic) and a mechanism for extracting energy from amino acids in protein breakdown and other breakdown products (cataplerotic).
- Transamination of α-ketoglutarate and oxaloacetate produces glutamate and aspartic acid, respectively. Oxaloacetate is needed for production of glucose in gluconeogenesis.
- Glutamate has an important role in movement of nitrogen through cells.
- Aspartate is a precursor of other amino acids and for making pyrimidine nucleotides.
- Succinyl-CoA is necessary for the synthesis of porphyrins, such as the heme groups in hemoglobin, myoglobin and cytochromes.
- Citrate carries an acetyl group for making acetyl-CoA across the inner mitochondrial membrane into the cytoplasm for fatty acid synthesis.
- Acetyl-CoA is produced by fatty acid oxidation, pyruvate decarboxylation, amino acid catabolism, and breakdown of ketone bodies.
- α-ketoglutarate is produced by amino acid metabolism.
- Succinyl-CoA comes from propionic acid metabolism.

- Fumarate is produced from the urea cycle and purine metabolism.
- Malate is made by carboxylation of PEP in plants.
- Oxaloacetate comes from many sources, including amino acid catabolism and pyruvate carboxylase action on pyruvate in gluconeogenesis.
- The glyoxylate cycle (plants and bacteria only) bypasses the decarboxylation reactions while using most of the non-decarboxylation reactions of the citric acid cycle thank to two enzymes - isocitrate lyase and malate synthase.
- Isocitrate lyase catalyzes the conversion of isocitrate into succinate and glyoxylate. Succinate continues in the cycle to form oxaloacetate.
- Glyoxylate combines with a second acetyl-CoA (one acetyl-CoA was used to start the cycle) to create malate (catalyzed by malate synthase). Malate also is converted to oxaloacetate.
- At the end of one turn of the glyoxylate cycle, two molecules of oxaloacetate are produced. Because of this, bacteria and plants can make glucose in net amounts from acetyl-CoA. Animals can't, since they only regenerate the oxaloacetate they start with in the citric acid cycle.
- The glyoxylate cycle is particularly important for plant seed germination, allowing the seedling to make glucose from stored lipids since it is not exposed to the sun.
- Each turn of the glyoxylate cycle produces one FADH2 and one NADH instead of the three NADHs, one FADH2, and one GTP made in each turn of the citric acid cycle.
- Control of the glyoxylate cycle in plants and bacteria occurs as a result of isocitrate dehydrogenase. The enzyme can be inactivated by phosphorylation by a kinase found only in plants and bacteria. Inactivation causes isocitrate to accumulate in the mitochondrion of the plants and when this happens, it gets shunted to the glyoxysome, favoring the glyoxylate cycle.
- Removal of the phosphate by a specific phosphoprotein phosphatase restores activity to the enzyme.
- In bacteria, where the enzymes for both cycles are present together in the cytoplasm, accumulation of citric acid cycle intermediates and glycolysis intermediates will tend to favor the citric acid cycle by activating the phosphoprotein phosphatase, whereas high energy conditions will tend to favor the glyoxylate cycle by inhibiting it.
- Acetyl-CoA is found in fatty acid oxidation/synthesis, pyruvate oxidation, the citric acid cycle, amino acid anabolism/catabolism, ketone body metabolism, steroid/bile acid synthesis, and (by extension from fatty acid metabolism) prostaglandin synthesis.
- Ketone bodies are molecules made in the liver when the blood levels of glucose fall very low.
- Pathways for ketone body synthesis and cholesterol biosynthesis overlap.
- In the beginning, two acetyl-CoAs are joined together by thiolase to make acetoacetyl-CoA.

- A third acetyl-CoA is added to form hydroxy-methyl-glutaryl-CoA, or HMG-CoA - the last common molecule of ketone body synthesis and cholesterol synthesis.
- For ketone body synthesis, HMG-CoA is broken down into acetyl-CoA and acetoacetate. Acetoacetate is a ketone body. It can be reduced to form another one, D-β-Hydroxybutyrate (not actually a ketone, though, but still called a ketone body).
- Acetoacetate can break down to acetone, which can be converted to pyruvate and made into glucose.
- D-β-Hydroxybutyrate can cross the blood-brain barrier. It can be then oxidized back to acetoacetate, converted to acetoacetyl-CoA, and then broken down to two molecules of acetyl-CoA for oxidation in the citric acid cycle.
- When a body is producing ketone bodies for its energy, this state in the body is known as ketosis.
- Ketone bodies can be made in animals from the breakdown of fat/fatty acids.
- Ketosis may arise from fasting, a very low carbohydrate diet or, in some cases, diabetes.
- Acidosis refers to conditions in the body where the pH of arterial blood drops below 7.35. In alkalosis, the pH of the arterial blood rises above 7.45.
- Blood pH values lower than 6.8 or higher than 7.8 can cause irreversible/deadly damage. Acidosis may have roots in metabolism (metabolic acidosis) or in respiration (respiratory acidosis).
- In metabolic acidosis, production of excess lactic acid or failure of the kidneys to excrete acid can cause blood pH to drop.
- Respiratory acidosis arises from accumulation of carbon dioxide in the blood. Causes include hypoventilation, pulmonary problems, emphysema, asthma, and severe pneumonia.

Fats and Fatty Acids

- Fat is the most important energy storage form of animals.
- Fat stores more energy per weight than carbohydrates.
- Fat's insolubility in water makes movement in the body more complicated.
- Dietary triglycerides are solubilized in the digestive system by the stomach and emulsification by the bile acids.
- In the intestines, triglycerides are acted on by lipases to release two fatty acids, leaving a monoacylglyceride, which is moved with the freed fatty acids into the lymph system where the fat is reassembled.
- Fat is stored in the body in adipocytes.
- In adipocytes, hormone sensitive triacylglycerol lipase (HSTL) removes the first fatty acid from the fat. Diacylglyceride lipase removes the second one and monoacylglyceride lipase removes the third.
- HSTL is the primary regulated enzyme in fat catabolism. It is activated by binding of epinephrine to the cell surface receptor

using the same system that activates glycogen breakdown enzymes.

- HSTL is inhibited by dephosphorylation and this is stimulated by binding of insulin to its cell membrane receptor.

- Perilipin is a protein that associates with fat droplets and helps regulate action of HSTL.

- When perilipin is not phosphorylated, it coats fat droplets and blocks HSTL from accessing it. Activation of protein kinase A in the epinephrine cascade, results in phosphorylation of perilipin and HSTL.

- Perilipin expression is high in obese organisms and some mutational variants have been associated with obesity in women.

- In fat synthesis, glycerol-3-phosphate is esterified at position 1 with a fatty acid (enzyme = glycerol-3 O-phosphate acyl transferase), followed by a duplicate reaction at position 2 to make phosphatidic acid.

- Phosphatidic acid gets dephosphorylated to diacylglycerol, which is then esterified with a third fatty acid to complete the synthesis of the fat.

- Fatty acids released from adipocytes travel in the bloodstream bound to serum albumin.

- Membrane-associated fatty acid binding proteins regulate the uptake of fatty acids by cells. These include CD36, plasma membrane-associated fatty acid-binding protein, and a family of fatty acid transport proteins (called FATP1-6).

- Fatty acids are oxidized in a process that chops off two carbons at a time to make acetyl-CoA.

- Long fatty acids (22 or more carbons) begin oxidation in peroxisomes and then move to the mitochondrion. Other ones get oxidized solely in the mitochondrion.

- In the cytoplasm, fatty acids are attached to coenzyme A and then they travel to the intermembrane space of the mitochondrion where CoA is replaced by carnitine. The enzyme catalyzing this, carnitine acyl transferase, helps to control how many fatty acids are moved into the mitocohondrial matrix. It is inhibited by malonyl-CoA, an intermediate in fatty acid synthesis.

- The acyl-carnitine is moved into the matrix where the carnitine is replaced by CoA.

- Oxidation occurs in the matrix. There are four steps -

1) dehydrogenation to form $FADH_2$ and a *trans* intermediate (enzyme = acyl-CoA dehydrogenase)

2) hydration to produce an L intermediate at position three (enzyme = enoyl-CoA hydratase)

3) oxidation of the hydroxyl group to form a ketone and NADH (enzyme = hydroxyacyl-CoA dehydrogenase)

4) thiolytic cleavage (catalyzed by thiolase). Thiolase is inhibited by acetyl-CoA.

- Acyl-CoA dehydrogenase comes in three different forms – ones specific for long, medium, or short chain length fatty acids. The one for long fatty acids is found in the peroxisomes.

- Plants and yeast perform **β**-oxidation exclusively in peroxisomes.

- The acyl-CoA dehydrogenase that works on medium length fatty acids is the one most commonly deficient in animals and has been linked to sudden infant death syndrome.

- Reversal of the thiolase reaction at the four carbon stage is the first step in ketone body synthesis.

- Oxidation of fatty acids is chemically very similar to oxidation of the four carbon compounds of the citric acid cycle.

- Oxidation of fatty acids with odd numbers of carbons ultimately produces an intermediate with three carbons - propionyl-CoA. It cannot be oxidized in the **β**-oxidation pathway.

- Oxidation of propionyl-CoA involves 1) carboxylation to make D-methylmalonyl-CoA; 2) isomerization to L-methylmalonyl-CoA; 3) rearrangement to form succinyl-CoA.

- The last reaction above requires vitamin B_{12}.

- Peroxisomal fatty acid oxidation is slightly different from mitochondrial fatty acid oxidation.

- Peroxisomes have no electron transport system, so they transfer the first set of electrons directly to oxygen to make H_2O_2.

- NADH made in the peroxisomes must be shuttled into the mitochondrion for making ATP.

- Peroxisomes are also involved in oxidation of branched chain fatty acids, leukotrienes, and some prostaglandins.

- Unsaturated fatty acids have *cis* bonds that interfere with **β**-oxidation and must be isomerized for metabolism.

- There are two relevant enzymes.

1. cis-**Δ**3-enoyl-CoA isomerase will convert a *cis* bond between carbons Δ3 and Δ4 to a *trans* bond between carbons Δ2 and Δ3, allowing β-oxidation to proceed at that point.

2. 2,4 dienoyl CoA reductase (using NADPH) will convert an intermediate with a *trans* double bond between carbons Δ2 and Δ3 and a *cis* double bond between carbons Δ4 and Δ5 to an intermediate with a single *cis* bond between carbons Δ3 and Δ4. cis-**Δ**3-enoyl-CoA isomerase will then convert it to a *trans* bond between carbons two and three, allowing **β**-oxidation to proceed

- **α**-oxidation is a peroxisomal pathway necessary for catabolism of fatty acids that have branches in their chains.

- Branched molecules like phytanic acid (from chlorophyll's phytol group) undergo hydroxylation and oxidation on carbon number two (in contrast to carbon three of **β**-oxidation), followed by decarboxylation and production of an unbranched intermediate that can be further oxidized by the β-oxidation pathway.

- Deficiency of **α**-oxidation leads to Refsum's disease.

- **ω**-oxidation is a minor oxidation pathway in the smooth endoplasmic reticulum of liver and kidney cells. In it, oxidation begins at the ω end of the fatty acid. Steps in the process involve 1) oxidation of the terminal methyl group of the fatty acid to an alcohol; 2) oxidation of the alcohol to an aldehyde, and 3) oxidation of the aldehyde group to a carboxylic acid.

- After the last oxidation, the fatty acid has carboxyl groups at each end and can be attached to coenzyme A at either end and subsequently oxidized, ultimately yielding succinate.

- Synthesis of fatty acids occurs in the cytoplasm and endoplasmic reticulum of the cell and is chemically similar to the reversal of the **β**-oxidation process.

- Transport of acetyl-CoA from the mitochondrial matrix occurs when it begins to accumulate, such as when the citric acid cycle slows or stops from lack of exercise.

- Movement of acetyl groups to the cytoplasm is done by citrate and acetylcarnitine. Carnitine can swap with CoA groups on acetyl-CoA when concentration of the latter increases. When citrate accumulates, it can be transported out of the mitochondrion to the cytoplasm where citrate lyase can cleave it to oxaloacetate and acetyl-CoA.

- In animals, six different catalytic activities necessary to fully make palmitoyl-CoA are contained in a single complex called fatty acid synthase.

- These include 1) transacylases (MAT) for swapping CoA-SH with ACP-SH on acetyl-CoA and malonyl-CoA; 2) a synthase (KS) to catalyze addition of the two carbon unit from the three carbon malonyl-ACP in the first step of the elongation process; 3) a reductase (KR) to reduce the ketone; 4) a dehydrase (DH) to catalyze removal of water; 5) a reductase (ER) to reduce the *trans* double bond and 6) a thioesterase (TE) to cleave the finished palmitoyl-ACP into palmitic acid and ACP.

- The process of making a fatty acid in the cytoplasm starts with two acetyl-CoA molecules. One is converted to malonyl-CoA by adding a carboxyl group (catalyzed by acetyl-CoA carboxylase - the only regulated enzyme of fatty acid synthesis and the only one separate from fatty acid synthase).

- Next, both acetyl-CoA and malonyl-CoA have their CoA-SH portions replaced by acyl carrier protein (ACP).

- In the next step, a fatty acyl-ACP (in this case, acetyl-ACP) is joined to malonyl-ACP which splits out the carboxyl group from malonyl-ACP and creates the acetoacyl-ACP intermediate.

- The ketone is then reduced to a hydroxyl (D-configuration) using NADPH.

- Next, water is removed from carbons 2 and 3 of the hydroxyl intermediate to form a *trans* intermediate.

- Last, the double bond is hydrogenated to yield a saturated intermediate. This completes the first round of synthesis.

- The acyl group produced at the end of the first round is the substrate for the second round of synthesis and this cycling continues until a 16-carbon acyl-ACP is produced - palmitoyl-ACP. At this point, a thioesterase on the fatty acid synthase cleaves the ACP

from the palmitoyl-ACP to yield palmitic acid and the cytoplasmic synthesis ceases.

- Acetyl-CoA carboxylase is regulated by both allosteric control and covalent modification.
- It can be phosphorylated by both AMP kinase and protein kinase A (inactivates and causes it to depolymerize).
- Dephosphorylation is stimulated by phosphatases activated by insulin binding. Dephosphorylation activates the enzyme and favors its assembly into a long polymer.
- Citrate is an allosteric activator of acetyl-CoA carboxylase and palmitoyl-CoA is an inhibitor.
- Elongation to make fatty acids longer than 16 carbons occurs in the endoplasmic reticulum catalyzed by elongases.
- The mechanism is similar to cytoplasmic synthesis (a malonyl group is used to add two carbons, for example), but CoA is attached to the intermediates and the enzymes are separable and not part of a complex.
- Desaturation of fatty acids occurs in the endoplasmic reticulum by desaturases, which make *cis*, not *trans* bonds.
- The delta (Δ) system numbers the carbon at the carboxyl end as number 1 and the omega (ω) number system numbers the carbon at the methyl end as number 1.
- Humans have desaturases named as Δ5, Δ6, and Δ9 - none greater than Δ9, making a requirement for linoleic (Δ9,12) and linolenic acid (Δ9,12,15) in the diet, since they cannot be synthesized (essential fatty acids).
- The mechanism of desaturases requires NAD(P)H, O_2, two membrane-bound cytochromes, the membrane bound desaturase, and the fatty acid.
- In the electron transfer, the O_2 is reduced to two molecules of H_2O. This reduction requires four electrons and four protons. Two electrons and two protons come from the fatty acid to form the double bond on it. Two electrons come from the NAD(P)H via the cytochromes and two protons come from the aqueous solution.
- *Trans* fatty acids found in trans fat of prepared food are produced not by biological processes, but rather by the process of partial hydrogenation of unsaturated fats.
- The pathway for making prostaglandins, leukotrienes, prostacyclin, and thromboxanes is an extension of fatty acid synthesis.
- Prostaglandins (eicosanoids) are synthesized from arachidonic acid when it has been cleaved from membrane lipids by a phospholipase - most commonly phospholipase A_2 (PLA_2). The bee venom known as mellitin activates PLA_2.
- Lipocortin (also called annexin) is a protein that inhibits PLA_2. Synthesis of lipocortin is stimulated by glucocorticoid hormones, such as cortisol.
- Synthesis of prostaglandins can be reduced by inhibiting the cyclooxygenase (also called prostaglandin synthase or COX) that catalyzes their synthesis from arachidonic acid.

- Non-steroidal anti-inflammatory drugs (NSAIDs) inhibit COX enzymes. Molecules in this class include aspirin, ibuprofen, Vioxx, and Celebrex. Aspirin is a suicide inhibitor.

- Since prostacyclin, and thromboxanes are made from arachidonic acid / prostaglandins, anything that inhibits their synthesis also reduces the amount of prostacyclins and thromboxanes. Thromboxanes are implicated in making platelets "stickier" and this is why aspirin is taken to reduce clotting, since platelet stickiness is part of the cellular response of blood clotting.

- COX enzymes come in at least two forms in humans - COX-1 and COX-2. COX-1 is synthesized constitutively whereas COX-2 enzymes are expressed in increasing amounts in areas of growth and inflammation.

- COX-2 specific inhibitors are associated with some serious side effects, including a 37% increase in incidence of major vascular events and some of the gastrointestinal problems of NSAIDs. The increased risk of heart attack, thrombosis, and stroke are apparently due to an imbalance between prostacyclin (reduced by COX-2 inhibitors) and thromboxanes (not reduced) by the same inhibitors.

- Phosphatidic acid is an intermediate in the synthesis of triacylglycerols and other lipids, including phosphoglycerides.

- Diacylglycerol (DAG), which is an intermediate in fat synthesis, also acts as a messenger in some signaling systems.

- Fatty acids twenty carbons long (eicosanoids) based on arachidonic acid are precursors of the leukotrienes, prostaglandins, thromboxanes, and endocannabinoids.

- Thiolase can join two acetyl-CoAs to make acetoacetyl-CoA - a precursor of both ketone bodies and the isoprenoids. Isoprenoids include steroid hormones, cholesterol, bile acids, and the fat soluble vitamins. In plants, acetyl-CoA can be made into carbohydrates in net amounts via the glyoxylate cycle.

- In 2014, over 600 million adults and 42 million children in the world were classified as obese.

- Adipokines are adipose tissue-synthesized cytokines.

- Examples include leptin, adiponectin (regulates glucose levels and fatty acid oxidation), apelin (control of blood pressure, angiogenesis promotion, vasodilator release, increased water intake), chemerin (stimulation of lipolysis, adipocyte differentiation, link to insulin resistance), and resistin (links to obesity, type II diabetes, LDL production in liver).

- Resistin stimulates insulin resistance, when injected. It is also linked to increased inflammation. Serum levels of it correlate with increased obesity. Resistin stimulates production of LDLs and adversely impacts the effects of statin drugs used to control levels of cholesterol in the body.

- Leptin is a peptide hormone that negatively impacts hunger and regulates energy balance. It is countered by ghrelin, also known as the hunger hormone. Both hormones act in the hypothalamus where hunger is controlled. Low levels of leptin correlate with a decrease in hunger.

- Leptin levels are highest between midnight and early morning, presumably to suppress appetite. Levels of leptin in humans do not strictly reflect levels of fat. Sleep deprivation can reduce leptin levels, as can increasing levels of testosterone and physical exercise. Estrogen increases leptin levels. Emotional stress and insulin can increase leptin levels.

- Obesity increases leptin levels, but doesn't fully suppress appetite.

- Neuropeptide Y is a potent hunger promoter whose receptors in the arcuate nucleus can be bound and blocked by leptin.

- Binding of leptin to the Ob-Rb receptor causes down-regulation of synthesis of endocannabinoids, whose normal function is to increase hunger. High fructose diets have been associated with reduced levels of leptin and of leptin receptor.

- Ghrelin exerts its effects on the central nervous system to increase appetite. It is able to cross the blood-brain barrier. The ghrelin receptor in the brain is found on the same cells as the leptin receptor (arcuate nucleus). Leptin can counter ghrelin by decreasing hunger. Stretching of the stomach reduces the expression of ghrelin.

- Circulating levels of ghrelin increase before eating and decrease afterwards.

- Ghrelin increases food seeking behavior and there is a negative correlation between levels of ghrelin and weight.

- Neuropeptide Y acts as a vasoconstrictor and favors growth of fat tissue. It appears to stimulate food intake, fat storage, relieve anxiety/stress, reduce pain perception, and lower blood pressure. Blockage of neuropeptide Y receptors in the brain of rats decreases food intake. Repeated stress and high fat, high sugar diets stimulate neuropeptide Y levels and cause abdominal fat to increase.

- High levels of neuropeptide Y may help individuals to recover from post-traumatic stress disorder and to reduce the fear response. It may also protect against alcoholism.

Other Lipids

- Acetyl-CoA is the building block of most lipids.

- Isoprenoids are molecules built from isoprene building blocks which, in turn, are built from acetyl-CoA.

- The two isoprene building blocks are isopentenyl pyrophosphate and dimethylallyl pyrophosphate.

- The pathway to make isoprene building blocks overlaps with that of ketone body synthesis.

- The first step begins with joining of two acetyl-CoAs by thiolase to make acetoacetyl-CoA.

- HMG-CoA synthase catalyzes addition of a third acetyl-CoA to form the six carbon compound known as hydroxymethyl glutaryl-CoA (HMG-CoA).

- HMG-CoA is a branch point with ketone body synthesis.

- In the direction of isoprene synthesis, HMG-CoA reductase acts on HMG-CoA to produce mevalonate

- Mevalonate gets phosphorylated twice and then decarboxylated to yield isopentenyl-pyrophosphate (IPP) - readily converted to dimethylallylpyrophosphate (DMAPP). These molecules are called isoprenes.

- HMG-CoA reductase is the most important regulated enzyme leading to cholesterol and is targeted by statin drugs, which act as competitive inhibitors of HMG-CoA for the enzyme.

- Statins also increase production of LDL receptors in the liver, which favors uptake and destruction of LDLs, thus lowering serum cholesterol levels.

- HMG-CoA reductase is feedback inhibited by cholesterol and its synthesis is favored by high levels of blood glucose.

- Phosphorylation of HMG-CoA reductase by AMP-activated protein kinase inhibits its activity.

- Transcription of the HMG-CoA reductase gene is enhanced by binding of the sterol regulatory element binding protein (SREBP) to the sterol recognition element (a promoter sequence) located near the gene coding sequence. As cholesterol levels rise, SREBP is proteolytically cleaved and transcription stops.

- Cholesterol is a precursor of steroid hormones and bile acids and its immediate metabolic precursor, 7-dehydrocholesterol, is also a precursor of vitamin D.

- The pathway leading to cholesterol is the isoprenoid pathway. Branches of it lead to fat-soluble vitamins.

- Joining of IPP and DMAPP forms geranyl-pyrophosphate (10 carbons). Addition of another IPP make farnesyl-pyrophosphate, a 15-carbon compound.

- Joining two farnesyl-PPs yields squalene, a 30 carbon compound.

- Squalene can be rearranged to form lanosterol - a cyclic intermediate resembling cholesterol

- 19 steps after lanosterol, cholesterol is made.

- Steroid hormones made from cholesterol include progestagens, androgens, estrogens, mineralocorticoids, and the glucocorticoids.

- Pregnenolone, made from cholesterol, is the precursor of all of the steroid hormones.

- Estrogens are made from androgens by formation of an aromatic (benzene) ring, catalyzed by aromatase.

- Aromatase inhibitors are use to stop cancers that are stimulated by estrogen.

- Oxidation of the terminal carbon on the side chain off the rings of cholesterol leads to bile acids. Hydroxylation of the rings and linkage to other polar compounds increases polarity.

- Bile acids include cholic acid, chenodeoxycholic acid, glycocholic acid, taurocholic acid, and deoxycholic acid.

- The more cholesterol there is made into bile acids, the less cholesterol there is available. The fewer bile acids recycled, the less

cholesterol there is. Reduced cholesterol promotes uptake of LDLs from the blood.

- Addition of isopentenyl pyrophosphate to farnesyl pyrophosphate creates a 20 carbon intermediate - geranylgeranyl pyrophosphate (GGPP).

- Combining two GGPPs creates a 40 carbon intermediate that decomposes to form phytoene. Desaturases oxidize two single bonds in phytoene, creating lycopene.

- Cyclization of end portions of lycopene give rise to **β**-carotene, the precursor of vitamin A.

- Catalysis by β-Carotene 15,15' monooxygenase cleaves **β**-carotene to form retinal (vitamin A aldehyde). It can be reduced to retinol (alcohol) or oxidized to retinoic acid.

- Retinoic acid binds to the retinoic acid receptor (RAR). RAR binds to DNA and affects transcription of Hox genes important for differentiation.

- Sphingolipid synthesis joins palmitoyl-CoA and serine to make an 18-carbon amine called 3-keto-sphinganine.

- Reduction of 3-keto-sphinganine yields dihydrosphingosine and addition of a fatty acid from an acyl-CoA yields N-acylsphinganine - a ceramide.

- A ceramide can be made into a cerebroside by addition of a glucose from UDP-glucose . It can be turned into a globoside by addition of a few simple sugars or a ganglioside by addition of a complex set of sugars. Alternatively, addition of phosphocholine yields sphingomyelin - important for the myelin sheath of nerve cells.

- Sphingolipid catabolism is critical. Deficiencies lead to severe problems.

- GM1 glandiosidoses (arising from inability to break down GM1 gangliosides) cause severe neurodeneration and seizures.

- Synthesis of glycerophospholipids begins with addition of a fatty acid to glycerol-3-phosphate. Addition of a second fatty acid creates phosphatidic acid.

- CDP serves as part of an activated intermediate in synthesis of phosphatidyl compounds by two methods

1. CTP combines with phosphatidic acid to make CDP-diacylglcyerol (activated intermediate) with release of a pyrophosphate. The phosphatidyl part can then to added to molecules like serine (making phosphatidylserine) or inositol (making phosphatidylinositol).

2 CTP can be combined with molecules to make intermediates that can be put onto diacylglycerol. Example - CDP-choline can be joined to diacylglycerol to make phosphatidylcholine.

- Phosphatidylserine can be decarboxylated to form phosphotidylethanolamine. Tri-methylation of phosphotidylethanolamine by SAM yields phosphatidylcholine.

- Phosphotidylethanolamine and phosphatidylserine can swap groups. So can phosphatidylserine and phosphatidylcholine.

- CDP-diacylglycerol and phosphatidylglycerol can combine to make cardiolipin

- CDP-diacylglycerol and glycerol-3-phosphate can combine to for phosphatidylglycerol
- In heme synthesis, δ-aminolevulinic acid is made first from glycine and succinyl-CoA.
- Joining of two δ-aminolevulinic acid molecules together with splitting out of two molecules of water yields porphobilinogen.
- Joining of four molecules of porphobilinogen together yields hydroxylmethylbilane
- Then a series of reactions including loss of water, six carbon dioxides, oxidation, loss of six protons, and attachment of an atom of iron yields heme.
- Two enzymes in heme synthesis are sensitive to lead, leading to 1) anemia and 2) accumulation of δ-aminolevulinic acid, which can be harmful to neurons in development.
- Deficient enzymes of the heme biosynthesis pathway lead to porphyrias - lead to accumulation of pathway intermediates.
- Severe porphyrias can lead to brain damage, nerve damage, mental disturbances and skin problems on exposure to light. The "madness" of King George III may have been due to porphyria and the vampire legend may similarly have arisen from porphyria.
- Targets for degradation are hemes within damaged red blood cells, which get removed from the blood supply due to their appearance, leading to anemia when blood cells in high enough numbers appear damaged, such as in sickle cell anemia.
- The first biochemical step in catabolism of heme is conversion of heme to biliverdin in the spleen, releasing iron. Biliverdin is converted to bilirubin by biliverdin reductase and is secreted from the liver into bile.
- Bilirubin is converted to urobilinogen by bacteria. Some is absorbed by intestinal cells and transported into kidneys and excreted. The yellow color of urine arises from the compound known as urobilin - an oxidation product of urobilinogen.
- The remaining urobilinogens are converted in the intestinal tract to stercobilinogen whose oxidation product is stercobilin, which gives the color associated with feces.

Amino Acid Metabolism

- Amino acid metabolism is not a single pathway
- Nitrogen moves in cells through the process of transamination
- α-ketoglutarate, glutamate, and glutamine play major roles in transamination, differing by one amine each.
- A common transamination is α-ketoacid + glutamate <=> amino acid + α-ketoglutarate
- Transamination reactions occur by a ping-pong mechanism and involve swaps of amines and oxygens in Schiff base reactions.

- Glutamine and asparagine are the products of gaining an amine in their respective R-groups from ammonium ion.
- Essential amino acids cannot be made by an organism and must be in the diet.
- Amino acids with common metabolic pathways are grouped in families.
- The **α**-ketoglutarate family includes glutamate, arginine, glutamine, and proline.
- Glutamate can be made by transamination of α-ketoglutarate or by addition of ammonium ion to α-ketoglutarate in a reaction catalyzed by glutamate dehydrogenase. Reversing the reaction releases ammonium ions, which can be important for the urea cycle and glutamine metabolism.
- Any citric acid cycle intermediate can be a precursor of glutamate.
- Glutamine can be made from glutamate via catalysis by glutamine synthetase,
- Glutamine synthetase is one of the most important regulatory enzymes in all of amino acid metabolism. It can be regulated by many allosteric effectors and by adenylylation of a tyrosine residue in the enzyme.
- The reaction catalyzed by glutamine synthetase is

$$\text{Glutamate} + \text{ATP} + NH_4^+ \rightleftharpoons \text{Glutamine} + \text{ADP} + P_i$$

- This removes toxic ammonia (ammonium) - an important consideration in brain tissue.
- Inhibitors of glutamine synthetase include histidine, tryptophan, carbamoyl phosphate, glucosamine-6-phosphate, CTP, and AMP. The glutamate substrate site can be inhibited by alanine, glycine, and serine. The ATP substrate site is inhibited by binding GDP, AMP, and ADP.
- When all of the substrate sites in the multiunit enzyme are found, the enzyme is inhibited. Partial binding results in partial activity.
- Proline synthesis starts with glutamate and can branch to form ornithine.
- Arginine is an intermediate in the urea cycle, so all of its metabolites are precursors, as well.
- Arginine can be made from citrulline in two ways - 1) urea cycle and 2) reversing the reaction catalyzed by nitric oxide synthase:

$$\text{Citrulline} + \text{Nitric Oxide} + 3/2\ NADP^+ \rightleftharpoons \text{L-arginine} + 3/2\ NADPH + H^+ + 2\ O_2$$

- Arginine can also be made from ornithine by action of arginase. Glutamate also can lead to formation of arginine in six steps.
- The last means of making arginine is by reversing the methylation of asymmetric dimethylarginine (ADMA). ADMA is a meta-

bolic byproduct of protein modification that interferes with production of nitric oxide.

- The serine family includes the amino acids serine, cysteine, and glycine.
- Serine can be made from 3-phosphoglycerate (3-PG) in three steps starting with a reaction catalyzed by 3-PG dehydrogenase to make 3-phosphohydroxypyruvate followed by transamination to make phosphoserine and hydrolysis to remove the phosphate, yielding serine.
- Serine and glycine can be made from each other.
- Serine has a role in metabolism of purines, pyrimidines, glycine, cysteine, and tryptophan. It also is used in metabolism of sphingolipids and folate.
- Serine in the active site of serine proteases is essential for catalysis. Serine in the active site of acetylcholinesterases is the target of nerve gases and insecticides. Serine's hydroxyl group in proteins can be phosphorylated or glycosylated.
- D-serine is a neurotransmitter in humans.
- Serine and glycine can be interconverted by the enzyme serine hydroxymethyltransferase. This reaction requires a folate one-carbon donor/acceptor and is important for the recycling of folates - needed for nucleotide synthesis.
- Glycine is abundant in collagen and is used in the synthesis of purines and porphyrins. It is an inhibitory neurotransmitter and is a co-agonist of NMDA receptors with glutamate.
- Cysteine can be synthesized in several ways. For example methionine can form SAM and after donating a methyl group to form SAH, can be converted to cystathionine and then cysteine. A byproduct of that pathway is formation of serine.
- Serine can lead to cysteine in a pathway where the sulfur comes from H_2S.
- Last, cysteine can be made from L-cysteic acid by replacing the sulfite with the reduced sulfur from H_2S.
- The aspartate family includes aspartate, asparagine, lysine, methionine, and threonine.
- Metabolism of aspartic acid is similar to that of glutamate. It can arise from transamination of a citric acid cycle intermediate (oxaloacetate). Thus, all citric acid cycle molecules can be precursors of aspartate.
- Aspartate and asparagine can be interchanged by action of the enzyme asparaginase, which catalyzes the following reaction

$$\text{Asparagine} + H_2O \rightleftarrows \text{Aspartate} + NH_4^+$$

- Like glutamate metabolism, this reaction be used to use or produce ammonium ion depending on cell needs.

- Aspartate is an important intermediate for gluconeogenesis when proteins are the primary energy source.

- Asparagine can be also made by transamination of aspartate. For example,

Aspartate + Glutamine + ATP

Asparagine + Glutamate + AMP + PPi

- Metabolism of methionine overlaps with that of cysteine

- There seven reactions going from aspartate to methionine. In the process, cysteine donates a sulfhydryl to form cystathionine (a common intermediate of the two pathways), which is converted to homocysteine. Methylation of homocysteine by a folate yields methionine.

- Methionine can also be made from homocysteine in the liver with glycine betaine serving as a methyl donor

Glycine Betaine + Homocysteine

Dimethylglycine + Methionine

- Methionine is formylated to serve as the first amino acid of bacterial proteins. This occurs after methionine is on the tRNA. The enzyme methionyl-tRNA formyltransferase catalyzes the modification.

- To go from aspartate to threonine requires five reactions - phosphorylation, two reductions (one with loss of phosphate), another phosphorylation, and a final hydrolysis.

- Breakdown of threonine produces acetyl-CoA and glycine. It can also produce α-ketobutyrate, which can be converted to succinyl-CoA for oxidation in the citric acid cycle.

- The pathway from aspartate to lysine is even longer - 9 reactions. They include one phosphorylation, two reductions, two losses of water, one amination, addition of pyruvate, addition of a succinyl group, hydrolysis of a succinyl group and (finally) a decarboxylation.

- Lysine is an important target in proteins for covalent modification. It can be methylated, acetylated, hydroxylated, ubiquitinated, sumoylated, neddylated, biotinylated, pupylated, and carboxylated in proteins that contain it.

- Hydroxylation of lysine is important for strengthening collagen and acetylation/methylation of lysine in histone proteins plays roles in control of gene expression and epigenetics.

- Metabolism of tryptophan, phenylalanine, and tyrosine all starts with PEP and erythrose-4-phosphate. The branch point in their synthesis occurs with the molecule known as chorismate.

- Chorismate is made in 6 steps from PEP and erythrose-4-P. Steps include 1) joining, which includes gain of water and loss of phosphate; 2) oxidation to form a ring; 3) loss of water to form a double bond in the ring (forming shikimic acid); 4) phos-

phorylation by ATP; 5) addition of enolpyruvate from PEP; and 6) loss of phosphate to form a second bond in the ring.

- From chorismate to tryptophan, there are an addition seven steps. They include transamination by glutamine, loss of pyruvate, gain of a phosphorylated ribose from PRPP, loss of a glyceraldehyde-3-phoshate and gain of a serine. The end product, tryptophan, is a precursor of serotonin (neurotransmitter), melatonin (hormone), niacin (vitamin), and auxin (plant hormone).

- Melatonin is a hormone signaling the onset of darkness each day and affecting the timing of sleep, seasonal responses, and blood pressure, among other physiological phenomena. It is used sometimes to help in treatment of sleep disorders.

- Melatonin production is affected by blue light and may be linked to sleep abnormalities. Varying day/night lengths during the year alter melatonin production and provide biological period signals.

- Serotonin is a monoamine neurotransmitter found in the gastrointestinal tract, blood platelets, and the central nervous system of animals that can cause vasoconstriction. The compound has some cognitive functions of enhancing memory and learning. It may be a contributor to feelings of happiness. Some anti-depressant drugs modulate action of serotonin at synapses.

- Niacin (vitamin B_3) is related to pyridine and the amide form of it is nicotinamide, an important component of NAD^+/NADH and $NADP^+$/NADPH.

- Deficiency of niacin in the diet can cause nausea, anemia, headaches, and tiredness and ultimately lead to the disease known as pellagra.

- Auxins are plant hormones that can stimulate factors, such as elastins, to loosen cell walls and stimulate cell elongation. With cytokinins, auxins stimulate cell division. They also promote rooting of plants and organization of xyloem and phloem.

- *Agrobacterium tumefasciens* stimulates the growth of plant tumors by secreting auxins.

- Phenylalanine is a precursor of tyrosine and the catecholamines (through tyrosine).

- Phenylalanine is a component of the artificial sweetener known as aspartame (Nutrasweet) and is dangerous for people suffering from phenylketonuria, due to their deficiency of the enzyme phenylalanine hydroxylase.

- Synthesis of phenylalanine begins the chorismate and proceeds through a molecular rearrangement, decarboxylation / loss of water, and transamination from either glutamate or alanine to produce the final product.

- Tyrosine is made from phenylalanine by hydroxylation by phenylalanine hydroxylase. Plants can synthesize tyrosine by oxidation of prephenate followed by transamination of the resulting 4-hydroxyphenylpyruvate

- Tyrosine is a phosphorylation target for protein kinase enzymes involved in signal transduction pathways.

- Tyrosine is an electron donor in plants' photosystem II to reduce oxidized chlorophyll during the photoexcitation phase of photosynthesis.

- Tyrosine forms a stable radical in the catalytic action of the enzyme ribonucleotide reductase.

- Tyrosine is a precursor of catecholamines, such as L-dopa, dopamine, norepinephrine, and epinephrine and thyroid hormones - triiodothyronine (T_3) and thyroxine (T_4).

- Thyroid hormone formation involves a series of iodinations to tyrosines bound on a protein known as thyroglobulin.

- Oxidation and polymerization of tyrosine occurs in synthesis of the family of melanin pigments and the benzoquinone ring of coenzyme Q is derived from it. Metabolism of CoQ depends on HMG-CoA reductase of cholesterol metabolism.

- Dopamine is a neurotransmitter made in brain and kidney (also in plants) that plays a major role in the brain's reward-mediated behavior. It is also involved in motor control and in managing the release of various hormones. In blood vessels, dopamine inhibits norepinephrine release and causes vasodilation. In the kidneys, it increases sodium excretion and urine output. In the pancreas, it reduces insulin production.

- Epinephrine (adrenalin) is used to treat anaphylaxis, cardiac arrest, croup, and, in some cases, asthma, when other treatments are not working, due to its ability to favor bronchodilation.

- Epinephrine exerts its effects on α- and **β**-adrenergic receptors and is produced and released by adrenal glands and some neurons.

- Norepinephrine is chemically related to epinephrine - it also is released into the blood stream from adrenal glands and affects α- and **β**-adrenergic receptors. Its primary function is to increase alertness, enhance memory functions, help to focus attention, increase heart rate and blood pressure, increase blood glucose and blood flow to skeletal muscle and decrease flow of blood to the gastrointestinal system.

- The pyruvate family of amino acids includes alanine, leucine, isoleucine, and valine. The last three are known as the branched chain amino acids (BCAAs).

- Transamination catalyzed by alanine transaminase produces alanine from pyruvate.

Glutamate + Pyruvate

Alanine + **α**-ketoglutarate

- Alanine can also be produced by catabolism of valine, leucine, and isoleucine.

- The glucose alanine cycle is an important means of moving amines in the body. In amine-rich tissue, pyruvate is converted to alanine, which travels in the blood to the liver where it is converted back to pyruvate, which is used to make glucose for export back to the blood. The amine from alanine is put on **α**-ketoglutarate to make glutamate, which can be used to make urea for excretion.

- The glucose alanine cycle provides an alternative means of reducing amine/ammonium concentration in cells beyond the removal by transaminating glutamate.

- Leucine may stimulate muscle synthesis. In aged rats, it slows muscle degradation. It is an activator of mTOR, a protein which, when inhibited, increases life span in *Saccharomyces cerevisiae*, *C. elegans*, and *Drosophila melanogaster*.

- Metabolism of BCAAs starts with decarboxylation of pyruvate and attachment of the resulting two-carbon hydroxyethyl fragment to thiamine pyrophosphate.

- Valine and leucine handle the hydroxyethyl fragment differently from isoleucine, making α-acetolactate.

- α-acetolactate is then rearranged, reduced, and loses water to make α-ketoisovalerate - a branch point for valine and leucine metabolism.

- To make leucine, an acetyl group is added, followed by rearrangement, oxidation, and transamination to give leucine.

- Making valine from α-ketoisovalerate requires only a transamination reaction.

- Isoleucine metabolism attaches the two carbon hydroxethyl fragment on TPP to α-ketobutyrate (a byproduct of threonine metabolism) to form α-aceto-α-hydroxybutyrate. Rearrangement, loss of water, and transamination yields isoleucine. Several of the enzymes of valine metabolism catalyze reactions in the isoleucine pathway. Though the substrates are slightly different, they are enough like the valine intermediates that they are recognized by the enzymes.

- The key molecule regulating BCAA synthesis is α-ketobutyrate. It is a breakdown product of threonine, catalyzed by threonine deaminase (an allosterically regulated enzyme). It is inhibited by its own product (isoleucine) and activated by valine.

- When valine is abundant, production favors isoleucine and since isoleucine competes with valine and leucine for hydroxyethyl-TPP, less valine and leucine are made.

- When isoleucine concentration increases, threonine deaminase is inhibited, stopping production of α-ketobutyrate and shifting the balance back to production of valine and leucine.

- Another control method used in bacteria to regulate amino acid levels is attenuation. Here, accumulation of leucine speeds the process of translation of a portion of the mRNA transcript of the leucine operon (coding sequences for enzymes necessary to make leucine). This, in turn, causes transcription of the operon to terminate prematurely, thus stopping production of the enzymes necessary to make leucine. On the other hand, when leucine levels fall, translation slows, preventing transcription from terminating prematurely and allowing leucine metabolic enzymes to be made.

- Histidine's metabolism is so distinct, it is in a family all by itself. There are ten steps to the synthesis of histidine, starting with ribose-5-phosphate. PRPP is an intermediate and glutamine and glutamate each serve as amine donors. Histidine itself is a feedback inhibitor of the second enzyme in the pathway - ATP-phosphoribosyltransferase.

- Selenocysteine, the “21st amino acid”, is a derivative of cysteine. It is incorporated into a protein as it is being made by using a tRNA that recognizes what normally is a stop codon.

- Human proteins known to contain selenocysteine include five glutathione peroxidases, three thioredoxin reductases, and a protein known as selenoprotein P with 10 selenocysteine residues.

- Other selenium containing amino acids include selenomethionine and Se-methylselenocysteine.

- The tRNA carrying selenocysteine (gene = sel C) starts with a serine on it, but the hydroxyl group on it is substituted using selenium in selenophosphate.

- The coding regions for selenocysteine-containing proteins have unusual mRNA structures around the UGA codon that make the ribosome “miss” it as a stop codon and use the tRNA with selenocysteine instead.

- Pyrrolysine is another rare, unusual, amino acid built into proteins during translation. The mechanism used is similar to that for incorporation of selenocysteine. A different stop codon (UAG) is used, but the result is the same - pyrrolysine gets incorporated during translation.

- Synthesis of pyrrolysine begins with two lysines. One is converted to (3R)-3-Methyl-D-ornithine, which is attached to the second lysine. After elimination of an amine group, cyclization, and dehydration, L-pyrrolysine is produced.

- The urea cycle was the first metabolic cycle discovered.

- It is important for balancing nitrogen and takes place primarily in the liver and kidney.

- Urea-excreting organisms are called ureotelic. Those that excrete uric acid are uricotelic and those that excrete ammonia are ammonotelic.

- Liver failure can lead to accumulation of nitrogenous waste.

- The cycle contains five reactions (three in cytoplasm, two in mitochondria), with each turn of the cycle producing a molecule of urea. The reaction making carbamoyl phosphate, a molecule that enters the cycle, is not counted by some as part of the cycle.

- The urea cycle doesn’t really have a starting point, but a common place to begin is with ornithine. Ornithine intersects the metabolic pathways of arginine and proline and is moved into the mitochondrion by the ornithine-citrulline antiport of the inner mitochondrial membrane.

- In the matrix, carbamoyl phosphate is made from bicarbonate, ammonia, and ATP - catalyzed by carbamoyl phosphate synthetase I.

- Next, carbamoyl phosphate joins with ornithine to make citrulline (enzyme = ornithine transcarbamoylase)

- Citrulline is transported out to the cytoplasm by the ornithine-citrulline antiport (same as above).

- In the cytoplasm, citrulline reacts with ATP and combines with AMP, yielding

citrullyl-AMP, a transient intermediate that combines with aspartate, releasing the AMP, and forming argininosuccinate (enzyme = argininosuccinate synthetase).

- Argininosuccinate lyase catalyzes the next reaction, which splits out a fumarate and produces arginine.

- The enzyme arginase then splits off a urea (less toxic than ammonia) for excretion and produces an ornithine to complete the cycle.

- In summary of the urea cycle, 1) ammonia is converted to urea using bicarbonate and an amine from aspartate; 2) aspartate is converted to fumarate; and 3) glutamate and aspartate are acting as shuttles to funnel ammonia into the cycle.

- The cycle requires N-acetylglutamate (NAG) for activation of carbamoyl phosphate synthetase I. The enzyme that makes NAG, NAG synthetase (reaction below), is activated by arginine and glutamate.

Acetyl-CoA + L-glutamate

CoA-SH + N-acetyl-L-glutamate (NAG)

- Reduction of ammonia concentrations relies on the glutamate dehydrogenase reaction

α-ketoglutarate + NH_3 + NAD(P)H

Glutamate + $NADP^+$

- Additional ammonia can be taken up by glutamate in the glutamine synthetase reaction,

Glutamate + NH_3 + ATP

Glutamine + ADP + P_i

- These reactions reduct the concentrations of glutamate (brain neurotransmitter), α-ketoglutarate (energy source), and ammonia (toxic substance), so while removing the toxic substance is good, loss of an energy source and a neurotransmitter may be problematic in the brain.

- The urea cycle is even or generates a small amount of energy, if one includes the energy produced in releasing ammonia from glutamate (one NADH). The cycle either breaks even in the worst case or generates 2 ATPs in the best case.

- Amino acids whose catabolic products yield intermediates in the glycolysis pathway are called glucogenic and those that produce intermediates of acetyl-CoA or acetoacetate are called ketogenic. Some are both.

- Citric acid cycle intermediates and glycolysis intermediates are common degradation products of amino acids.

- Amino acids like tryptophan, phenylalanine, and tyrosine yield hormones or neurotransmitters on further metabolism.

- Cysteine and methionine must dispose of their sulfur and all of the amino acids must rid themselves of nitrogen, which can

happen via the urea cycle, transamination, or both.

- Breakdown of tyrosine is a five step process that yields acetoacetate and fumarate.
- Leucine breakdown is a multi-step process ultimately yielding the ketone body acetoacetate and acetyl-CoA.
- BCAAs rely on branched chain amino transferase (BCAT) and (after that) branched chain α-ketoacid dehydrogenase (BCKD) for catabolism.
- Isoleucine catabolism yields intermediates that are both ketogenic and glucogenic. These include acetyl-CoA and propionyl-CoA.

Nucleotide Metabolism

- Nucleotide metabolism is organized by metabolism of 1) purines; 2) pyrimidines; and 3) deoxyribonucleotides.
- These pathways can make nucleotides from simple precursors (*de novo* pathways). Others use pieces of nucleotides to reassemble full ones (salvage pathways).
- De novo synthesis pathways for all nucleotides begins with synthesis of ribonucleotides.
- Deoxyribonucleotides are made from the ribonucleotides.
- Purines are made by building the purine rings on a ribose.
- Purine synthesis by the *de novo* pathway begins with addition of a pyrophosphate to carbon 1 of ribose-5-phosphate, creating phosphoribosylpyrophosphate (PRPP). It proceeds with amination by glutamine, addition of a glycine with loss of a phosphate, addition of a carbon from a folate, another amination by glutamine, ring closure (with ATP hydrolysis), a carboxylation, addition of an aspartate, loss of a fumarate (net gain of amine), addition of another carbon from a folate, and loss of water to close the second ring. The intermediate at that point is inosine monophosphate (IMP).
- Atoms in the purine ring come from folates, glutamine, glycine, bicarbonate, and aspartate.
- PRPP amidotransferase (PPAT), which catalyzes addition of the first amine in the pathway, is the most important regulatory enzyme of the pathway.
- AMP and GMP both inhibit the enzyme and PRPP activates it. Full inhibition of the enzyme requires binding of both AMP and GMP.
- At IMP synthesis of AMP and GMP branches. Each branch has two reactions and the first enzyme of each branch is feedback regulated.
- On the route to GMP, IMP dehydrogenase (inhibited by GMP) catalyzes oxidation of IMP followed by a transamination (from glutamine) that produces GMP. ATP energy is required and AMP is produced.
- For making AMP, adenylosuccinate synthetase (inhibited by AMP) catalyzes addition of an aspartate, using energy of GTP

and then fumarate is lost in the second reaction to produce AMP.

- Synthesis of GMP from IMP requires energy from ATP and that synthesis of AMP from IMP requires energy from GTP.
- Purine nucleotide levels are balanced by the combined regulation of PRPP amidotransferase, IMP dehydrogenase, adenylosuccinate synthetase and the nucleotides AMP and GMP.
- When AMP and GMP both are abundant, PPAT is fully inhibited. When one is abundant and the other is not, PPAT remains partly active so synthesis can proceed to IMP. The branch of the abundant nucleotide will be blocked and the other branch will remain active, allowing synthesis of it to catch up.
- Properly balancing nucleotide levels in cells is critical, because imbalances favor mutation.
- GMP reductase can catalyze conversion of GMP to IMP using electrons from NADPH.
- AMP can also be converted back to IMP by the enzyme AMP deaminase.
- From IMP, either AMP or GMP could be made, thus providing cells with another mechanism of balancing AMP and GMP.
- To convert AMP to ATP and GMP to GTP requires nucleoside monophosphate kinase enzymes.
- Adenylate kinase catalyzes the reaction that follows

AMP + ATP

2 ADP

- In reverse, this reaction is used to generate ATP when the cell's ATP concentration is low. When ATP is made in reverse reaction, AMP levels increase and this is one way the cell senses that it is low on energy.
- GMP has its own monophosphate kinase and it catalyzes this reaction

GMP + ATP

GDP + ADP

- To make triphosphates, NDPK catalyzes reactions of the form

(d)XTP + (d)YDP

(d)XDP + (d)YTP

- where X and Y refer to any base.
- Salvage reactions to make purine nucleotides start with attachment of ribose to purine bases using phosphoribosylpyrophosphate.
- Hypoxanthine/guanine phosphoribosyltransferase (HGPRT) catalyzes the following reactions

Hypoxanthine + PRPP

IMP + PPi

and

Guanine + PRPP

GMP + PPi

- Reduction in levels of HGPRT leads to hyperuricemia, a condition where uric acid concentration increases in the body, causing gout. Complete lack of HGPRT is linked to Lesch-Nyhan syndrome.

- Adenine phosphoribosyltransferase (APRT) catalyzes the reaction corresponding to HGPRT for salvaging adenine bases.

Adenine + PRPP

AMP + PPi

- *De novo* synthesis of pyrimidine bases occurs apart from the ribose and then they are attached later. The first reaction is catalyzed by carbamoyl phosphate synthetase. It is the rate limiting step in pyrimidine biosynthesis. The enzyme is activated by ATP and PRPP and is inhibited by UMP.

- The second reaction is catalyzed by ATCase, a classic enzyme exhibiting allosteric regulation and feedback inhibition, having both homotropic and heterotropic effectors.

- ATCase exists in two states - a low activity T-state and a high activity R-state.

- Binding of the aspartate substrate (homotropic effector) to the active site shifts the equilibrium in favor of the R-state.

- Binding of ATP (heterotropic effector) to the regulatory units favors the R-state, whereas binding of CTP (heterotropic effector) to the regulatory units favors the T-state. The latter is an example of feedback inhibition.

- Thus, regulation of the first two enzymes of the pathway is consistent - a high concentration of purine nucleotides stimulates synthesis of pyrimidines and high concentration of pyrimidines turns off the pathway that synthesizes them.

- The remaining reactions involve loss of water, oxidation, addition of ribose-5-phosphate from PRPP, and decarboxylation to form UMP. The last reaction is catalyzed by OMP decarboxylase, an enzyme that speeds its reaction by 10^{17}, compared to the uncatalyzed reaction.

- UMP/CMP kinase catalyzes conversion of UMP to UDP, CMP to CDP, and dCMP to dCDP, using energy from ATP in each case.

- NDPK, of course, converts UDP to UTP.

- UTP is the substrate for synthesis of CTP via catalysis by CTP synthase.

UTP + Glutamine + ATP

CTP + Glutamate + ADP + P_i

- CTP synthase is inhibited by its product, CTP and activated by ATP, GTP, and glutamine. It exists as an inactive monomer at low enzyme concentrations or in the absence of UTP and ATP.
- CTP is the only nucleotide synthesized *de novo* as a triphosphate, It needs to be converted to CDP for dCDP synthesis. One enzyme, apyrase, sequentially converts CTP to CDP and then CMP.
- Pyrimidine salvage synthesis allows cells to remake pyrimidine triphosphate nucleotides starting from either the C or U pyrimidine bases, nucleosides, or nucleotides.
- The enzymes of pyrimidine salvage are rather flexible. Seven of them can work on both uracil and cytosine containing molecules.
- Cytidine and uridine can be interconverted by cytidine deaminase, providing an alternative to the CTP synthase reaction.
- Both UTP and CTP are converted in the breakdown process to UMP and CMP, respectively and then these can be phosphorylated to UDP and CDP for dUDP and dCDP synthesis by ribonucleotide reductase.
- dCDP and dUDP are converted to dCTP and dUTP by NDPK, but dUTP is then converted to dUMP, which is converted by thymidylate synthase to dTMP. It then gets converted to dTDP by a monophosphate kinase and to dTTP by NDPK.
- Ribonucleotide reductase (RNR) converts all ribonucleoside diphosphates to equivalent deoxyribonucleoside diphosphates.
- Class I RNRs (in humans) use a ferrous iron center that loses an electron to generate a free radical on a tyrosine ring and only work in aerobic conditions.
- Class II RNRs use 5'-deoxyadenosyl cobalamin (vitamin B12) to generate a radical and work under aerobic or anaerobic conditions.
- Class III RNRs generate a glycine radical using S-adenosyl methionine (SAM) and an iron-sulfur center. They work under anaerobic conditions.
- In class I enzymes, RNR is an iron-dependent dimeric enzyme with each monomeric unit containing a large subunit (known as α or R1) and a small subunit (known as β or R2). R1 contains regulatory binding sites. The R2 subunit houses a tyrosine residue that forms a radical critical to the reaction mechanism of the enzyme.
- Electrons needed in the reaction come from NADPH and start by reducing a sulfhydryl in the enzyme.
- A tyrosine side chain in the R2 subunit must be radicalized to start. This electronic change is transmitted through the small R2 subunit to the active site of the large R1 subunit.
- The tyrosine radical contains an unpaired electron delocalized across its aromatic ring.

- Transfer of the electronic instability to the R1 unit radicalizes a cysteine side chain (to form a thiyl radical) at the active site.

- The thiyl radical abstracts a proton plus electron from carbon 3 of ribose on the bound ribonucleoside diphosphate, creating a radical carbon atom. Radicalization of carbon #3 favors release of the hydroxyl group on carbon #2 as water. The extra proton comes from the sulfhydryl of the enzyme's cysteine. Next, a proton and two electrons from the same cysteine are transferred to carbon #2. Then carbon #3 takes back the proton originally removed from it to yield a deoxyribonucleoside diphosphate. The enzyme's thiyl group gains an electron from R2 and the disulfide bond created in the reaction must be reduced by electrons from NADPH again in order to catalyze again.

- RNR has a complex system of regulation, with two sets of allosteric binding sites, both in the R1 subunit.

- RNR is allosterically regulated via two molecular binding sites - a specificity binding site (binds dNTPs and induces structural changes in the enzyme that determines which substrates preferentially bind at the active site) and an activity control site (controls whether or not enzyme is active).

- At the activity control site, ATP activates catalysis, dATP inactivates it.

- In Severe Combined Immunodeficiency Disease (SCID), the salvage enzyme adenosine deaminase is deficient, leading to a rise in concentration of dATP in cells of the immune system, resulting in little or no immune cells for fighting infection.

- dTTP binds to RNR's specificity site and inhibits binding and reduction of CDP and UDP but stimulates binding and reduction of GDP. Binding of ATP or dATP at the specificity site stimulates binding and reduction of CDP and UDP. Binding of dGTP to the specificity site induces binding and reduction of ADP.

- Notable enzymes in the dTTP synthesis pathway include dUTPase and thymidylate synthetase. dUTPase keeps the concentration of dUTP low so it does not end up in DNA. DNA polymerase recognizes dUTP the same as dTTP.

- Thymidylate synthetase is an important target for anticancer therapies. The enzyme requires a reduced tetrahydrofolate to convert dUMP to dTMP.

- Methotrexate is a competitive inhibitor of DHFR, the enzyme that recycles tetrahydrofolate from dihydrofolate. By inhibiting DHFR, tetrahydrofolate can't be remade, so thymidylate synthetase runs out of substrate. For a rapidly dividing cancer cell, that is deadly.

- 5-fluorouracil is a suicide inhibitor of thymidylate synthetase.

- Purine nucleotide catabolism starts with nucleoside monophosphates. Metabolism of AMP and GMP converge at xanthine.

- AMP is dephosphorylated by nucleotidase to create adenosine, which is then deaminated by adenosine deaminase to yield inosine. Alternatively, AMP can be deaminated by AMP deaminase to yield IMP.

- Dephosphorylation of IMP yields inosine. Ribose is removed from it by purine nucleotide phosphorylase to release hypoxanthine. Hypoxanthine is oxidized to xanthine in a hydrogen peroxide-generating reaction catalyzed by xanthine oxidase.
- For GMP, phosphate is removed by nucleotidase to yield guanosine. Guanosine is cleaved from ribose to yield a free guanine base, which is deaminated by guanine deaminase (also called guanase) to produce xanthine.
- Xanthine can be oxidized by xanthine oxidase (same enzyme as above) to yield uric acid and H_2O_2.
- Uric acid is problematic because it is only not very soluble in water. Consequently it precipitates out of solution, forming crystals in joints and (frequently) in the big toe, causing gout.
- There may be a negative correlation between gout and contracting multiple sclerosis.
- Gout is treated with allopurinol. It inhibits xanthine oxidase, which favors an increase in the concentration of hypoxanthine and purine salvage synthesis.
- Uric acid can be excreted into the urine (in humans) or broken down into allantoin by the uricase enzyme.
- Catabolism of cytidine nucleotides proceeds through uridine by deamination of cytosine.
- Free bases of thymine and uracil are released by the enzyme ribosylpyrimidine nucleosidase.
- Uracil and thymine reduction gives dihydrothymine and dihydrouracil respectively. Addition of water to these creates 3-ureidoisobutyrate and 3-ureidopropionate respectively. Hydrolysis of these yields ammonia and carbon dioxide for both (which are made into urea) plus 3-aminoisobutyrate for the thymine pathway and **β**-alanine for the products of the uracil pathway. 3-aminoisobutyrate is produced during exercise and activates expression of thermogenic genes in white fat cells.
- **β**-alanine is a rate-limiting precursor of carnosine, a dipeptide of histidine and β-alanine. Carnosine functions as an antioxidant that scavenges reactive oxygen species and may play a role in aging.
- Ribose and deoxyribose can be recycled (ribose) or catabolized (ribose and deoxyribose).
- Ribose an be reattached to bases by phosphorylase enzymes, such as uridine phosphorylase, or converted into PRPP for the same purpose to create nucleosides. Ribose-5-phosphate can be metabolized to other sugars in the pentose phosphate pathway.
- Deoxyribose-5-phosphate can be broken into glyceraldehyde-3-phosphate and acetaldehyde by deoxyribose-5-phosphate aldolase.

Distance Ed

To the tune of "*Mr. Ed*"
Metabolic Melodies Website HERE

A course is a source, of course, of course
Of all of the knowledge that we endorse
A major force for better/worse is the campus Distance Ed

It's true to outsource a college course
There are a few standards to be enforced
The long and short's we reinforce the campus Distance Ed

Bridge
A classroom class meets every week the same time every day
But Distance Ed is most unique - its flexible schedule's okay

E-course is a source, of course, of course
Of online assistance for lab reports
You're not enrolled in an online course?

Then sign up for this!

"You'll love Distance Ed"

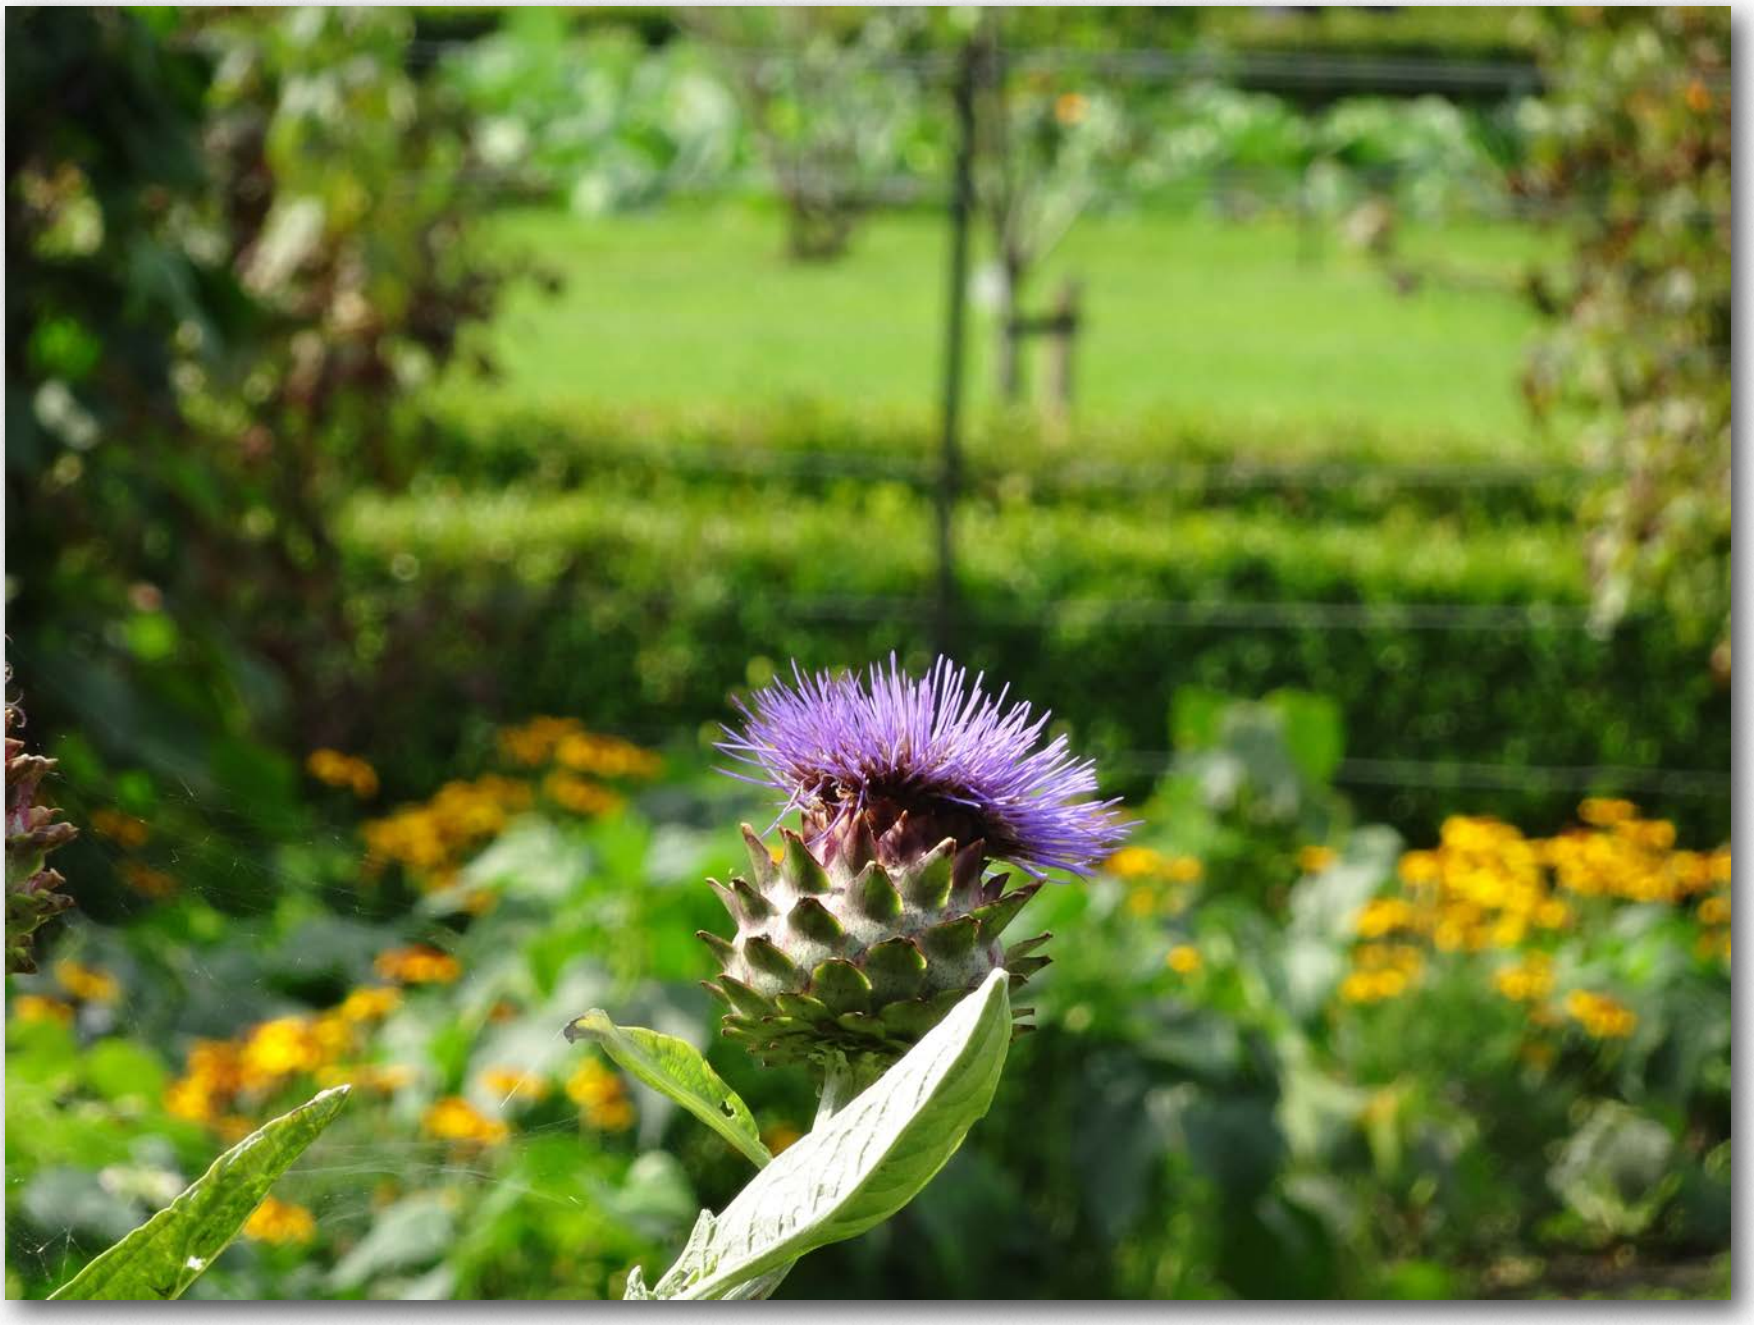
Point by Point: Information Processing



Genes and Genomes

- Key experiments, done between the 1920s and the 1950s, established convincingly that genetic information was carried by DNA.
- The word genome describes all of the genetic material of a cell.
- A genome includes all of the DNA sequences found in chromosomes.
- Eukaryotic cells have organelles like mitochondria and chloroplasts with their own DNA. These are referred to as the mitochondrial or chloroplast genomes to distinguish them from the nuclear genome.
- The complete genome sequences have been determined for thousands of species from all domains of life.
- The Global Genome Initiative is a collaborative effort to sequence at least one species from each of the 9,500 described invertebrate, vertebrate, and plant families.
- Phenotypic traits are controlled by specific regions of the DNA that were termed genes.

- Genes are separated by non-coding regions that are simply referred to as intergenic sequences.
- Early experiments in molecular biology suggested a simple relationship between the DNA sequence of a gene and its product, and led scientists to believe that each gene carried the information for a single protein.
- This simple picture has been modified by subsequent discoveries that demonstrated that the use of genetic information by cells is somewhat more complicated.
- There is not a simple relationship between the complexity of an organism and the size of its genome.
- While genes are made up of DNA, all DNA does not consist of genes (gene = a section of DNA that encodes an RNA or protein product).
- Less than 2% of the total human DNA seems to be the sort of coding sequence that directs the synthesis of proteins.
- Non-coding genomic DNA was believed to be useless, and was described as “junk DNA”.
- We now know much of this so-called junk DNA may play important roles in evolution and in regulation of gene expression.
- In almost all eukaryotes, coding regions in DNA are interrupted by non-coding sequences called introns.
- Non-coding intron sequences can be much longer than the coding sections of the gene (exons).
- Introns can vary in size from several hundred base-pairs to many thousands of base pairs versus only a few hundred bases for most exons.
- Intron sequences account for roughly a quarter of the entire genome in humans.
- Other non-coding DNA in genomes specifies when and to what extent a gene is used, or expressed - these are called regulatory sequences.
- Almost half of the human genome appears to consist of several kinds of repetitive sequences.
- Many of the repetitive sequences are transposons - sections of DNA that can move around within the genome.
- Some transposon movements are simple “cut and paste” events that cut the sequence out of one region of the DNA and inserts it into another location. Others move via a process called retrotransposition involving an RNA intermediate.
- There are two major classes of such transposable elements, the LINEs (Long Interspersed Elements) and SINEs (Short Interspersed Elements) in our genomes.
- LINEs and SINEs are both a kind of transposable element called retrotransposons, sequences that are copied into RNA, then reverse transcribed back into DNA before being inserted into new locations.
- Transposons tend to be inserted randomly in the genome, in many cases within coding regions, causing problems.

- Transposons are a major cause of mutation in genomes and play a role in evolution.

- Much of the genome is transcribed into RNAs, even though only about 2% encodes proteins.

- RNAs that do not encode proteins include ribosomal RNAs, transfer RNAs, small nuclear RNAs that function in splicing, and regulatory RNAs, which are small RNA molecules that play an important role in controlling gene expression.

DNA Replication

- Each time a cell divides, all of its DNA must be copied faithfully - a process called DNA replication.

- Watson and Crick's DNA structure suggested a mechanism by which double-stranded DNA could be copied to give two identical copies.

- Meselson and Stahl demonstrated that DNA replication was semi-conservative - resulting in two DNA molecules each made up of one old strand and one new strand.

- In DNA replication, a parental DNA molecule serves as the template and a new strand is assembled across from it. Base pairing rules dictate joining together of nucleotides to make the new strand.

- Nucleotides used in DNA synthesis are deoxyribonucleoside triphosphates (dNTPs).

- dNTPs have a deoxyribose sugar and three phosphates, in addition to one of the four DNA bases, A, T, C or G.

- DNA polymerases catalyze creation of phosphodiester linkages between one nucleotide and the next.

- Several challenges to DNA replication - 1) genomes are very large; 2) double stranded DNA must be unwound for replication; 3) unwinding must not distort molecule topologically; 4) unwound strands must be kept apart during replication; 5) DNA polymerases must work from a 3' OH; 6) DNA polymerases only work 5' to 3'; 7) short RNAs serve as primers and must be removed.

- In eukaryotes, DNA is broken up into many chromosomes, each of which is composed of a linear strand of DNA. Most bacteria have smaller, circular chromosomes.

- DNA replication is initiated at sites called origins of replication where special proteins called initiator proteins bind the DNA.

- *E.coli* replication origins have small regions of A-T-rich sequences that are "melted" to separate the strands, when the initiator proteins bind to the origin or replication.

- *E. coli* has a single origin of replication on its circular chromosome. Eukaryotes have thousands.

- Unwinding of the DNA duplex requires the enzyme called helicase, which uses energy from ATP hydrolysis to break hydrogen bonds between bases.

- A replication bubble is made up of two replication forks that "move" or open up, in opposite directions.
- Local unwinding of the double helix causes over-winding (increased positive supercoiling) ahead of the unwound region
- Enzymes called topoisomerases relieve the topological stress caused by local “unwinding” of of the double helix.
- Topoisomerases cut one or both strands of the DNA and strands to swivel around each other to release the tension before rejoining the ends.
- A topoisomerase in *E. coli* that does this is called gyrase.
- When the two strands of the parental DNA molecule are separated, they must be blocked from re-forming double-stranded DNA with each other.
- To prevent this, separated strands of the parental DNA are bound by many molecules of a protein called single-strand DNA binding protein (SSB).
- DNA polymerases cannot begin synthesis of a complementary strand *de novo* and can only add new nucleotides on to the 3' end of a pre-existing chain.
- Some enzyme other than a DNA polymerase must first make a small region of nucleic acid, complementary to the parental strand to provide a free 3' OH.
- Primase is an enzyme which makes a short base-paired region, called the RNA primer, with a free 3'OH group to which a DNA polymerase can add the first new DNA nucleotide.
- A protein called clamp loader helps to load a protein complex called the sliding clamp onto the DNA at the replication fork.
- The sliding clamp is a multi-subunit ring-shaped protein joined to the DNA polymerase to help it stay bound at the replication fork.
- The property of staying associated with the template for a long time before dissociating is known as the processivity of the enzyme.
- DNA polymerases linked to sliding clamps are much more processive than those that are not linked.
- DNA polymerase catalyzes addition of a deoxyribonucleotide to a growing chain by facilitating a nucleophilic attack by the 3’OH group at the end of a nucleic acid strand on the α phosphate of the incoming dNTP.
- A pyrophosphate is released by the reaction and a phosphodiester bond is created between the new nucleotide and the growing chain. Its 3’ end becomes the addition site for the next nucleotide.
- Parental strands of DNA are antiparallel and DNA polymerases can only synthesize DNA in the 5’ to 3’ direction. This requires two different types of bidirectional DNA replication at each fork - a continuous leading strand and a discontinuous lagging strand, both being catalyzed by the same DNA polymerase.
- Discontinuous replication on the lagging strand leads to creation of DNA pieces about 1000-2000 nucleotides long, each with an RNA primer at the 5’ end. The

DNA pieces are called Okazaki fragments.

- To complete DNA synthesis, RNA nucleotides must be removed and the gaps must be filled in with DNA nucleotides, a task accomplished by DNA Polymerase I.
- DNA polymerase I has an exonuclease activity acting in the 5' to 3' direction that removes the RNA nucleotides ahead of it, while the 5' to 3' polymerase activity replaces the RNA nucleotides with dNTPs. After the DNA nucleotides have replaced the RNA, DNA ligase seals the gap between the 3' end of the new strand and the 5' end of the strand ahead of it.
- Many DNA polymerases have a proofreading function that enables them to detect when the wrong base has been inserted across from a template strand, back up and remove the mistakenly inserted base, before continuing with synthesis.
- Proofreading is a function of a 3' to 5' exonuclease activity possessed by a DNA polymerase.
- Proofreading reduces by about a 100-fold the mistakes made when DNA is copied.
- In *E.coli*, DNA polymerase III is the major replicative polymerase.
- DNA polymerase I is responsible for DNA repair and removal of RNA primers and replacement with DNA nucleotides.
- DNA polymerase II plays a role in restarting replication after DNA damage stalls replication. DNA polymerase IV and DNA polymerase V are both required in translesion, or bypass synthesis, which allows replication around sites of DNA damage.
- Eukaryotes have over fifteen different DNA polymerases - the primary one are DNA polymerase **∂** and DNA polymerase **ε**. DNA polymerase **α** is also important because it has primase and repair activities.
- Replication is initiated in eukaryotic cells by DNA polymerase **α**. It binds to the initiation complex at the origin and makes an RNA primer plus about 25 nucleotides of DNA. It is then replaced by another polymerase, in a step called the pol switch. DNA polymerase **∂** or **ε** then continues synthesizing DNA, depending on the strand - polymerase **ε** on the leading strand and polymerase **∂** on the lagging strand.
- Protein RFC plays the role of clamp loader, while another protein, PCNA acts like the sliding clamp.
- Other DNA polymerases like β, γ and μ function in repairing gaps. Yet others are involved in *trans*-lesion synthesis following DNA damage.
- DNA polymerases have a structure that has been compared to a human right hand. The palm region forms a cleft where the DNA lies and the polymerase activity resides. Here incoming nucleotides are added on to the growing chain. The fingers region positions the DNA in the active site, while the thumb holds the DNA as it exits the polymerase. A separate domain contains the proofreading activity.
- When a mismatched base pair is in the polymerase catalytic site, the 3'end is moved from the polymerase site to the 3' exonu-

clease site. The mispair at the end is removed followed by repositioning of the 3' end in the polymerase active site to continue synthesis.

- In bidirectional, circular bacterial chromosome replication, binding of a protein called Tus, at a Ter (termination) site on the chromosome prevents further movement of the replication fork *at a site opposite the origin) and ends replication.

- There is no fixed site for termination in linear eukaryotic chromosomes. Leading strand synthesis goes all the way to the end of its template strand. On the lagging strand, the RNA primer at the end (needed to start synthesis) creates a challenge. When it is removed, there is a small stretch of the template strand that cannot be copied (no primer). As a result, in each round of replication a short sequence at the ends of linear chromosomes will be lost.

- Over time, chromosomes can become noticeably shorter.

- The ends of linear chromosomes are characterized by structures called telomeres.

- Telomeres contain many copies of short repeated sequences and special proteins that bind to them. Losing some of the repeats does not lead to loss of important coding information. Thus, the repeats act as a buffer zone, where the loss of non-coding sequence does not doom the cell.

- Shortening of the telomeres may act like a clock, with the extent of shrinkage of the chromosomes serving as a measure of aging.

- At the end of a chromosome, the original template strand has a 3' overhang resulting from the removal of the RNA primer across from it. To fill in this region, another primer would be needed, situated past the end of the template strand. But in order to build such a primer, it would be necessary for the template overhang to be longer.

- The parental template strand is extended by the enzyme telomerase, which adds telomere repeats and lengthens the template.

- Telomerase contains a piece of RNA (used as a template) and a reverse transcriptase (used to copy the RNA).

- A reverse transcriptase is an RNA-dependent DNA polymerase (copies an RNA template to make DNA).

- A part of the RNA carried by telomerase can base-pair with the last telomere repeat on the parental DNA strand, while a portion of it remains unpaired. Thus the extended template strand gets replicated.

- After replication, the telomerase can then dissociate, and repeat the process multiple times to add many repeats of the telomere sequence.

- Once the overhang has been extended by the addition of at least several telomere repeats, there is then room for the synthesis of an RNA primer complementary to the newly extended overhang (pointing back towards the rest of the chromosome). The primer can be extended and replication back towards the duplex region results in double stranded chromosomal lengthening.

- This happens in reproductive cells, explaining why each generation does not have shorter chromosomes than the parental generation.

- DNA is found in eukaryotic cells as chromatin. Chromatin contains DNA wrapped around histone protein cores to make nucleosomes. The nucleosomes must be disrupted to make DNA open for replication and restored after replication is completed.
- Ahead of the replication fork, chromatin structure is disassembled by ATP-dependent chromatin remodeling complexes, allowing access to the DNA template.
- After replication, both the original nucleosomes and new nucleosomes must be reassembled behind the replication fork.
- It appears that newly synthesized DNA is packaged into nucleosomes using the original histones that were displaced to allow the replication fork to pass, plus newly synthesized histones
- Post-translational modifications like acetylation, methylation or phosphorylation can regulate the degree to which a given region of the genome is accessible for use.

DNA Repair

- DNA is the master copy of instructions for an organism so it is important not to make mistakes when copying it to pass on to new cells.
- Minor changes in DNA sequence, such as point mutations can sometimes have far-reaching consequences.
- Damage caused by radiation, environmental chemicals or even normal cellular chemistry can interfere with the accurate transmission of information in DNA.
- Not all mistakes are fixed on the fly by DNA polymerases using proofreading.
- Errors that slip by proofreading during replication can be corrected by a mechanism called mismatch repair.
- Mismatch repair scans newly made DNA to 1) identify mispaired bases; 2) remove the region around the mismatch; and 3) correctly fill in the gap created by the excision of the mismatch region.
- A mismatch repair system must have a means to distinguish the newly made DNA strand from the template strand.
- Bacteria identify the parental strand in newly replicated DNA with methylation of GATC sequences.
- DNA adenine methylase (Dam) that adds methyl groups onto the adenines in GATC sequences. Newly replicated DNA has not yet undergone methylation, so can be distinguished from the template strand, which is methylated.
- The mismatch repair proteins selectively replace the strand lacking methylation.
- Mismatch repair proteins are encoded by a group of genes collectively known as the mut genes.
- Mut gene products include MutS (acts to recognize the mismatch and binds to it); MutL (binds to MutS); and MutH (an endonuclease that binds MutS/MutL and cuts the newly synthesized (unmethylated) DNA strand at a GATC.
- DNA helicase and an exonuclease that help unwind and remove the region containing the mismatch. DNA polymerase III

fills in the gap and DNA ligase joins the ends, to restore a continuous strand.

- The eukaryotic mismatch repair system repairs single base mismatches and also insertions and deletions. Human gene homologs (in parentheses) to the *E. coli* mut genes are MutS (hMSH1 and hMSH2) and MutL (hMLH 1). These, together with additional proteins, carry out mismatch repair in eukaryotic cells.

- It is not yet completely understood how the eukaryotic mismatch repair system "knows" which strand to repair.

- DNA that is not being replicated can get damaged or mutated at any time.

- Major causes of DNA damage are 1) radiation (e.g., UV rays in sunlight and in tanning booths, or ionizing radiation); 2) exposure to damaging environmental chemicals, such as nitrosamines or polycyclic aromatic hydrocarbons; and 3) chemical reactions within the cell (such as the deamination of cytosine to give uracil, or the methylation of guanine to produce methylguanine)

- Two adjacent pyrimidine bases one the same strand of DNA can be cross-linked by UV light to form cyclobutane pyrimidine dimers.

- Another type of UV damage is formation of a (6-4) photoproduct

- Ionizing radiation can cause breaks in the DNA backbone, in one or both strands.

- Molecules like benzopyrene can attach themselves to bases, forming bulky DNA adducts in which large chemical groups are linked to bases in the DNA.

- These types of damage can physically distort the DNA, causing DNA and RNA polymerases to stall when they attempt to copy those regions of DNA.

- Other types of chemical alterations don't physically change the shape of DNA, but can favor mispairing during replication. These include deamination of cytosine to uracil or formation of oxidized bases like 8-oxo-guanine or alkylated bases like O^6-methylguanine.

- Many organisms (not humans) contain photolyase enzymes that can repair UV damage. They work work through a process called photoreactivation using blue light energy to catalyze a photochemical reaction that breaks the problem bonds in the damaged DNA.

- O6-methylguanine methyltransferase acts directly to remove the methyl group from the guanine and transfers it onto a cysteine residue in the enzyme. This results in enzyme inactivation, meaning that each enzyme can only be used once.

- There are several different kinds of excision repair, but they all involve cutting out the portion of the DNA that is damaged, followed by repair synthesis using the other strand as template, and finally, ligation to restore continuity to the repaired strand.

- Nucleotide excision repair (NER) fixes damage such as the formation of chemical adducts, as well as UV damage.

- NER proteins cut the damaged strand on either side of the lesion. A short portion of the DNA strand containing the damage is then removed and a DNA polymerase fills in the gap with the appropriate nucleotides.

- Recognition and excision of the damaged DNA in *E. coli* is carried out by a group of proteins encoded by the uvrABC and uvrD genes. uvrA, uvrB and uvrC genes function together as the so-called UvrABC exinuclease. UvrA and UvrB proteins recognize the damage. After they bind, the UvrA dissociates, leaving the UvrB attached to the DNA, where it is then joined by the UvrC protein. UvrB and C then acts to cut the phosphodiester backbone on either side of the damage, creating nicks in the strand about 12-13 nucleotides apart.

- Then uvrD (a helicase) unwinds the region containing the damage, displacing it from the double helix together with UvrBC. The gap in the DNA is filled in by DNA polymerase I and the nick is sealed with DNA ligase.

- Nucleotide excision repair is important in eukaryotes, particularly in the removal of UV damage in humans, since we lack photolyases.

- Mutations in the genes encoding human NER proteins lead to a number of genetic diseases, like Xeroderma pigmentosum, which leaves people extremely sensitive to UV light.

- Nucleotide excision repair operates in two modes- 1) global genomic repair and 2) transcription-coupled repair.

- In global genomic repair, damage is identified by scanning the entire genome for helix distorting lesions.

- In transcription-coupled repair, stalling of the RNA polymerase at a site of DNA damage is what flags nucleotide excision repair.

- Base excision repair (BER) is a repair system dealing with damage that does not typically distort the DNA helix - for example, deamination of cytosine to uracil or the methylation of a purine base.

- In base excision repair a single damaged base is first removed from the DNA, followed by removal of a region of the DNA surrounding the missing base. The gap is then repaired by DNA polymerase and DNA ligase.

- Removal of uracil from DNA is catalyzed by uracil-DNA glycosylase. It recognizes uracil in DNA and breaks the glycosidic bond between the uracil and the sugar in the nucleotide, leaving an apyrimidinic site (AP site).

- Next, an AP endonuclease cuts the strand with the AP site 5' to the AP site and then a DNA polymerase uses its exonuclease and polymerase activities to remove and replace nucleotides around the damage site. DNA ligase seals the strands at the end.

- Double strand breaks (DSB) in DNA are a potentially lethal form of damage that, in addition to blocking replication and transcription, can also lead to chromosomal translocations.

- Two cellular mechanisms exist to help repair DSBs - 1) homologous recombination (HR) and 2) non-homologous end joining (NHEJ).

- Homologous recombination repair commonly occurs in the late S and G2 phases of the cell after chromosome replication.

- Here, a sister chromatid can be used as a template to achieve error-free repair.

- Detection of the double-strand break triggers nuclease activity that chews back one strand on each end of the break, resulting in the production of single-stranded 3' overhangs on each end.

- These single-stranded ends are bound by several proteins, creating a nucleoprotein filament that can then "search" for homologous (matching) sequences on a sister chromatid.

- When homologous sequences are found, the nucleoprotein filament invades the undamaged sister chromatid, forming a crossover and creating heteroduplexes made up of DNA strands from different chromatids.

- Branch migration follows, during which the Holliday junction moves along the DNA, extending the heteroduplex away from the original site of the crossover.

- Branch migration in *E.coli* depends on the activity of two proteins, RuvA and RuvB. RuvC resolves the structure, giving complete, error-free strands.

- Non-homologous end joining (NHEJ) is error-prone. It does not use or require a homologous template to copy, and works by simply chewing back the broken ends of DSBs and ligating them together.

- NHEJ introduces deletions in the DNA as a result.

- Translesion synthesis occurs when a DNA polymerase encounters DNA damage on the template strand, but instead of stalling or skipping past the damage, replication switches to an error-prone mode, ignoring the template and incorporating random nucleotides into the new strand.

- Translesion synthesis depends on proteins encoded by the umuC and umuD genes.

- SOS repair refers to a cellular response to UV damage. It involves activating/ synthesizing a large number of genes necessary for DNA repair.

- Genes activated in SOS repair inclue uvr genes (nucleotide excision repair) and recA (involved in homologous recombination). These can perform error free repair. In addition, the SOS response can also induce the expression of translesion polymerases encoded by the dinA, dinB and umuCD genes.

- All of the genes induced in the SOS response are regulated by two components acting ahead of their coding regions.

- The first is a short DNA sequence upstream of their coding region, called the SOS box.

- The second is a protein, the LexA repressor, that binds to the SOS box and prevents transcription of the downstream genes.

- The presence of single-stranded DNA regions resulting from DNA breaks triggers the activation and binding of RecA proteins to them. Interaction of the activated RecA with the LexA repressor leads to autocleavage of the repressor, which falls off the DNA, allowing the downstream gene(s) to be expressed.

- These are expressed in a specific order - nucleotide excision repair genes, followed by homologous recombination genes. These are both error-free mechanisms for repair.

- If the damage is too extensive to be repaired by these systems, error-prone repair genes are activated as a last resort.

Transcription

- The flow of information from DNA to RNA to protein is the central dogma of molecular biology.
- All cells in a multicellular organism have the same DNA.
- Cells with identical DNA can turn out different because of differences that arise in gene expression.
- Each different cell type uses a different subset of the genes in that DNA to direct the synthesis of a distinctive set of RNAs and proteins.
- The first step in gene expression is transcription.
- Transcription is the process of copying DNA to make RNA.
- Only one of the two DNA strands is copied into RNA.
- Not all of a cells' DNA is copied in transcription. Transcription copies short stretches of the coding regions of DNA to make RNA.
- RNAs are, essentially, temporary copies of the information in DNA and different sets of instructions are copied for use at different times and by different cells.
- The primary RNAs are 1) mRNAs that code for proteins; 2) rRNAS that form part of ribosomes; 3) tRNAs that serve as adaptors between mRNA and amino acids during translation; Small RNAs that regulate gene expression and control splicing, including miRNAs and siRNAs; 4) other small RNAs that have a variety of functions, including the small nuclear RNAs that are part of the splicing machinery; and 5) Long noncoding RNAs (lncRNAs)
- Transcription is catalyzed by an RNA polymerase - there are several different kinds in eukaryotes, but only one in prokaryotes.
- RNA polymerases synthesize new strands only in the 5' to 3' direction using ribonucleotides - ATP, GTP, CTP, and UTP.
- RNA polymerases do not require a primer to make RNA.
- In humans, there are 20,000 to 30,000 genes in each cell.
- Patterns in the DNA sequence indicate where RNA polymerase should start and end transcription.
- The DNA sequence at which the RNA polymerase binds to start transcription is called a promoter.
- The DNA sequence that indicates where the RNA polymerase should stop adding nucleotides and dissociate from the template is known as a terminator sequence.
- The promoter and terminator, thus, bracket the region of the DNA that is to be transcribed.
- The promoter sequence is "before" or "upstream" of the gene - on the side of the gene opposite to the direction of transcription.

- Expression of the gene is dependent on the binding of RNA polymerase to the promoter sequence to begin transcription, so a promoter is said to "control" a gene.
- Common sequence patterns are present in many promoters.
- The transcription start site is the base in the DNA across from which the first RNA nucleotide is paired
- Bacteria have a "-10 sequence" - a 6 bp region centered about 10 bp upstream of the start site. The consensus sequence at this position is TATAAT. In other words, if you count back from the transcription start site, which by convention, is called the +1, the sequence found at roughly -10 in the majority of bacterial promoters studied is TATAAT.
- The -35 sequence is a 6 bp sequence at about 35 basepairs upstream from the start of transcription. The consensus sequence at this position is TTGACA.
- Sequences at -10 and -35 are necessary for recognition of the promoter region by RNA polymerase.
- It is only when the RNA polymerase has stably bound at the promoter that transcription can begin.
- *E. coli* RNA polymerase is made up of a core enzyme of four subunits ($\alpha 2\beta\beta'$) and an additional subunit called the σ (sigma) subunit. The together make up the RNA polymerase holoenzyme.
- The σ subunit helps the core polymerase specifically bind to promoter sequences.
- The initial binding of the holoenzyme at the promoter results in what is called a "closed" complex - DNA has not unwound for transcription to begin.
- The "open" complex is marked by the separation of the DNA strands to create a transcription bubble about 12-14 base-pairs long. The σ subunit is required for the conversion.
- After the open complex has formed, the DNA template can begin to be copied, and the core polymerase adds nucleotides complementary to one strand of the DNA.
- At this stage, known as initiation, the RNA polymerase adds several nucleotides while still bound to the promoter, and without moving along the DNA template.
- Elongation occurs when an RNA of 8-9 bases is made and the enzyme moves beyond the promoter region. When this occurs, the σ subunit is no longer necessary and may dissociate from the core enzyme.
- The core polymerase then can move along the template, unwinding the DNA ahead of it to maintain a transcription bubble of 12-15 base-pairs while copying DNA to make RNA.
- RNA polymerase joins the 5' phosphate of an incoming ribonucleotide to the 3' OH on the last nucleotide of the growing RNA.
- A sequence of nucleotides called the terminator site is the signal to the RNA polymerase to stop transcription and dissociate from the template.
- There are two kinds of terminator - 1) intrinsic terminators, allow termination by

RNA polymerase without the help of any additional factors and 2) rho-dependent terminators, require the assistance of a protein factor called rho (ρ).

- The terminator sequence precedes the last nucleotide of the transcript.
- In intrinsic terminators, the terminator sequence in the RNA has self-complementary regions that can base-pair with each other to form a hairpin structure. It is followed by a single-stranded region that is rich in U's.
- Folding of the end of the RNA into the hairpin causes the RNA polymerase to pause.
- The run of U's at the end of the hairpin permits the RNA-DNA duplex in this region to come apart and the transcript to be released from the DNA template and from the RNA polymerase.
- In rho-dependent termination, an additional protein factor, rho, is necessary for termination.
- Rho is a helicase that separates the transcript from the template it is paired with.
- Rho-dependent termination also requires the formation of a hairpin structure in the RNA that causes pausing of the RNA polymerase.
- Rho binds to a region of the transcript called the rho utilization site (rut) and moves along the RNA till it reaches the paused RNA polymerase where it unwinds the RNA-DNA duplex and releases the transcript and RNA polymerase from the DNA.
- In prokaryotes (but not eukaryotes) mRNA is immediately available to the translation machinery, as the transcript is coming off the template DNA. Translation can begin before the entire gene has been transcribed.
- In eukaryotes, the DNA template exists as chromatin, where the DNA is tightly associated with histones and other proteins
- DNA must therefore be opened up to allow the RNA polymerase access to the template for transcription to occur.
- Eukaryotes have multiple, specialized RNA polymerases.
- RNA polymerase I transcribes the ribosomal RNA genes.
- RNA polymerase II transcribes protein-coding genes to make mRNAs.
- RNA polymerase III copies tRNA genes.
- All eukaryotic RNA polymerases need additional proteins called transcription factors to help get transcription started.
- Transcription happens in the nucleus in eukaryotes, and the mRNAs produced are processed further before they are sent into the cytoplasm for translation.
- Transcription starts about 25 bp downstream of the eukaryotic TATA box, and creates a transcript that begins with a 5' untranslated region (5' UTR) followed by the coding region which may include multiple introns and ending in a 3' untranslated region or 3' UTR.

- Eukaryotic genes also have promoters that determine where transcription will begin.
- Specific sequences in the promoter regions are recognized and bound by proteins involved in the initiation of transcription.
- Eukaryotic promoters commonly have a TATA box (similar to the -10 sequence in prokaryotic promoters) about 25-35 base-pairs upstream of the start of transcription (+1).
- Eukaryotic promoters that lack TATA boxes have, instead, other recognition sequences, known as downstream promoter elements.
- The TATA box is not directly recognized and bound by RNA polymerase II. Instead, this sequence is bound by other proteins that, together with the RNA polymerase, form the transcription initiation complex.
- Other short stretches of sequences within about 100 to 200 base-pairs upstream of the transcription start site affect eukaryotic transcription.
- These upstream elements or promoter-proximal upstream elements, are bound by activator proteins that interact with the transcription complex at the TATA box. Examples include the CAAT box and the GC box.
- General transcription factors are proteins that help eukaryotic RNA polymerases find promoter sites and initiate transcription.
- These transcription factors that assist RNA polymerase II are named TFIIA, TFIIB and so on.
- A complex between general transcription factors and the RNA polymerase at the TATA box is called the basal transcription complex or transcription initiation complex.
- The first step in the formation of the complex is binding by TFIID to the TATA box. TFIID has several proteins, one of which is called the TATA Binding Protein or TBP. Binding of the TBP causes the DNA to bend at this spot and favor binding of additional transcription factors and RNA polymerase.
- Binding of TBP is a necessary step in forming a transcription initiation complex even when the promoter lacks a TATA box.
- The order of binding of additional proteins appears to be TFIIB, followed by TFIIF and RNA polymerase II, then TFIIE. The final step in the assembly of the basal transcription complex is binding of a general transcription factor called TFIIH.
- The presence of all of these general transcription factors and RNA Polymerase II at the promoter is necessary for the initiation of transcription.
- In order for RNA polymerase II to move down the template and elongate the transcript, TFIIH must act. It is a multifunctional protein with a helicase activity and a kinase activity. The kinase activity of TFIIH adds phosphates onto the C-terminal domain of the RNA polymerase II. This phosphorylation by TFIIH appears to be the signal releasing the RNA polymerase II from the transcrip-

tion initiation complex and allow it to move forward on the template.

- For termination, the polyadenylation signal in the 3' UTR of the transcript appears to play a role in RNA polymerase pausing, and subsequent release of the completed primary transcript. Recognition of the polyadenylation signal triggers the binding of proteins involved in 3'end processing and termination.

RNA Processing

- Both prokaryotes and eukaryotes process their rRNAs and tRNAs.
- Prokaryotes and eukaryotes differ in the processing of mRNAs.
- In bacterial cells, the mRNA is translated directly as it comes off the DNA template.
- RNA synthesis in eukaryotes occurs in the nucleus, apart from translation in the cytoplasm.
- After RNA processing in the nucleus, RNAs exported to the cytoplasm are called mature mRNAs.
- The three main processing steps for mRNAs are 1) capping at the 5' end; 2) splicing to remove introns; and 3) addition of a polyA tail at the 3' end.
- There is evidence that some of the processing occurs co-transcriptionally.
- Proteins involved with mRNA processing are associated with the phosphorylated C-terminal domain (CTD) of RNA polymerase II.
- The addition of an mRNA cap at the 5' end is the first step in mRNA processing.
- Capping occurs once the first 20-30 nucleotides of the RNA have been synthesized.
- Addition of the cap involves removal of a phosphate from the 5' nucleotide in the mRNA creating a diphosphate which gets joined to a guanosine monophosphate that is subsequently methylated at N7 of the guanine to form the 7mG cap structure.
- The cap protects the 5' end of the mRNA from degradation by nucleases and also helps to position the mRNA correctly on ribosomes for translation.
- Introns are noncoding regions that interrupt a gene.
- These introns must be removed before the mRNA is sent out of the nucleus to be used to direct protein synthesis.
- Introns are removed from the pre-mRNA by a complex called the spliceosome.
- The spliceosome contains proteins and small RNAs that are associated to form protein-RNA enzymes called small nuclear ribonucleoproteins or snRNPs.
- The splicing machinery recognizes splice junctions (where each exon ends and its associated intron begins) in order to correctly remove the introns and make the mature, spliced mRNA.
- The consensus sequence at the junction of 5' exon-introns (also called the 5' splice site) is AG*GURAGU, where the * indicates the boundary between the end of the exon (on the left) and the beginning of the intron (on the right).

- The 3' splice junction (at the other end of the intron) has the consensus sequence YAGRNNN, where YAG is the end of the intron, and RNNN is the beginning of the next exon. (Y = pyrimidine and N = any nucleotide).

- Another important splicing sequence within the intron, about a hundred nucleotides from the 3' splice site, is called a branch site. It is defined by the presence of an A followed by a string of pyrimidines. This site plays an important role in the mechanism of splicing.

- The first step in splicing is the nucleophilic attack by the 2'OH of the A at the branch point on the 5' splice site (the junction of the exon and the 5' end of the intron). This makes a lariat structure composed of the second exon still linked to the intron sequence.' The intron containing the lariat is completely released in the second step.

- In the second step of splicing, the 3' OH of the first exon (the one freed in the first reaction) attacks the 3' splice site, resulting in the two exons being joined together and the lariat-shaped intron is released in the process.

- Five small RNAs (snRNAs) are crucial to the spliceosome complex. They are U1, U2, U4, U5 and U6 and are found associated with proteins, as snRNPs.

- Components of the splicing machinery associate with the CTD of the RNA polymerase II for improved splicing efficiency.

- The initial step in spliceosome assembly is the interaction of the U1 snRNP with the 5' splice site. This is followed sequentially by binding of U2AF (U2 associated factor) near the branch site; U2 snRNA (to the branch site); and U4/U6 and U5 snRNPs. This creates the pre-catalytic complex.

- Rearrangements displace U4 and U2 snRNPs, resulting in the catalytically active spliceosome. It is this structure that catalyzes the splicing reactions above.

- On average, human genes have about 9 exons each.

- Exons in a pre-mRNA can be spliced together in different combinations to generate different mature mRNAs in a process known as alternative splicing.

- A single mRNA with many exons can, by combining different exons during splicing, create many different protein coding messages.

- Because of alternative splicing, each gene in our DNA gives rise, on average, to three different proteins, which can be made at different developmental stages or in different cell types.

- The 3' end of a processed eukaryotic mRNA typically has a "poly(A) tail" consisting of about 200 adenine-containing nucleotides.

- The poly(A) tail is added by a template-independent enzyme, poly(A)polymerase, following cleavage of the RNA at a site near the 3' end of the new transcript.

- C Components of the polyadenylation machinery are also associated with the phosphorylated CTD of the RNA polymerase.

- The polyA tail plays a role in efficient translation of the mRNA, as well as in the stability of the mRNA.
- The cap and the polyA tail on an mRNA are also indications that the mRNA is complete.
- After these processing events, mRNAs are transported out of the nucleus for translation in the cytoplasm.
- RNA editing is another type of mRNA processing that occurs to some messages and to rRNAs and tRNAs.
- In RNA editing, the sequence of the transcript is altered post-transcriptionally.
- The apolipoprotein B mRNA is one that gets edited.
- The editing here results in the deamination of a cytosine in the transcript to form a uracil, at a specific location in the mRNA, converting the codon at this position, CAA, which encodes a glutamine, into UAA, a stop codon.
- As a result, a shorter version of the protein is made, when the edited transcript is translated.
- Notably, editing of this mRNA occurs in intestinal cells but not in liver cells. Thus, the protein product of the apolipoprotein B gene is longer in the liver than it is in the intestine.
- Mitochondrial RNAs of trypanosome undergoes a different kind of editing in which nucleotides are inserted or deleted. These are specified by guide RNAs that indicate the sites of insertion or deletion.
- Editing changes the properties of proteins made from a transcript and provide another point at which the product of expression of a gene can be controlled.
- tRNAs are synthesized as pre-tRNAs by RNA polymerase III. They must undergo processing to generate mature tRNAs.
- Initial transcripts contain extra RNA sequences at both the 5' and 3' ends and some contain introns. All these extra sequences must be removed from the transcript during processing.
- The 5' end (leader sequence) of the pre-tRNA is cleaved by a catalytic RNA (ribozyme) - an endonuclease called ribonuclease P.
- Extra 3' end sequences (trailer sequence) are later removed by a different nucleases.
- All tRNAs must have a 3' CCA sequence for the charging of the tRNAs with amino acids. In bacteria, this CCA sequence is encoded in the tRNA genes. In eukaryotes, the CCA sequence is added post-transcriptionally by an enzyme called tRNA nucleotidyl transferase.
- Introns in tRNAs are spliced out with the help of a tRNA splicing endonuclease and a ligase.
- Mature tRNAs contain a high proportion of bases other than the usual A,G,C, and U.
- They are produced by chemically modifying the bases in the tRNA to form variants, such as pseudouridine or dihydrouridine. Modifications occur at the final processing step by a variety of specialized enzymes.

- Cells contain many copies of rRNA genes (between 100 and 2000 copies for mammalian cells).

- Each transcription unit contains rRNA sequences coding for 18S, 5.8S and 28S rRNA, and it is transcribed by RNA polymerase I into a single long transcript.

- Sizes of rRNAs are, by convention, indicated by their sedimentation coefficients (Svedberg units, given by the letter S), which is a measure of their rate of sedimentation during centrifugation. Higher values indicate greater mass.

- The primary transcript is first trimmed at both ends by nucleases to give a 45S pre-rRNA.

- Further processing of the pre-rRNA through cleavages is guided by RNA-protein complexes containing snoRNAs (small nucleolar RNAs). This yields the mature 18S, 5.8S and 28S rRNAs.

- rRNAs are also modified on the ribose sugars (methylation and acetylation) and on various alterations to the bases. The modified base pseudouridine is also common in rRNA.

- Modifications may be important in modulating ribosome function.

Translation

- Translation is the process by which information in mRNAs is used to direct the synthesis of proteins.

- Translation occurs in the cytoplasm of cells and is carried out by ribosomes.

- Ribosomes contain ribosomal RNA (rRNA) and proteins organized into a large subunit and a small subunit.

- Ribosomes bind mRNAs and hold them to allow amino acids (carried by tRNAs) encoded by the RNA to be joined sequentially.

- The mRNA sequence, copied from a gene, directly specifies the sequence of amino acids in the protein it encodes.

- Each amino acid in a protein is specified by a sequence of 3 bases called a codon in the mRNA coding for it.

- With the exception of the amino acids methionine and tryptophan, all the other amino acids are encoded by multiple codons - degeneracy.

- Codons for the same amino acid are often related, with the first two bases the same and the third being variable.

- Three of the 64 codons are stop codons - they indicate the end of a protein coding sequence.

- The codon for methionine, AUG, is used as the initiation or start codon for the majority of proteins.

- tRNAs are small RNA molecules, about 75-90 nucleotides long, that function to 'interpret' the instructions in the mRNA during protein synthesis.

- tRNAs are extensively modified post-transcriptionally and contain a large number of unusual bases.

- tRNAs have several self complementary regions, where the single-stranded tRNA folds on itself and base-pairs to form what is

sometimes described as a clover leaf structure.

- tRNAs contain sites for attachment of the appropriate amino acid and for recognition of codons in the mRNA at opposite molecular ends.
- A given tRNA is specific for a particular amino acid - corresponding to the anticodon it carries.
- A tRNA is linked covalently to its specific amino acid at its 3' end by aminoacyl tRNA synthetase, which “reads” the anticodon and attaches the proper amino acid.
- A tRNA with an amino acid attached to it is said to be charged.
- The amino acid sequence of the protein is determined by the order of the codons in the mRNA.
- The RNA sequence is converted into amino acid sequence by the appropriate charged tRNAs’ antiparallel base pairing of their anticodons with the codons in the mRNA. This occurs in special sites in the ribosome.
- Thus, base-pairing of the anticodon of a charged tRNA with the codon on the mRNA is what brings the correct amino acids in to the ribosome to be added on to the growing protein chain.
    - Ribosomes have two sites (P-site and A-site) for binding and positioning charged tRNAs so each can form base pairs between their anticodon and a codon from the mRNA.
- The start codon (AUG) is positioned to base pair with the tRNA in the P-site (peptidyl site).
- Then, the charged tRNA complementary to the second codon binds and occupies the A-site (aminoacyl site).
- The ribosome then joins the amino acids carried on each tRNA by making a peptide bond, leaving the two amino acids attached to the tRNA in the A-site.
- The ribosome then moves one codon further down the mRNA, with the first (empty) tRNA exiting through the E site. The process continues until a stop codon is reached.
- When a stop codon is reached, a release factor binds at the A-site, and helps to free the completed polypeptide from the ribosome and the two ribosomal subunits come apart, releasing the mRNA as well.
- Examining translation more closely, it occurs in three steps - initiation, elongation, and termination.
- In the initiation process, small and large subunits of ribosomes assemble on mRNAs to form complete ribosomes that carry out translation.
- The small subunit of prokaryotic cells is called the 30S ribosomal subunits (40S subunit in eukaryotes). The large ribosomal subunit in prokaryotes is the 50S subunit (60S in eukaryotes).
- rRNA components of ribosomes help to orient the 5’ end of the mRNA, and catalyze formation of peptide bonds.

- mRNAs have non-coding sequences at the 5’ end (5’ UTR) and 3' end (3’ UTR) with the protein-coding region between them.
- The ribosome must recognize the mRNA’s 5' end, bind to it, then determine where the start codon is located.
- Ribosomes assemble at the 5’ end of a transcript by the stepwise binding of the small and large subunits.
- The small subunit binds first at specific sequences in the 5’ UTR. Binding of the first tRNA to the ribosome occurs next and then the large subunit binds to the complex of the mRNA, initiator tRNA, and small subunit, to form the complete ribosome.
- In bacteria, the methionine on the initiator tRNA is modified by the addition of a formyl group, and is designated $tRNA^{fmet}$. it is different from the tRNAs carrying methionine intended for other places in the protein.
- The Shine-Dalgarno sequence in the mRNA helps to properly orient the 5’ end of the mRNA on the small subunit of the ribosome. This happens as a result of complementarity between the Shine-Dalgarno sequence and a separate sequence on the 16S rRNA of the small ribosomal subunit.
- When this pairing occurs, the AUG start codon is properly positioned at the P-site.
- Three initiation factors, IF1, IF2, and IF3 facilitate the initial ribosome/mRNA complex.
- IF3 facilitates binding of the small subunit to the mRNA.
- IF2 brings the initiator tRNA to the partial P-site of the small ribosomal subunit.
- IF1 occupies the A-site, preventing binding of the initiator tRNA at that site.
- Binding of the 50S ribosomal subunit (which occurs next) is accompanied by the dissociation of all three initiation factors.
- Translation initiation in eukaryotes is similar in many ways, but differs in some.
- Eukaryotes have a large number of IFs that are known as eIFs and they together perform the same functions carried out by IFs.
- Binding of the small subunit of the eukaryotic ribosome to the mRNA requires the assistance of eIF2 and eIF3. Next, the small subunit with the initiator tRNA binds to the mRNA’s 7-methyl G cap.
- The 40S subunit then moves along the mRNA, scanning for a proper start codon, since eukaryotes do not have a Shine Dalgarno sequence. They do have a Kozak sequence that includes a few specific bases around the proper AUG.
- After the small subunit is properly positioned, the large subunit binds.
- Elongation of translation in prokaryotes and eukaryotes requires proteins called elongation factors (EFs). EF-Tu (bound to GTP) in bacteria brings the second charged tRNA to the A-site for proper pairing and orientation.
- When the charged tRNA has been loaded at the A-site, EF-Tu hydrolyzes the GTP to GDP and dissociates from the ribosome.

eEF1α.GTP performs the same function in eukaryotes.

- Next, the methionine carried by the tRNA in the P-site is joined to the amino acid carried by tRNA in the A-site, forming a peptide bond.
- The reaction occurs in the ribosomal peptidyl transferase center of the large ribosomal subunit, catalyzed by rRNA components.
- The result of the peptidyl transferase activity is that the tRNA in the A-site now has a dipeptide attached to it, while the tRNA at the P-site has nothing.
- This “empty” tRNA is moved to the E-site on the ribosome, where it exits. The tRNA in the A-site, moves to occupy the vacated P-site, leaving the A-site open for the next incoming charged tRNA.
- EF-G complexed with GTP translocates the ribosome along the mRNA one codon further (in bacteria - eEF2.GTP in eukaryotes), ending one cycle of the elongation phase.
- The elongation cycle repeats until a stop codon appears in the A-site to begin termination.
- In termination, release factors (RFs) recognize the stop codon and cleave and release the newly made polypeptide. In bacteria, RF1 acts when UAG or UAA are in the A-site, whereas RF2 acts when UGA or UAA are in the A-site.
- RF3, works with RF1 and RF2 to hydrolyze the polypeptide from the final tRNA and release the newly synthesized protein. The ribosomal subunits then dissociate.
- The released polypeptide must fold properly in order to function. It may also undergo modifications such as the addition of phosphates, sugars, lipids,and/or may be cleaved by proteases to remove inactivating precursor sequences.
- Proteins made in the cytoplasm must be delivered to the appropriate cellular compartment in which it functions.
- Some proteins are delivered to their destinations in an unfolded state, and are folded within the compartment in which they function. Others are fully folded and may be post-translationally modified before they are sent to their cellular (or extracellular) destinations.
- Some proteins are delivered as they are being synthesized. Others are sent post-translationally. With the exception of cytosolic proteins, all proteins must cross membrane barriers, through membrane channels or other "gates", or by transport within membrane vesicles that fuse with the membrane of the target organelle to deliver their contents.
- Folding of a protein is largely influenced by hydrophobic interactions that position hydrophobic residues in the interior of the protein.
- As a polypeptide emerges from the ribosome, the N-terminal region may begin to fold on itself, with adjacent parts of the chain interacting in inappropriate ways, before the entire protein has been made. This can result in misfolding of the protein and consequent malfunction.
- Protein chaperones bind to and shield regions of polypeptides as they emerge from

the ribosome to keep them from improperly interacting until they can fold properly.

- Some chaperones sequester proteins to permit unfolding and refolding of misfolded polypeptides.

- Protein sorting is the process by which proteins are identified and delivered to a proper compartment.

- Proteins have "address labels" or sorting signals (also called signal sequences) in their amino acid sequences that indicate which cellular compartment they are destined for.

- Signal sequences may be found at the N-terminal or C-terminal region of proteins, or they may be within the amino acid sequence of the proteins.

- Signal sequences targeting proteins to the endoplasmic reticulum, mitochondrion, or chloroplast are at the N-terminus of a protein. Nuclear proteins, by contrast, have the signal internal to the polypeptide.

- Proteins are synthesized by ribosomes in the cytoplasm or by those that associate with membranes temporarily (membrane-bound ribosomes). The latter make proteins that are destined for the nucleus, as well as those going to chloroplasts, mitochondria and peroxisomes.

- Nuclear proteins are delivered in their folded state, while chloroplast and mitochondrial proteins are folded at their destination.

- Proteins destined for the ER, the Golgi apparatus, lysosomes and those that are to be secreted from the cell are first delivered to the ER by ribosomes that associate with the membrane of the rough ER and synthesize the protein directly into the ER.

- All proteins delivered to the ER, regardless of their final destination, have an ER N-terminal signal sequence of 15-30 amino acids.

- If the sequences that emerges first from a ribosome in translation of a protein is an ER signal, it will be recognized and bound by a ribonucleoprotein complex called the Signal Recognition Particle (SRP) and translation will pause.

- The SRP, in turn, is bound by an SRP receptor in the ER membrane, effectively anchoring the ribosome to the membrane.

- When the ribosome is docked over the channel, the SRP releases the signal sequence, which is threaded through the channel, with its hydrophobic residues interacting with the hydrophobic interior of the membrane. Translation resumes at this point and the rest of the protein is delivered into the lumen of the ER as it is made.

- The signal sequence is cleaved off by a membrane associated signal peptidase, releasing the completed protein into the ER lumen.

- Integral membrane proteins differ in that they do not pass all the way through to the lumen, but, instead, are anchored in the membrane of the ER by hydrophobic stop transfer sequences.

- Chaperones in the ER lumen help proteins to fold properly. The ER environment is more oxidizing than the cytosol, and permits the formation of disulfide bonds more readily to stabilize the folded proteins.

- Protein disulfide isomerase in the ER lumen helps to make disulfide bonds and removes bonds that were incorrectly made during folding.
- Proteins in the ER undergo modifications such as glycosylation and addition of glycolipids. Multimeric proteins are also assembled from subunits in the ER.
- Correctly folded and modified proteins are transported in membrane vesicles to their final destinations. Improperly folded proteins are sent back to the cytoplasm to be degraded in proteasomes.

Gene Expression

- Gene expression is the process by which information in DNA directs the production of the proteins needed by the cell.
- The first step in gene expression is transcription.
- The basic mechanism by which transcription is regulated depends on highly specific interactions between transcription regulating proteins and regulatory sequences on DNA.
- Besides the promoter, genes have additional *cis* regulatory sequences that control when it is transcribed.
- Transcriptional regulators are proteins that can recognize DNA sequences and bind to them, affecting transcription.
- In bacteria, genes are often clustered in groups that need to be expressed at the same time. Many are controlled as a single unit (operon) by the same promoter.
- Transcription regulator DNA binding proteins act as either repressors (preventing transcription) or activators (increasing transcription of genes).
- Binding of these proteins to DNA targets is allosterically controlled by the binding of specific small molecules that signal the state of the cell.
- The *lac* operon is a group of coordinately regulated genes that encode proteins needed for the uptake and breakdown of the sugar lactose.
- *E.coli* cells prefer glucose for energy, but if glucose is unavailable and lactose is present, they will take up lactose and use it for energy
- Proteins for utilizing lactose are only needed when glucose is absent and lactose is available. The cells need to express the genes of the *lac* operon only under those conditions.
- The default state of the *lac* operon is OFF.
- A repressor protein that binds to a region of the DNA just downstream of the -10 sequence of the *lac* promoter is the primary regulator of operon's transcription.
- The location on the DNA where the *lac* repressor binds is called the operator.
- The lac repressor's binding here physically blocks the RNA polymerase from transcribing the genes.
- When lactose is present, a small amount of it is taken up by the cells and converted to allolactose, which binds to the lac repressor, changing its conformation so that it no longer binds to the operator.

- When the lac repressor is gone, the roadblock to transcription is gone. Only when lactose is present can transcription of the operon to make proteins to break down lactose be activated. Thus, these genes are not expressed unless they are needed.

- Glucose too is a factor - if it is present, lactose will not be used.

- A second protein involved in *lac* operon regulation is the Catabolite Activator Protein (CAP).

- It binds on the side of the promoter opposite that of the *lac* repressor and its binding is necessary for RNA polymerase to begin transcription of the operon.

- CAP binds to its site only when glucose levels are low.

- When glucose levels are low, adenylate cyclase makes a molecule called cyclic AMP (cAMP), which can bind to CAP. CAP binds to its site ahead of the *lac* promoter only when bound to cAMP. Thus, only when glucose levels are low will CAP bind and favor RNA polymerase to bind and start transcription of the *lac* operon.

- For genes whose default state is ON, they are expressed unless conditions turn the signal OFF. An example is the trp operon. The trp operon makes proteins that allow the cell to synthesize tryptophan. Unless tryptophan is available from the cell's surroundings, the genes in the trp operon are always expressed. When tryptophan is abundant, the trp operon is turned off. This is achieved by a repressor protein that will bind to the operator only in the presence of tryptophan. Tryptophan is a co-repressor of the operon.

- The trp operon has two systems of regulation. The second is called attenuation.

- Attenuation is a process by which the expression of an operon is controlled by termination of transcription before the first gene of the operon.

- This functions as follows: Transcription begins upstream of the first gene in the operon, producing what is termed a 5' leader sequence. This leader sequence contains an intrinsic terminator that can form a transcriptional terminator when high levels of tryptophan are available to the cells. It can also form a different structure that permits continued transcription of the genes in the operon when tryptophan levels are low.

- The 5' end of the mRNA is the first part of the transcript to be made and since bacterial translation is linked to transcription, the 5' end of the RNA begins to be translated before the entire transcript is made.

- The 5' leader sequence of the trp operon mRNA encodes a short peptide that contains two tryptophan codons. When tryptophan is abundant, the leader sequence is easily translated and it forms a transcriptional terminator, which stops transcription immediately - long before the entire transcript is made.

- If tryptophan levels are low, the ribosome stalls at the tryptophan codons. In this case, the leader sequence adopts a different structure that allows transcription to continue.

- Thus, when tryptophan levels are high, transcription of the trp operon is stopped quickly and when tryptophan levels are low, transcription of the complete

operon occurs, allowing the cell to make the proteins necessary to synthesize tryptophan.

- Riboswitches are sequences that can control transcription of the downstream genes based on the conformation they adopt. Two features are important for their function.
- One is a region of the sequence called an aptamer. It folds into a three-dimensional shape that can bind a small effector molecule. The second is an adjacent region of the RNA, called the expression platform. It can fold into different conformations depending on whether or not the aptamer is bound to the effector.
- The guanine riboswitch of bacteria controls the expression of genes required for purine biosynthesis. The aptamer region binds to guanine when levels are high.
- Binding of guanine triggers causes the downstream expression platform to adopt a conformation that terminates transcription of the genes needed for the synthesis of guanine.
- In the absence of guanine, the expression platform assumes a different conformation that allows transcription of the purine biosynthesis genes.
- Thus, when guanine it high, transcription of genes for making guanine is turned off and when guanine is low, transcription of these genes progresses.
- For most eukaryotic genes, general transcription factors and RNA polymerase are necessary but not sufficient for high levels of transcription.
- Distant DNA sequences like the CAAT box and GC box bind proteins that interact with the transcription initiation complex, influencing its formation.
- Enhancers and the proteins that bind to them are needed to achieve high levels of eukaryotic transcription.
- Enhancers are short DNA sequences that regulate the transcription of genes, but may be located a long distance away from the gene they control (upstream, downstream, or within).
- Enhancers work by binding transcriptional activator proteins that can, in turn, interact with the proteins bound at the promoter.
- Transcriptional activator(s) on enhancers can come in contact with the promoter that is a long distance away by looping of the DNA.
- This interaction can assist in recruiting proteins necessary for transcription, like the general transcription factors and RNA polymerase to the promoter.
- Enhancers may also play a role in facilitating the transition of the RNA polymerase to the elongation phase of transcription.
- Enhancers can also affect transcription by recruiting to the promoter proteins to modify the chromatin structure of that region of the chromosome to allow access of transcription proteins to promoters.
- In addition to enhancers, there are also negative regulatory sequences called silencers.

- Silencers bind to transcriptional repressor proteins that interact with the transcription initiator complex and reduce transcription.

- Transcriptional activators and repressors are modular proteins- they have a part that binds DNA and a part that activates or represses transcription through interactions with the transcription initiation complex.

- The DNA binding domain of the protein confers specificity for determining which gene(s) will be activated or repressed (which sequences are bound - usually through the major groove of DNA).

- The activation domain is the part of the protein that stimulates or represses transcription through interactions with the transcription initiation complex.

- Combinatorial regulation provides great versatility, with different combinations of regulatory elements and proteins working together in response to a wide variety of conditions and signals.

- Alternative splicing and editing of transcripts can also modify the proteins that are produced by the cell and thus affect gene expression.

- Another way of affecting gene expression is through histone modification because for a gene to be transcribed, the relevant regions of the chromatin must be opened up to allow access to the RNA polymerase and transcription factors.

- Chromatin remodeling factors assist in reorganizing the nucleosome structure at regions that need to be made accessible.

- Transcriptional activator proteins bound at enhancers, sometimes work by recruiting histone modifying enzymes to the promoter region. Histone acetyl transferase (HAT), for example works to acetylate specific amino acid residues in the tails of the histones forming the nucleosome core.

- Acetylation of histones may be responsible for loosening interactions between histones and DNA in nucleosomes and help to make the DNA more readily accessible for transcription.

- Histone deacetylases which remove acetyl groups from the tails of the histones in the nucleosome may reverse the activation by leading to tighter packing of the chromatin.

- Other enzymes may add or remove methyl groups, phosphate groups, and other chemical moieties to specific amino acid side chains on the histone tails. The patterns of these covalent modifications are called the histone code.

- Histone methyltransferases are “writers” that add the chemical groups on to the histone tails. Other enzymes, like the histone demethylases, may act as "erasers", removing the chemical groups added by the "writers".

- “Readers” are proteins that bind to specific combinations of the modifications and assist in either silencing gene expression in the vicinity or making the region more transcriptionally active.

- Gene expression can also be regulated by methylation of DNA.

- DNA methyltransferases (DNMTs) catalyze the covalent addition of a methyl group to C5 of cytosines in DNA.

- In vertebrates, cytosines that are methylated are generally next to a guanine (referred to as CpG).

- Methylation of DNA seems to correlate with gene silencing while demethylation is associated with increased transcription

- Methylation might block the binding of proteins necessary for transcription or the binding of transcriptional activators at enhancers. Proteins that bind to methylated CpG sites also seem to interact with histone deacetylases - favoring tighter packing of chromatin and less access for transcription proteins to DNA.

- MicroRNAs (miRNAs) and Short Interfering RNAs (siRNAs) are small, non-coding RNAs that act at the post-transcriptional level to regulate gene expression.

- They appear to silence genes by base-pairing with target mRNAs and marking them for degradation, or by blocking their translation.

- The functional forms of both miRNAs and siRNAs are from 20-30 nucleotides long and are derived by processing from longer primary transcripts.

- miRNAs are transcribed from specific genes by RNA polymerase II. The primary transcript, known as a pri-miRNA folds on itself to form double-stranded hairpin structures that are cleaved by the Drosha RNase in the nucleus to about 60-70 nucleotides (pre-miRNAs). These are exported to the cytoplasm where the enzyme known as Dicer cuts them to

- 20-30 nucleotides are the sizes of mature double-stranded miRNAs. The RNAs contain loops and mismatches.

- siRNAs also derive from double-stranded RNAs, but they may arise from either endogenous or exogenous (viral) sources

- These double-stranded RNAs are also processed in the cytoplasm by Dicer to generate mature miRNAs - 20-30 nucleotide double-stranded RNAs. Mature siRNAs are perfectly base-paired along their lengths.

- Both miRNAs and siRNAs then are assembled with Argonaute proteins to form a silencing complex called RISC (RNA-induced silencing complex).

- One strand of each of these double-stranded RNAs is referred to as the guide RNA, while the other is called the passenger RNA.

- During the process of loading the RNA onto the Argonaute protein, the guide strand of the RNA remains associated with the protein, while the passenger strand is removed.

- The guide RNA associated with the Argonaute protein is the functional gene silencing complex.

- Sequence specific base-pairing of the guide RNA with a complementary mRNA sequence leads to either the degradation of the mRNA by the Argonaute protein (in the case of the siRNAs) or in suppression of translation of the mRNA (for miRNAs).

- The expression of at least a third of all human genes has already been shown to be modulated by miRNAs.

- Long noncoding RNAs (lncRNAs) are RNAs of greater than 200 nucleotides that do not code for proteins. Some come from introns or antisense transcripts of coding genes. Others from intergenic sequences. The last ones are called lincRNAs.

- lncRNAs appear to affect gene expression by 1) modification of chromatin structure, 2) regulation of splicing, 3) serving as structural scaffolds for the assembly of nucleoprotein complexes or 4) other unknown ways.

- Gene expression can also be regulated by mechanisms that alter the rate of mRNA degradation.

- Regulation of translation is used to control the production of many proteins. Examples are ferritin and the transferrin receptor.

- Ferritin is an iron-binding protein that sequesters iron atoms in cells to keep them from reacting. When iron levels are high, there is a need for more ferritin than when iron levels are low.

- The 5'UTR of the ferritin mRNA contains a sequence called the Iron Response Element (IRE). When iron levels are low, the IRE is bound by a protein. The presence of the IRE-binding protein at the 5'UTR blocks translation of the ferritin mRNA. When iron levels are high, it binds to the IRE-binding protein, which undergoes a conformational change and dissociates from the IRE. This frees up the 5' end of the ferritin mRNA for ribosome assembly and translation, producing more ferritin.

- The transferrin receptor is required for uptake of iron into cells - when intracellular iron levels are low. It is only when iron levels are low that more transferrin receptor is needed.

- The mRNA encoding the transferrin receptor also has multiple IRE sequences in the 3'UTR of the transcript.

- When cell iron levels are high, the iron binds the IRE-binding protein, which dissociates from IRE, leaving the 3'UTR susceptible to attack by RNases and to degradation of the transferrin receptor mRNA.

- When iron levels are low, the IRE-binding protein remains bound to the 3' UTR of the mRNA, stabilizing it and permitting more transferrin receptor to be made by translation.

Signaling

- Cells must know when to divide, when to undergo apoptosis (programmed cell death), when to store food, and when to break it down.

- Signaling is dependent on molecular recognition.

- In signaling, a molecule, sent by a signaling cell, is recognized and bound by a receptor protein in (or on the surface of) a target cell.

- Signals may be proteins, short peptides, lipids, nucleotides or catecholamines, to name a few.

- Signal molecules that are small and hydrophobic can cross the cell membrane and bind a receptor inside the cell.

- Signal molecules that are charged, or very large, are not be able to diffuse through the plasma membrane and need receptors on the cell surface - usually transmembrane proteins.

- In the transmembrane receptor proteins, the extracellular portion binds the signal and an intracellular part passes on the message within the cell.

- Different cells have different sets of receptors, so they respond to different signals or combinations of signals.

- Binding of a signal molecule to a receptor sets off a chain of events (called signal transduction) in the target cell that include, but are not limited to, alterations in metabolic pathways or gene expression.

- Signal transduction pathways all have some features in common - 1) binding of a signal to its receptor is usually followed by the generation of a new signal(s) within the cell; 2) most have multiple steps involving a series of molecular messengers that amplify and distribute the message to various parts of the cell; and 3) the last of the messengers usually interacts with a target protein(s) and changes its activity, often by phosphorylation.

- When a signal sets a particular pathway in motion, it is acting like an ON switch. This means that once the desired result has been obtained, the cell must have a mechanism that acts as an OFF switch.

- The simplest and fastest of signal pathways are where receptors are gated ion channels.

- Each ion channel is specific to the passage of a particular ionic species. Gates are opened by the binding of an incoming signal (ligand) to the receptor, allowing the almost instantaneous passage of millions of ions from one side of the membrane to the other.

- Changes in the interior environment of the cell are thus brought about in microseconds and in a single step.

- This type of swift response is seen in neuromuscular junctions, where muscle cells respond to a message from the neighboring nerve cell.

- Nerve cells release a neurotransmitter signal (acetylcholine, for example) into the synaptic cleft. It diffuses rapidly till reaching receptors on the membrane of the muscle cell. Its binding causes the gate in the ion channel to open, resulting in ion flow that immediately changes the membrane potential of the cell. This, in turn, can trigger other changes in the cell.

- Sensory neurons carry information to the brain. Motor neurons send signals to muscles.

- Receptors for signals like steroid hormones are part of a large group of proteins known as the nuclear hormone receptor superfamily.

- They recognize and bind not only steroid hormones, but also retinoic acid, thyroid hormone, and vitamin D.

- Nuclear hormone receptors that bind steroid hormones are intracellular proteins.
- Steroid hormones are able to cross the cell membrane by themselves.
- Inside the cell, steroid hormones bind to their receptors, which may reside in the cytoplasm or in the nucleus.
- Steroid hormone receptors are transcriptional regulating proteins that are inactive till a steroid hormone binds and causes a conformational change in them. Receptors, with the hormone bound, bind to regulatory sequences in DNA and regulate gene expression.
- Responses to steroid hormones are slow, since gene expression is a relatively slow process.
- Steroid receptors have a DNA-binding domain (DBD), an activation domain, and a ligand binding domain for the hormone.
- Glucocorticoid receptors are examples.
- In the absence of the signal, glucocorticoid receptors are bound to a protein chaperone, Hsp90, which keeps the receptors from moving to the nucleus.
- Binding of a glucocorticoid molecule causes it to undergo a conformational change, dissociate from the Hsp90, and translocate into the nucleus.
- There it increase the transcription of target genes by binding to specific regulatory sequences (called HRE for hormone-response elements).
- Binding of the hormone-receptor complex to the regulatory elements of hormone-responsive genes modulates their expression. Many such genes encode anti-inflammatory proteins, thus causing the physiological effect of corticosteroid therapies.
- Most other signaling pathways involve multiple steps in which the original signal is passed on and amplified through a number of intermediate steps.
- G-protein coupled receptors (GPCRs) are involved in responses of cells to many different kinds of signals, from epinephrine, to odors, to light.
- GPCRs are cell surface receptors that pass on signals they receive with the help of guanine nucleotide binding proteins (a.k.a. G-proteins).
- GPCRs all have the same basic structure - a single polypeptide chain that threads back and forth seven times through the lipid bilayer of the plasma membrane (called 7TMs).
- One end of the polypeptide forms the extracellular domain that binds the signal. The other end is in the cytosol of the cell.
- Binding of a a ligand (signal) causes the receptor to undergo a conformational change on its cytoplasmic side allowing it to interact with a G-protein which then passes the signal on to other intermediates in the signaling pathway.
- G-proteins are associated with the cytosolic side of the plasma membrane, where they interact with the tail of the GPCR

- All G-proteins share a characteristic structure- they are composed of three subunits called α, β and γ.

- The guanine nucleotide binding site is on the α subunit of the G-protein. It can bind GDP or GTP. It also has a GTPase activity to convert GTP to GDP.

- In the absence of a signal bound to GPCR, G-proteins are in the trimeric form (α-β-γ bound together) and the α subunit has a GDP molecule bound to it. In this form, the α subunit is inactive.

- Binding of a signal molecule by the extracellular part of the GPCR causes its cytosolic tail alter the conformation of a G-protein on the inner face of the plasma membrane. The α subunit then swaps GDP for GTP and it splits into the GTP-bound α part and the β-γ part.

- The now activated α subunit can diffuse freely along the cytosolic face of the plasma membrane and act upon its targets.

- G-proteins interact with different kinds of target proteins.

- Some targets for G-proteins are gated ion channels. The change in the distribution of ions across the plasma membrane causes a change in the membrane potential.

- G-proteins also interact and affect the activity of specific enzymes. The change in activity of the target enzyme resulting from G-protein interaction causes downstream changes in other proteins in the cell, and alters the metabolic state of the cell.

- An example is binding of epinephrine (a catecholamine signal), mediated through the **β**-adrenergic receptor (GPCR).

- In response to stressful stimuli, epinephrine is secreted into the blood, to be carried to target organs whose cells will respond to this signal.

- Binding of epinephrine to the **β**-adrenergic receptor causes the receptor to activate a G-protein with its cytoplasmic tail. This leads to the α subunit exchanging its GDP for GTP and dissociating from the β-γ subunits. The activated α subunit then interacts with the enzyme adenylate cyclase, stimulating it to produce cyclic AMP (cAMP) from ATP.

- cAMP is a second messenger. It binds to an enzyme, protein kinase A (PKA). Upon binding of cAMP, the catalytic subunits of PKA are released from the regulatory subunits, allowing the latter to carry out their function - phosphorylating other proteins.

- One protein activated by PKA is the enzyme, phosphorylase kinase, which can then activate glycogen phosphorylase, the enzyme ultimately responsible for breaking glycogen down into glucose-1-phosphate, a molecule that can readily be converted to glucose.

- So, epinephrine binding ultimately increases glucose concentration, providing energy to escape dangerous situations.

- Simultaneously, PKA also phosphorylates the enzyme glycogen synthase, inactivating it, and preventing free glucose from being used up for glycogen synthesis, thus ensuring cells are amply supplied with glucose they can use.

- Amplification of the signal occurs at every step of the pathway - binding of one epinephrine molecule to its receptor results in the activation of a million glycogen phosphorylase enzyme molecules.

- Turning off of the GPCR signal involves several actions.

- First, G-protein receptor kinase phosphorylates the cytoplasmic tail of the receptor. The phosphorylated tail is then bound by a protein called arrestin, preventing further interaction with a G-protein.

- Second, the α subunit of the G-protein's GTPase activity enables it to hydrolyze the GTP it carries to GDP, causing it to reassociate with the β-γ part and become inactive again.

- Third, cAMP is broken down by an enzyme called phosphodiesterase. When cAMP levels drop, PKA returns to its inactive state, putting a halt to the changes brought about by the activation of adenylate cyclase by an activated G-protein.

- Receptor tyrosine kinases (RTKs) are part of other signaling systems. They are cell surface receptors with tyrosine kinase activity (phosphorylate tyrosine side chains).

- The ligand binding domain of the receptor tyrosine kinase is on the cell surface, while the tyrosine kinase enzymatic activity is in the cytoplasmic part of the protein. A transmembrane α helix connects these two regions.

- Binding of signal molecules to the extracellular domains of two receptor tyrosine kinase proteins causes them to dimerize (come together and associate). It also causes the tyrosine kinase activity of their tails to be turned on and they phosphorylate tyrosine residues in each other (autophosphorylation).

- This phosphorylation triggers the assembly of an intracellular signaling complex on the tails since the phosphorylated tyrosines serve as binding sites for a variety of signaling proteins.

- RTKs mediate responses to a large number of signals, including peptide hormones like insulin and growth factors like epidermal growth factor (EGF).

- Insulin increases glucose uptake by cells by stimulating the movement of glucose receptor GLUT4 to their plasma membranes.

- Binding of insulin to the insulin receptor (IR), results in dimerization of the receptor monomers and subsequent autophosphorylation of the cytosolic kinase domains. The activated tyrosine kinase domains also phosphorylate intracellular proteins called Insulin Receptor Substrates or IRS proteins.

- These proteins interact with, and activate PI_3-kinase which then catalyzes the formation of the molecule PIP_3, which activates yet another kinase, PDK_1, which in turn, activates the Akt group of kinases. It is this group of enzymes that appears to increase the translocation of the GLUT4 to the plasma membrane, as cells that lack functional Akts exhibit poor glucose uptake and insulin resistance.

- Epidermal growth factor (EGF) is an important signaling molecule involved in growth, proliferation and differentiation in mammalian cells. EGF acts through the

EGF receptor, EGFR, a receptor tyrosine kinase.

- EGF binding to the EGFR is followed by receptor dimerization and stimulation and autophosphorylation of the tyrosine kinase domains of the cytosolic domains of the EGFR. This is followed by assembly of a signaling complex nucleated by the binding of proteins that recognize phosphotyrosine residues.
- An important protein activated by the EGFR signaling complex is called RAS. RAS is a monomeric guanine nucleotide binding protein associated with the cytosolic face of the plasma membrane. Like the α subunit of a G-protein, RAS is active when GTP is bound to it and inactive when GDP is bound to it. Also, like the α subunit, RAS can hydrolyze the GTP to GDP.
- Activation of RAS accompanies the exchange of the GDP bound to the inactive RAS for a GTP. Activated RAS then triggers a phosphorylation cascade of three protein kinases (MAP kinases), which relay and distribute the signal.
- The final kinase in the cascade phosphorylates enzymes (alters activities) and transcriptional activators (alters gene expression).
- To turn off RTK signaling, several steps are involved.
- First, RTKs with the signal bound can be endocytosed into the cell and broken down.
- Second, RAS, which is activated by GTP binding, can be deactivated by its hydrolysis of GTP to GDP. Cells that have a mutant Ras gene make RAS proteins with defective GTPase activity that can't shut off RAS. These cells continue to receive a signal to proliferate. More than 30% of human cancers are driven by mutations in Ras genes.
- Binding of EGF to its receptor triggers a signaling pathway that results in the activation of a series of Mitogen Activated Protein Kinases (MAP kinases).
- The final kinase in the MAP kinase cascade phosphorylates a number of target proteins, many of them transcription factors, that when activated, cause cell proliferation.
- Malfunctions in EGF pathway lead to uncontrolled cell proliferation, or cancer.
- The human EGF receptor (HER) family has four members, HER1, HER2, HER3 and HER4 - all receptor tyrosine kinases.
- A crucial step in the signal transduction pathway is the dimerization of the receptors following binding of the signal, EGF, to the receptor.
- The structure of the HER2 receptor allows the receptor monomers to dimerize independently of EGF binding.
- Thus, downstream events of the signaling pathway can be triggered even in the absence of a growth signal.
- In normal cells, only a few HER2 receptors are expressed at the cell surface, so this property of HER2 plays a relatively minor role in stimulating cell division.
- However, overexpression of HER2 leads to increased dimerization and subsequent uncontrolled cell proliferation.

- Herceptin, a monoclonal antibody against the HER2 receptor, has been shown to be an effective treatment against Her2-positive breast cancers.
- Herceptin works by binding specifically to the extracellular domain of the HER2 receptor preventing dimerization of the receptor and thus blocks downstream signaling.
- Additionally, the binding of the Herceptin antibody to the receptor acts signals the immune system to destroy the HER2-positive cells.
- Defects in an RTK signaling pathway lead to chronic myeloid leukemia (CML).
- Patients with CML have an abnormal receptor tyrosine kinase that is the product of a hybrid gene called bcr-abl, formed by the breakage and rejoining of chromosomes 9 and 22.
- The abnormal tyrosine kinase formed is constitutively dimerized, even when there is no signal to bind. As a result, it continuously signals cells to divide, leading to the massive proliferation of a type of blood cells called `.
- The approach to treating CML is to target the tyrosine kinase domain of the receptor.
- In the case of the bcr-abl RTK, the drug Gleevec (imatinib) was designed to bind near the ATP-binding site of the tyrosine kinase domain. This "locks" the site in a conformation that inhibits the enzymatic activity of the tyrosine kinase and thus blocks downstream signaling. With no "grow" signal passed on, cells stop proliferating.

Point by Point: Techniques

Techniques

- The traditional approach used for the study of biochemistry is to isolate molecules, enzymes, DNAs, RNAs, and other items of interest so they can be analyzed independently of the millions of other processes occurring simultaneously.
- To separate compounds from cellular environments, one must first burst open (lyse) the cells. There are several ways to do this. Variables to consider include 1) sample size; 2) number of samples; 3) toughness of cells; 4) disruption efficiency; and 5) stability of material being isolated.
- Lysis methods include lowering the ionic strength of the media cells are kept in - can cause cells to swell and burst. Mild surfactants may improve the efficiency.
- Most bacteria, yeast, and plant tissues are resistant to osmotic shocks, however, and stronger disruption techniques are usually required.
- The enzyme lysozyme is very useful for breaking down bacterial walls. Other enzymes commonly employed include cellulase (plants), proteases, and mannases.

- Mechanical agitation may be employed in the form of beads shaken with cells.

- Sonication (20-50 kHz sound waves) provides an alternative type of agitation that can be effective, but it generates heat that can be problematic for heat-sensitive compounds.

- The “cell bomb” method involves placing cells under very high pressure (up to 25,000 psi) and then releasing it rapidly. The rapid pressure change causes dissolved gases in cells to be released as bubbles which, in turn, break open cells.

- Cryopulverization is often employed for samples having a tough extracellular matrix, such as connective tissue, seed, and cartilage. In this technique tissues are frozen with liquid nitrogen and then impact pulverization is performed.

- Whatever method is employed, crude fractions obtained from it must be further processed via fractionation.

- Fractionation of samples is typically initiated with steps involving centrifugation. Using a centrifuge, one can remove cell debris, and fractionate organelles, and cytoplasm.

- Depending upon where in the cell a desired compound is found, it can be collected in a tube along with a multitude of other cellular products using different speeds to precipitate different components.

- Separating the item of interest from the milieu of other materials is where chromatography comes into play.

- Chromatography is commonly performed in columns. Materials performing the separation are called supports and they are commonly contained within columns through which a buffer/solvent containing the items to be separated flows.

- Molecules in the sample interact differentially with the support and travel through it consequently at different speeds, thus enabling separation.

- In ion exchange chromatography, the support consists of tiny beads to which are attached chemicals possessing a charge. Each charged molecule has a counterion that can be replaced by a similarly charged molecule in the sample.

- A cation exchange resin has a negative molecule on the support and a positive counterion. Positively charged sample molecules will be attracted to the negatively charged support molecule and replace (exchange) with the positive counterion.

- Negatively charged and neutrally charged sample molecules will not be attracted to the support molecules and will quickly pass through the column.

- The positively charged molecules “stuck” to the column can be eluted with an excess of positively charged counterion.

- Anion exchange chromatography has the same principle, except that the support has a positive charge, the counterions are negatively charged, and the molecules retained by the resin are negatively charged.

- Size exclusion chromatography (also called molecular exclusion chromatography, gel exclusion chromatography, or gel filtration chromatography) is a low resolution isolation method that employs support beads with tiny “tunnels” in them that each have a precise opening.

- The size of the opening is referred to as an "exclusion limit," which means that molecules above a certain molecular weight will not typically fit into the tunnels.
- Molecules with physical sizes larger than the exclusion limit do not enter the tunnels and pass through the spaces between the beads and exit column relatively quickly. Smaller molecules take a longer path through the column because they pass through both the beads and the spaces between the beads.
- Affinity chromatography exploits the binding affinities of sample molecules for substances covalently linked to the support beads.
- To separate all of the proteins in a sample that bound to ATP from proteins that do not bind ATP, one could covalently link ATP to support beads and then elute the sample through a column of these beads.
- All proteins that bind ATP will "stick" to the column, whereas those that do not bind ATP will pass quickly through it. The proteins are then released from the column by adding ATP.
- Histidine tagging (his-tagging) is a special kind of affinity chromatography
- It relies on altering the DNA coding region for a protein to fuse a series of at least six histidine residues at one end of it (carboxyl or amino terminus) to the amino acids in the remainder of the protein.
- The segment of histidine side chains will bind to nickel or cobalt ions. By passing the sample mixture through a column with nickel or cobalt attached to beads allows the his-tagged proteins to "stick," while the remaining cell proteins all pass quickly through.
- The his-tagged proteins are then eluted by addition of imidazole (same structure as histidine side chain) to the column.
- Histidine tags can be cleaved off of the purified protein by treatment with a protease that excises the added histidines.
- High performance liquid chromatography (HPLC) is a powerful tool for separating smaller molecules based on their differential polarities.
- HPLC employs columns with tightly packed supports and very tiny beads such that flow of solvents/buffers through the columns requires high pressures.
- The supports used in HPLC can be polar (normal phase separation) or non-polar (reverse phase separation).
- In normal phase separations, non-polar molecules elute first followed by the more polar compounds. This order is switched in reverse phase chromatography.
- Separation methods for large molecules, such as DNA, RNA, and proteins use charge and size as means of separating them.
- For DNA and RNA, this is trivial, as the length of the nucleic acid is proportional to the charge coming from the phosphate backbone.
- The charge of proteins varies enormously and is not a function of the size of the protein.

- To use charge and size as a basis of protein separation, they are denatured, disulfide bonds are cleaved, and the protein is treated with a detergent (SDS) coats it and gives it uniform negative charge (SDS is negatively charged).

- Treated in this way, proteins have a size that is related to their charge - longer proteins have more SDS and more charge. Shorter ones have less SDS and less negative charge.

- Separating DNA and RNA molecules is usually accomplished using gel electrophoresis.

- Agarose gel electrophoresis is a technique used to separate nucleic acids. Agarose is a polysaccharide that provides a matrix which encases a buffer. The matrix provides openings for macromolecules to move through and the largest macromolecules have the most difficult time navigating through the matrix, whereas the smallest macromolecules slip through it the fastest.

- Electrophoresis uses electricity as a force to move molecules through the matrix. This is why they must be charged.

- Since the size to charge ratios for DNA and RNA are constant for all sizes of these nucleic acids, the size per force is also constant (since force is directly proportional to charge), so the molecules simply sort on the basis of their size - the smallest move fastest and the largest move slowest. Visualization of the DNA fragments is enabled by addition of a dye, such as ethidium bromide with viewing under ultraviolet light.

- Polyacrylamide is the support material used to separate proteins and small nucleic acids. To make it for a gel, monomeric acrylamide is polymerized and the polymers are cross-linked using N,N'-Methylene-bisacrylamide to create a mesh-like structure. One can adjust the size of the openings of the matrix/mesh by changing the percentage of acrylamide in the reaction. Higher percentages of acrylamide give smaller openings and are more effective for separating smaller molecules, whereas lower percentages of acrylamide reverse that.

- A small "stacking gel" may be employed at the top of a polyacrylamide gel to provide a way of compressing the samples into a tight band before they enter the main polyacrylamide gel (called the resolving gel).

- The buffer and sample for polyacrylamide gel electrophoresis (PAGE) contains SDS and mercaptoethanol, as noted above, to denature and give the proteins a uniform charge per size. The resulting technique is called SDS-PAGE.

- Just like DNA fragments in agarose gel electrophoresis get sorted on the basis of size (largest move slowest and smallest move fastest), the proteins migrate through the gel matrix in an electric field at velocities inversely related to their size.

- Proteins can be visualized on the gel by staining with Coumassie Brilliant Blue or silver nitrate (50 times more sensitive).

- Separating proteins by isoelectric focusing requires establishment of a pH gradient in a tube containing an acrylamide gel matrix. The matrix's pores are adjusted to be large to avoid size separations.

- When the matrix is placed in an electric field, positively charged molecules, for example, move towards the negative electrode, but since they are traveling through a pH

gradient, as they pass through it, their charge changes and they ultimately reach a pH region where their charge is zero. At that point, their pI, they stop moving. Using isoelectric focusing, it is possible to separate proteins whose pI values differ by as little as 0.01 units.

- SDS-PAGE and isoelectric focusing are combined in the technique of 2-D gel electrophoresis - a powerful tool of proteomics. The method has two steps. First, proteins are separated in a tube by isoelectric focusing. Then the tube is treated with SDS and laid on top of a polyacrylamide gel and SDS-page is performed. The first separation is on the basis of pI and the second is on the basis of size.

- The power of 2-D gel electrophoresis is that virtually every protein in a cell can be separated and appear on the 2-D gel array as spots.

- For cancer analysis, comparison a 2-D plot of proteins from a non-cancerous tissue with proteins from a cancerous tissue of the same type provides a quick identification of those proteins whose level of expression differs between the the different tissues.

- Working with intact proteins in analytical techniques, such as mass spectrometry, can be problematic.

- Consequently, it is often desirable to break a large polypeptide down into smaller pieces.

- Proteases are enzymes that (typically) break peptide bonds by binding to specific amino acid sequences in a protein and catalyzing their hydrolysis.

- Chemical reagents can also be used. A protein sample treated with cyanogen bromide, for example will have fragments of proteins each one terminating at a methionine, since cyanogen bromide breaks proteins uniformly at that amino acid.

- Fluorescence Recovery After Photobleaching (FRAP) is used to measure the two dimensional lateral diffusion of molecules in thin films, like membranes, using fluorescently labeled probes.

- In the method, a lipid bilayer is uniformly labeled with a fluorescent tag and then a portion of the tag is bleached using a laser. The spread of the bleached molecules is followed using a microscope. Information obtained in this manner provides data about the rate of lateral diffusion occurring in a lipid bilayer.

- Fluorescence resonance energy transfer (FRET - also called Förster resonance energy transfer, resonance energy transfer (RET) or electronic energy transfer (EET)) is a method for determining interactions between biomolecules.

- In the technique, a donor chromophore or an acceptor chromophore is covalently attached to separate molecules of interest. The acceptor chromophore is designed to accept energy through from the donor molecule and fluoresce at a unique wavelength when it receives that energy from the donor. Only if the proteins containing the donor and acceptor chromophores are physically close in the cell will the unique fluorescence resulting from the transfer occur and be detected.

- Microarrays employ a matrix of “boxes” on a glass slide containing support materials, each box containing thousands of copies

of the same support material covalently linked to the slide. For DNA/RNA microarrays, the support materials would be short sequences of nucleic acid. The position of each set of materials on the grid is known.

- To the slide matrix are added sample molecules that recognize and bind specifically to the support materials. Binding between the sample molecules and support materials occurs by base pairing, for example in the case of DNA or RNA. The slide is washed to remove sample molecules not specifically bound to the support materials.

- Consider a matrix containing all of the known mRNA sequences of a genome. Each box of the grid would contain the sequence from one gene. With this grid, one could analyze the transcriptome - all of the mRNAs being made in selected cells. For a simple analysis, one could take a tissue (say liver) and extract the mRNAs from it. Each sample mRNA can easily be tagged with a color (blue, for example) and then the mixture of tagged mRNAs would added to the matrix on the slide and base pairing conditions are created to allow each mRNA molecule to find and base pair with its complementary sequence on the matrix.

- The matrix is then washed to remove unhybridized mRNAs. The presence/absence/abundance of each mRNA is then readily determined by measuring the amount of blue dye at each box of the grid.

- Such analyses can also be performed with two different sets of mRNAs, each one marked with a different dye color. One set of mRNAs could come from a cancerous tissue (red) and the other from a non-cancerous tissue (green), for example. The mRNAs are mixed and then added to the matrix and complementary sequences are once again allowed to form duplexes, followed by washing of unhybridized mRNAs.

- On analysis, red grid boxes correspond to mRNAs present in the cancerous tissue, but not in the non-cancerous tissue (Figure 7.23 and 7.24). Green grid boxes correspond to mRNAs present in the non-cancerous tissue, but not in the cancerous tissue. Yellow would correspond to mRNAs present in equal abundance in the two tissues. The intensity of each spot also gives information about the relative amounts of each mRNA in each tissue.

- Blotting provides a means of identifying and quantitating specific molecules in of a mixture. A sample is collected and the mixture of molecules is separated by gel electrophoresis. The mixture could be DNA, RNA, or protein and the gel could be either agarose (DNA/RNA) or polyacrylamide (protein).

- After the gel run is complete, the material in the gel is transferred onto a membrane/paper that physically binds to the material.

- The composition of the material that is blotted gives rise to different blot names. Analysis of DNA by this method is known as a Southern Blot (named for the person who invented it). Analysis of RNA is called a Northern Blot and analysis of protein is called a Western Blot.

- The blotting membrane may be treated by UV light, heating, or chemicals to make covalent bonds between the membrane and the material on it.

- Next, a visualizing agent called a labeled probe that is specific for the molecule of interest in the mixture is added to the membrane.

- Labeled probes are designed to be complementary to (DNA/RNA) or have binding affinity for (proteins) the desired target sequence bound to the membrane.

- Binding of the probe to the target sequence allows one to determine 1) if target sequence was in the sample and 2) an estimate of abundance of the target sequence based on the intensity of the probe binding.

- Labels in probes can be radioactive or chemical reagents that give colored light. For DNA/RNA, a probe might be a complementary nucleic acid sequence that is labeled in some fashion (^{32}P in DNA, for example).

- For a protein, a probe would typically involve an antibody that specifically binds to the target protein of interest. Protein analysis usually employs two antibodies and the first one is not labeled. The label is on the second antibody, which is designed to recognize only the first antibody in a piggyback fashion. The first antibody specifically binds to the protein of interest on the blot and the second antibody recognizes the first antibody.

- The second antibody commonly carries an enzyme or reagent which can cause a reaction to produce a color upon further treatment. So, if the molecule of interest is in the original mixture, it will "light" up and reveal itself. The utility and importance of restriction enzymes for making recombinant DNAs lies in their ability to recognize sequences in DNA and cut near or (usually) at the site they recognize. Over 3000 such enzymes are known. Sequences recognized by these enzymes are typically 4-8 base pairs long and the most commonly used enzymes recognize sequences described as palindromic.

- Restriction enzymes recognize sequences (typically 4-8 palindromic base pairs) in DNA and cut near or (usually) at the site they recognize.

- In molecule biology, the term palindrome means that the sequence of a DNA, when read in the 5‘ to 3‘ direction for the top strand is exactly the same as that of the bottom strand. The following sequence is a palindrome

5’ -A-A-G-C-T-T-3’
3’ -T-T-C-G-A-A-5’

- There are four categories of restriction enzymes:

Type I - cut at sites a random distance away from the recognition site
Type II - cut within or near the recognition site.
Type III - cut a short distance away from the recognition site and must bind ATP for action
Type IV - cut modified DNAs

- The cut sites of Type II enzymes vary from enzyme to enzyme. They are grouped into three categories - 1) those that leave a staggered sequence after cutting that has an overhang at the 5’ end of one strand of the duplex; 2) those that leave a staggered sequence after cutting that has an overhang at the 3’ end; and 3) those that cut both strands in the same place, leaving no overhanging sequence - called blunt end cutters.

- HindIII is a type 2 restriction enzyme in the first category. It cuts and leaves a 5’ overhang

5’ -N-N-N-A 3‘ 5’A-G-C-T-T-N-N-N-N-3’
3’ -N-N-N-T-T-C-G-A-5‘ 3’ A-N-N-N-N-5’

- Pst I is a type 2 restriction enzyme of the second category. It cuts and leaves a 3' overhang

5' -N-N-N-C-T-G-C-A 3' 5'G-N-N-N-N 3'
3' -N-N-N-G 5' 3' A-C-G-T-C-N-N-N-N 5'

- Ssp I is a type 2 enzyme of the third category. It cuts and leaves a blunt end

5' -N-N-N-A-A-T 3' 5' A-T-T-N-N-N-N 3'
3' -N-N-N-T-T-A 5' 3' T-A-A-N-N-N-N 5'

- If they have the same overhanging sequence, the ends of different DNAs can be joined together using an enzyme called DNA ligase.

- If one took different DNAs cut with the same enzyme, such as Hind III and tried to join them together, they would react and get joined easily, since they would have the same overhanging (called sticky) ends.

- If one tried to join a DNA cut with Hind III to one cut with either Pst I or Ssp I, then virtually none of the ends would get joined, since the ends of their DNAs are not the same (said to be incompatible).

- Bacteria use restriction enzymes as protection against invading DNA viruses. Viruses that infect bacteria are known as bacteriophages. When a DNA-containing virus injects its DNA into a bacterial cell, if it contains a recognition for the restriction enzyme contained in the bacterium, the enzyme will cut it, thus disabling the virus.

- Restriction enzymes do not cut cellular DNA because bacterial cells protect their genomes with a modification system. This is another enzyme that recognizes exactly the same sequence as the restriction enzyme except that instead of cutting it, the modification system alters the cellular DNA so that the restriction enzyme cannot work.

- The modifying enzyme in a modification system is known as a methyl transferase (or a methylase), since it puts one or more methyl groups on the same sequence that the restriction enzyme would otherwise cut. When the methyl group is added, the restriction enzyme no longer can recognize the sequence and therefore no longer cuts the DNA. As a result, the genome gets protected from cutting, but invading DNAs from viruses lack those methyl groups and get cut.

- Creating recombinant DNA typically involves the use of plasmids.

- Plasmids are circular, autonomously replicating DNAs found commonly in bacterial cells.

- Plasmids have been adapted to 1) replicate in high numbers; 2) carry genes that allow researchers to identify cells carrying them (antibiotic resistance, for example) and 3) contain sequences (such as a promoter and Shine Dalgarno sequence) necessary for expression of the desired protein in the target cell.

- A plasmid which has all of these features is referred to as an expression vector .

- Some plasmids contain what is called a "polylinker" which is a short stretch of DNA within a selectable marker that contains numerous recognition sites for restriction enzymes. Each of these sites occurs only once in the plasmid, ensuring DNA gets placed precisely in the plasmid where desired.

- Making a recombinant DNA with such a plasmid is a relatively simple process. It involves 1) cutting the DNA of interest with a restriction enzyme; 2) similarly cutting the plasmid DNA to generate ends that are compatible; 3) ligating the DNA of interest into the plasmid DNA using an enzyme called DNA ligase; 4) inserting the ligated material into a bacterial cell; and 5) growing cells that contain the plasmid.

- Steps 3 and 4 are tricky. Let's start with step 4. Cells take up plasmid DNAs very inefficiently.

- It is for this reason that plasmids carry a selectable marker, such as antibiotic resistance. With it can easily identify the bacteria that take up a plasmid by virtue of the fact that the rare bacteria that get a plasmid are resistant to the antibiotic, whereas those bacteria that don't take up the plasmid will be killed by the antibiotic and don't grow.

- The second consideration (step 3) is that getting the DNA of interest inserted into the expression vector is also inefficient. Consequently, the most common thing that occurs is that most re-ligated expression vectors have no DNA insertions, so a selection method is desirable for identifying which of those cells that got a plasmid contain one with an insert. One solution this is to use blue-white screening.

- To understand the strategy of blue-white screening, one must first understand the *lacZ* gene of the *lac* operon.

- The enzyme coded by the *lacZ* gene is **β**-galactosidase. It catalyzes the hydrolysis of lactose into glucose and galactose. An artificial substrate called X-gal has been created that the enzyme also cleaves.

- The result of this cleavage is that one of the product molecules of X-gal cleavage has a blue color. Thus, if one adds X-gal to cells expressing the *lacZ* gene, blue color will be produced and the amount of blue color is a measure of the amount of Lac-Z gene present.

- Another tool for blue-white screening is an artificial "inducer" of expression of the *lac* operon (including *lacZ*) known as isopropyl β-D-1-thiogalactopyranoside or, as it's more commonly called, IPTG.

- Induction of Lac operon expression is important because mRNA for the operon is normally produced in bacterial cells at a very low level.

- In the presence of IPTG, transcription and translation of the Lac-Z gene increases dramatically.

- Thus, when you treat cells containing the lac operon (and lac Z) with X-gal and IPTG, blue color will be produced. If the cells are not making functional lac Z, no blue color will be produced and the cells will be white.

- To use blue-white screening, one must start with *E. coli* cells that lack the *lacZ* gene.

- Functional *lacZ* gene coding sequences have been placed on a plasmid. The coding sequence has been altered slightly to contain a "polylinker" in the middle of the coding. The polylinker does not interfere, though with making a completely functional *lacZ* protein.

- The polylinker is a short region containing several restriction enzyme cutting sites,

each of which is unique in the plasmid containing it (See Figure 7.32).

- There is, for example, a BamHI site in the polylinker. If DNA is inserted into the BamHI site of the polylinker, it disrupts the coding for *lac*Z so cells can no longer make functional LacZ enzyme. Thus, when the cells that take up plasmids with an insert are treated with X-Gal and IPTG, they do not produce a blue color and instead remain white.

- On the other hand, if the plasmid's sticky ends simply ligate to each other and do not get an inserted gene, then the lac-Z gene coding sequence is restored intact (no interruption) and functional LacZ enzyme is made. Treating these cells with X-Gal and IPTG will yield a blue color.

- It is trivial then to identify cells with a plasmid with an insert from those with a plasmid having no insert. The ones with the insert will have a white color. The ones with no insert will have a blue color.

- Some RNA-encoded viruses have a phase in their life cycle in which their genomic RNA is converted to DNA by a virally-encoded enzyme known as reverse transcriptase. The ability to convert RNA to DNA is a method that is desirable in the laboratory.

- To use reverse transcriptase to make DNA from RNA, one creates a DNA oligonucleotide to serve as a primer for reverse transcriptase to use on a target RNA. The primer must, of course, be complementary to a segment (near the 3' end) of the RNA to be amplified.

- The RNA, reverse transcriptase, the primer, and four dNTPs are mixed. Replication converts RNA to a single strand of DNA.

- Denaturation frees the single stranded DNA, which can then be amplified by PCR or simply replicated using a primer specific for the other end of the DNA.

- PCR allows one to use DNA replication to amplify DNA enormously in a short period of time.

- In contrast to cellular DNA replication, which amplifies all of a cell's DNA during a replication cycle, PCR does targeted amplification to replicate only a segment of DNA bounded by the two primers used to direct DNA polymerase where to start.

- PCR involves three cycles, each of which occurs at a different temperature. The process also requires four things - a target DNA to be amplified, 4 dNTPs, 2 primers complementary to sequences around the region of DNA to be amplified, and a DNA polymerase stable at high temperatures (thermostable).

- The thermostability of the DNA polymerase is necessary because the first step requires near boiling temperatures to separate the DNA strands.

- First, all of the reagents are mixed together. Primers are present in millions of fold excess of the target sequence to be amplified. This is important because each double stranded DNA made requires two primers.

- The first cycle of the process involves separating the strands of the target DNA by heating to near boiling.

- Second, the solution is cooled to a temperature that favors complementary DNA se-

quences finding each other and making base pairs.

- Since the primers are present in millions of fold excess, the complementary sequences they target are readily found and base-paired to the primers.

- These primers direct the synthesis of DNA. Only where a primer anneals to a DNA strand will replication occur, since all DNA polymerases require a primer to begin.

- In the third step in the process, the DNA polymerase replicates DNA by extending from the 3' end of the primer forward, making a new DNA strand.

- Then the process repeats itself, usually about 30 times. At the end of the process, there is a theoretical yield of 2^{30} (over 1 billion times) more DNA than there was to start.

- Yeast two-hybrid screening is a sophisticated technique for identifying which protein(s) out of a collection of all of a cell's proteins interacts with a specific protein of interest. To understand this method, it is important to understand what a library is, in biological terms.

- Biological libraries contain collections of DNAs (called a genomic library) or mRNAs (called a cDNA library), typically, though there are many different kinds of libraries.

- Imagine you had collected together all of the mRNAs of a cell type (for example, bone cells), and made double-stranded cDNA copies of them using reverse transcriptase.

- If you ligated those cDNAs into expression vectors and transformed the mixture into cells, then the collection of cells that arose from that experiment would be a cDNA library of the bone cells expressing every protein that a bone cell makes.

- Making a cDNA library is the first step (and primary step) in a yeast two-hybrid analysis.

- Instead of fusing the cDNA coding regions into an ordinary expression vector, one inserts it into an expression vector that has a coding region for a transcription factor - a protein that binds to DNA and helps to start transcription.

- This creates a library of cDNAs, each one fused to the coding of this transcription factor. Each bone cell protein would be fused to the transcription factor coding region meaning that the protein made would be partly composed of the transcription factor and partly composed of each protein. These proteins would be called the bait.

- Now, imagine that you took your protein of interest - let's call it XYZ protein. You are interested in learning which of the proteins in your cDNA fusion library interacts with XYZ protein. So, you make a second fusion protein - this one is partly a transcriptional activator protein and part XYZ protein. It is called the prey.

- At this point you have two collections - A) a library of cDNA proteins fused to transcription factor and B) XYZ protein fused to a transcription activator.

- The transcription factor (collection A) can't start transcription of a particular gene by itself. Neither can the transcription activator (collection B). These two proteins

can only function to activate transcription when you put the pieces into close enough proximity.

- Any cDNA proteins fused to transcription factors in A that are bound by the XYZ protein fused to the transcriptional activator of B will activate transcription, since that puts the transcription factor together with the transcriptional activator.

- The gene that the two pieces activate is chosen to be a "reporter gene" and a promoter is selected that will respond to the combination of transcription factors 1 and 2, but to neither one alone.

- The reporter gene's protein gives a phenotype that is easy to identify. For example, it could be β-galactosidase which, if it is produced on treating the cells with X-gal, will make a blue color.

- When collections A and B are transformed together into yeast, most of the cells will have no color because they have no means of putting the fusion proteins containing transcription factors 1 and 2 together (no interaction between XYZ and most of the cDNA proteins).

- If there are protein(s) that bind to XYZ protein, then they will be in the mixed libraries and when they appear together in a cell, they they will interact and physically put transcription factors 1 and 2 together. As a result, transcription will start, translation will make the β-galactosidase protein and blue color will be produced when X-gal is present. Then it will be a simple matter of retrieving the plasmids from the blue cells to identify the coding of the protein(s) that interact with XYZ protein.

- CRISPR stands for Clustered Regularly Interspaced Short Palindromic Repeats (short repeated sequences found in prokaryotic DNA)

- The short repeats are separated by spacer sequences derived from past encounters with, for example, a bacteriophage.

- Inserted into the bacterial genome, these sequences can be transcribed into a guide RNA that matches, and base-pairs with, sections of the viral genome if it is encountered again.

- A nuclease associated with the guide RNA cleaves the sequence base-paired with the guide RNA. (The nucleases are named Cas for CRISPR-associated.)

- The essential elements of this system are a guide RNA that homes in on the target sequence and a nuclease that can make a cut in the sequence that is bound by the guide RNA.

- In the CRISPR/Cas9 system, the Cas9 endonuclease cuts both strands of the gene sequence targeted by the guide RNA. This generates a double-strand break that the cell attempts to repair.

- Double-strand breaks in DNA can be repaired by simple, nonhomologous end joining (NHEJ) or by homologous recombination. When a break is fixed by NHEJ, there is good chance that there will be deletions or insertions that will inactivate the gene they are in.

- Targeted cleavage of a site by CRISPR/Cas9 can easily and specifically inactivate a gene, making it easy to characterize the gene's function.

- If a homologous sequence bearing the specific mutation is provided with the CRISPR system, homologous recombination can repair the break, and at the same time insert the exact mutation desired.

- There are some creative variations on the CRISPR/Cas9 system.

- One variant inactivates the nuclease activity of Cas9. The guide RNA in this system pairs with the target sequence, but the Cas9 does not cleave it. Instead, the Cas9 blocks the transcription of the downstream gene, allowing specific genes to be turned off without actually altering the DNA sequence.

- Another variation also uses a disabled Cas9, but this time, the Cas9 is fused to a transcriptional activation domain.

- Here, the guide RNA positions the Cas9-activator domain in a place where it can enhance transcription from a specific promoter.

- Other variations on this theme attach histone modifying enzymes or DNA methylases to the inactive Cas9. Again, the guide RNA positions the Cas9 in the desired spot, and the enzyme attached to Cas9 can methylate the DNA or modify the histones in that region.

- MALDI-TOF (Matrix-assisted Laser Desorption Ionization - Time of Flight) is an analytical technique allowing one to determine the molecular masses of molecules with great precision.

- The MALDI-TOF process involves three basic steps. First, the material to be analyzed is embedded in solid support material (matrix) that can be volatilized in a vacuum chamber by a laser beam.

- In the second part of the process, a laser focused on the matrix volatilizes the sample, causing the molecules within it to vaporize and, in the process, to form ions by either gaining or losing protons.

- Third, the ions thus created in the sample are accelerated by an electric field towards a detector. Their rate of movement towards the detector is a function of the ratio of their mass to charge.

- An ion with a mass of 100 and a charge of +1 will move twice as fast as an ion with a mass of 200 and a charge of +1 and at the same rate as an ion with a mass of 200 and a charge of +2.

- By precisely determining the time it takes for an ion to go from ionization (time zero of the laser treatment) to being detected, the mass to charge ratio for all of the molecules in a sample can be readily determined.

- Ionization can also result in destabilization of larger molecules, which fragment into smaller ones in the MALDI-TOF detection chamber.

- Precise determination of the size of each of the sub-fragments of a larger molecule allows one to determine its identity and structure if this is not previously known.

- Polypeptides can have their amino acid sequence determined by a computer in MALDI-TOF by analyzing precise molecular mass of the many pieces they contain.

- When one amino acid, for example, fragments from a larger peptide, this can be detected as the difference in mass between the fragment with and without the amino acid, since each amino acid will have a characteristic molecular mass. By determining the iden-

tity of each amino acid breaking off of a larger polypeptide, the structure of the larger polypeptide is realized.

- When a larger polypeptide fragments into all of its pieces in MALDI-TOF, the composition of each of the pieces can be determined from their masses and the entire sequence of a peptide can thus be determined.
